Os he enseñado hace poco, un hilo de platino enrojecido hasta el blanco, por el paso de una corriente. Una varilla de carbono, de grafito, nos daria una luz todavía más viva. Se puede ir más lejos. Imaginemos que el circuito presenta una solucion de continuidad de varios milímetros: la corriente eléctrica es bastante poderosa para conseguir vencer esta enorme resistencia; calentará los extremos de los conductores y franqueará el espacio arrastrando las partículas de la sustancia que las constituye. Esta cadena de partículas, será elevada toda ella á la temperatura del blanco deslumbrador. Si los conductores son de carbono, produciremos el arco voltáico.

La luz depende del calor y el calor depende de la corriente. Debemos, para completar esta exposicion rápida, examinar qué cualidades conviene exigir al orígen eléctrico. Un sabio inglés, el profesor Joule, ha determinado las leyes que rigen la elevacion de temperatura de un circuito por una corriente. Ha encontrado que el calor es proporcional á la tension de la corriente, y á su intensidad, es decir á la masa eléctrica gastada en la unidad de tiempo. Esto os hará ver que un arco voltáico de gran brillo no puede obtenerse sino por medio de muchos elementos asociados por sus polos de nombres contrarios, y representando cada uno una fuerte aglomeracion de energía eléctrica.

Hoy que este medio de alumbrado tiende cada vez mas á penetrar en la industria, ha sido preciso renunciar á las pilas y reemplazarlas por aparatos mas económicos. Las pilas consumen zinc, cuyo precio es relativamente elevado: este solo hecho, que nada tiene que ver con la teoría, ha bastado para anular casi por completo la aplicacion de la luz eléctrica. Las máquinas magneto-eléctricas han sido dotadas de esta necesidad que se hacia sentir. Estas transformam, ya en acumuladores, la energía mecánica en energía eléctrica. Estudiemos, pues, indicando proporcionarles el movimiento por medio de nuestros motores ordinarios, las máquinas de vapor. En pues, en suma, el trabajo de combustion de la hulla el que se halla de nuevo en el arco voltáico bajo formas de calor, despues de haber pasado por otras intermedias.

El estudio de las máquinas magneto-eléctricas, nos conduciria muy lejos.

Los límites que el tiempo impone á una conferencia, no me impiden entreteneros con las maravillas de ingenio que se han desplegado para la realizacion de estos aparatos próximos á la perfeccion.

La explosion casi instantánea de los focos tan numerosos que iluminan en este momento nuestra ciudad, atestiguan mas que las palabras, la importancia y la oportunidad de estos descubrimientos.

Hemos llegado al fin de nuestro trabajo. Tratamos de resumirle en breves palabras. No he intentado siquiera emprender la ingrata tarea de describiros minuciosamente algunos aparatos principales. Lo que he querido ha sido haceros ver la ciencia telegráfica bajo el punto de vista mas culminante. Os habeis colocado, conmigo, en las alturas de la mecánica general. Desde allí hemos abarcado de una ojeada el conjunto de diversos agentes naturales. Habeis comprendido que la resolucion de los unos en los otros, es incesante.

Despues de habernos así preparado y fortificado ante un horizonte tan vasto, hemos descendido al terreno particular de la energía eléctrica. Este terreno, fortilizado por el génio de los hombres, ha producido, vosotros lo sabeis, la telegrafía, la galvanoplastia y un nuevo medio de alumbrado. Y cuando se piensa que estas sorprendentes aplicaciones no cuentan mas de medio siglo ¿quién puede prever lo que el porvenir nos reserva todavía?

"Revista de comunicaciones de la Habana."

THE TELEPHONE AND MICROPHONE.

W[1702]—I SHOW if R. H. Hawkins (letter W[1702]—I SHOW if R. H. Hawkins (letter 10711, Vol. XXX. p. 10) will try a microphone of this description, he would be as well satisfied with it as with mine. First, I turned an ordinary thin tin pan upside down, and screwed it on to a square piece of wood, previously inserting the diaphragm (thin sheet of charcoal), on the centre of which I carefully fixed a piece of carbon (I stand [illegible] square, a rod [illegible] connected by fine copper wire to a sort binding screw; next, I procured a piece of carbon in the shape of A (fig.), making the point as fine as possible, and fastening B to a fine, but rather strong, spring, to which was connected with the other binding screw. This carbon hammer I adjusted by means of an ordinary screw. I then screwed the whole into a cigar-box, which I think increases the effect.

Whispering, singing, talking, and whistling can be heard distinctly with it. It is rather loud, and when properly adjusted, very distinct; two telephones also increase the effect. It requires two Leclanche cells to work it properly.

By two telephones I mean one for each ear, of course.

W. E. B.

The Electrician, July 16, 1881.

239,618. TELEPHONE, *Joseph T. McConnel, Brooklyn, assignor to himself and Edward A. Titsworth, Hawkins Station, Pa.*—*Filed November 15th, 1880.*

Claim.—A receiving telephone having three or more line or points of attachment for electric circuit wires, two of which are connected by a make-and-break mechanism with the telephone, in combination with a separate battery, transmitter, a main line circuit passing through the receiving telephone proper by the unconnected posts, and through the secondary coil of the transmitter, a local battery and a local circuit from each battery through the speaking telephone and primary coil of the same, substantially as and for the purposes set forth.

English Mechanic & World of Science, July 22nd, 1881.

[1101]—Telephone Transmitters.—To my A[illegible] [illegible] as there came under the notice of [illegible] [illegible] under the section "Answers," [illegible]

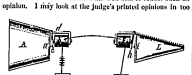
I [illegible] that the carbon only applies to the one described in my previous letter, I only specified [illegible] acoustic microphone would be easily [illegible] [illegible] I [illegible] [illegible] [illegible]

THE TELEPHONE.—JUDGE LOWELL'S OPINIONS COMMENTED UPON.—INGENIOUS TRANSFORMATIONS.

OF SOUNDS.

A few days ago I chanced to see a small pamphlet that is being sent out by the American Bell Telephone Company to their agents, and containing the decision of Judge Lowell in relation to the alleged infringement of those-called Bell telephone. Having been wrestling with the element electricity, experimentally and otherwise, for a number of years, and with scientific and other forms of telephones, I at once found the pamphlet very interesting and exceedingly amusing.

Now, basing my opinion upon Judge Lowell's decision, I cannot believe that he had very much aged telephone information laid before him by the defendants; for if he had his conscience would never have allowed him to render such an opinion. I may look at the Judge's printed opinions in too



Bell's Apparatus.

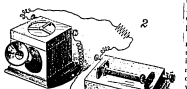
strong a light, and I may not understand them just as he would have me; but be that as it may, I do think that when he rendered this now famous decision he little thought of what valuable material he was furnishing for the future use of the defendants. Take the following for example—the italics are mine:

"There is some evidence that Bell's experiments with the instrument, described in Fig. 7 (see Fig. 1), before he took out his patent, were not entirely successful; but this is now immaterial: *for it is proved that the instrument will do the work, whether the inventor knew it or not.*"

Now, if that is rock bottom law, Bell and his followers (especially the "followers"—for Bell is out of the business, slick and clean) must feel a little squeamish; because, according to the above ruling - the father of the telephone, and the rightful claimant, would be the person who took out the first patent upon an instrument or apparatus that would transmit articulate speech, "whether the inventor knew it or not."

Who is the fortunate parent?

Bope, undoubtedly, was the first to discover and make public the fact that articulate sounds could be transmitted telegraphically. But, according to Judge Lowell, Reis can-

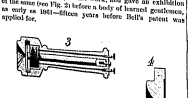


Reis's Telephone.

not be credited with it, because, before Reis's discovery there were thousands of instruments in use, and being made daily, that would transmit articulate speech, "whether the inventors knew it or not."

There is great satisfaction in knowing that Reis cannot come down on us for exorbitant rentals, because he is not protected (?) in so doing by U. S. patents.

Why did Reis neglect to patent his discovery and apparatus? Probably because he did not attach much importance to the discovery, or else that he was satisfied that he had not made an invention, and was too conscientious to try to benefit say one iota the belief that he had. It would not do to credit it to Reis anyway, because he *did know* that his apparatus (telephone) would work, and gave an exhibition of the same (see Fig. 2) before a body of learned gentlemen, as early as 1861—fifteen years before Bell's patent was applied for.

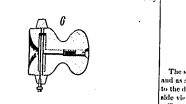


Meme, "ils inventent analogue," cannot bring in a legal claim for the telephone, because the Meme patents have expired. But then it might be credited to him, for two reasons: First, because he lectured and cannot object; second, Judge Lowell's reason, because Meme's instruments will transmit articulate speech, "whether the inventor knew it or not."

Here is another quotation: "But Bell discovered a new art, that of transmitting speech by electricity." Now why not give Judge Lowell a patent for the discovery of a new art—the art of discovering that *Bell* was the discoverer of the art of transmitting speech by electricity? Certainly no one but Judge Lowell has made this discovery, therefore he is entitled.

How, in the name of common sense, Bell can be credited with making the discovery of "a new (?) art," when, as long ago as 1861, Prof. Reis published and gave to the world full particulars of this same "new art," and not only Bell, but all other scientists throughout the globe were acquainted with the fact! Perhaps they were not aware of it at the Patent Office at the time Bell put in his application. It is not well that the examiners in my department should be thoroughly posted, because if they were it would greatly lessen the number of new patents issued upon old devices, and that would never do, for the business of the Patent Office is to issue patents—the more the merrier. Never mind whether they will hold water or not; the Office grinds them out, medical college fashion, and the people must abide by the results.

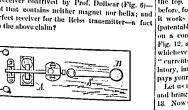
The judge is probably correct when he says: "It seems to me that the defendants use both the method and the apparatus of Bell." There is not a particle of doubt about that; but what did Bell use for his experiments, and as a model? Simply nothing but the methods and the apparatus of former experimenters. How much of the so-called Bell telephone, as now constructed (Fig. 3), was invented or contrived by



Bolleot's Receiver.

Bell? The most reliable information upon the subject credits the "permanent magnet" (as applied to an instrument constructed purely for telephonic purposes) to Prof. Dolbear, of Tufts College; the "converging mouthpiece," Fig. 4, to Prof. Pierce, of Providence, R. I.; and the general makeup of the instrument into the "butter-stamp" form, Fig. 5, to Edson S. Jones, of the same city. The butter-stamp form of telephone, Fig. 5, is the one now in general use. Compare it with Bell's apparatus, Fig. 1.

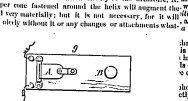
In referring to the Reis telephone, the judge says: "The rogue of all its admirers was, that articulate speech could not be sent and received by it," all of which is an exceedingly elevated mistake, for the Reis apparatus will transmit articulate speech, and as perfectly as any of the hundreds of other forms that have since been constructed—a fact that is well known by telephone investigators throughout the land. Also, that "a Bell receiver must be used to gather up the sound before the instrument (Reis's) can even now be adapted to a limited practical use." Bosh! Can it be possible that Judge Lowell *believes* such nonsense? Has he been misled up in this cow, all this time, and never heard of the simple little receiver contrived by Prof. Dolbear (Fig. 6)—an instrument that contains neither magnet nor bells; and yet it is a perfect receiver for the Reis transmitter—a fact that explodes the above claim?



I devoted considerable time last winter to the examination of the Patent Office reports for the self-satisfaction of knowing what had been patented in the electrical line, in years gone by, that bore any relation to the articulating telephone of to-day. And, without entering into details, suffice it to say that I found one instrument—a "magnetic sounder"—patented by one Wm. Henman in 1871, two years before Bell was heard of, and containing every part—armature, helix, and *permanent* magnet—of the most perfect magneto tele phone as now made; and without one particle of alteration or change in construction, it answers nicely for transmitting and receiving articulate speech.

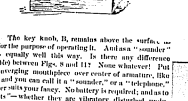
Within a few weeks I have had the pleasure of using these instruments, both double and single helix, for conversing over lines of considerable length, and the results were quite satisfactory—equally as good as I have obtained from many forms of specially constructed telephones.

Fig. 7 is a top and Fig. 8 a side view of the magnetic telegraph instrument. A is the soft iron armature; C, the coils; P M, the permanent magnet; and in this instrument it is of the horseshoe form, with both pole ends turned up at right angles, and carrying the coils. C. The spring, S, retains the magnet in its normal position. The instrument is operated by working the knob, B, in the usual way; and it is as simple in adjustment, etc., that the merest tyro cannot fail to understand. To work it as a transmitter and receiver of articulate speech, you will simply hold or fasten down the knob, B—which will bring the magnet and armature nearly together; then talk and listen closely to the armature, A. A paper ruse fastened around the helix will augment the sound very materially; but it is not necessary, for it will work nicely without it or any changes or attachments whatever.



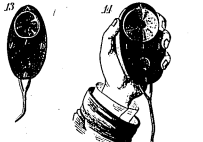
The single helix instrument is of a much cheaper form, and as a transmitter and receiver of vocal sounds is superior to the double helix instrument. Fig. 9 is a top and Fig. 10 a side view.

To save expense in finish the spring, S, and spool, C, are placed within the case; and all metal work reduced to the lighter and plainest form. In principle and operation it is identical with Fig. 8. To make it still less expensive in construction the armature can be placed within the case, as shown in Fig. 11, and the adjusting screw, H, left flush with



the top. The key knob, B, remains above the surface, as before, for the purpose of operating it. And as a "sounder," it works equally well this way. Is there any difference discernible between Figs. 8 and 11? None whatever! Put on a converging mouthpiece over center of armature, like Fig. 12, and you can call it a "sounder," or a "telephone," whichever suits your fancy. No battery is needed; and as to "currents"—whether they are vibratory, disturbed, undulatory, intermittent, or pulsatory—they are all there—" you pays your money and takes your choice."

Let us make the case in an oval form, instead of square, and bring the line wires out at the bottom, as shown in Fig. 13. Now compare it with the Phelps telephone, as illustrated



on page 61 of Prescott's book, "The Speaking Telephone, etc.," and as shown here in Fig. 14, and tell me if they wouldn't make pretty fair twins?

Franklin Mass., September 19, 1881.

Le télégraphe souterrain en Allemagne

On lit dans la *Post* du 25 septembre :

« Le réseau télégraphique souterrain est maintenant achevé; il relie entre elles 221 villes et s'étend de Hanovre jusqu'à Strasbourg, de Breslau à Emden, de Thorn à Aix-la-Chapelle.

« La première section, celle de Berlin à Halle, a été commencée au mois de mars 1877, et la dernière section, celle de Cologne à Aix-la-Chapelle, a été terminée il y a trois mois.

« La longueur totale du câble actuellement construit—la réseau a donc près de 38 mois et les dépenses se sont élevées à 30,300,000 marks.

« La longueur totale du câble estale 5,913,950 kilomètres, et celle des différents fils de 37,372,284 kilomètres.

« Des 23 lignes dont se compose le réseau, 18 comptent 7 fils et 5 n'en ont que 4.

« 70 pièces du câble passent sous les rivières »

THE TELEPHONIC TRANSMISSION OF MUSIC.

TELEPHONIC communication for general business purposes has been for some years an every-day occurrence, and some 1200 different firms are now connected in London alone with the Telephone Exchange in Coleman-street. One of the striking features of the late Electrical Exhibition at Paris consisted in the rooms fitted up with telephones where the performances from the Grand Opera could be listened to at a considerable distance from the theatre and heard with great distinctness. The installation by means of which this result was obtained was illustrated and described in ENGINEERING, page 555, ante. On Tuesday evening last, the United Telephone Company, Limited, exhibited a similar effect to a small audience, a room at the Bristol Hotel, Buckingham Gate, being fitted with a number of telephones, through which the performances of the opera of "La Mascotte," at the Comedy Theatre, about half a mile distant, was most effectively transmitted. The installation appeared to be of the simplest possible character; two Hicks microphonic transmitters were placed in the Comedy Theatre, fixed to the wooden posts supporting the curtain hangings, and about 10 ft. above the stage level. From each of these transmitters one wire passed direct to the house, the current being supplied by a battery of four large Leclanché cells contained in the same case as the transmitters. At the house, connecting with every set of telephones in groups of eight in each, making a total of eight telephones, was placed a single bell wire, and a single bell at his disposal two telephones, one connected to a Gower transmitter at one side, the other to that on the other side of the stage. All these telephones were in full use throughout the evening, and the effect produced was a very remarkable one. In some the voice of the singer was distinctly recognisable, every word being plainly audible; still there was a peculiar vagueness about the transmission of which there can be no doubt that distance lends enchantment to the listener, who involuntarily presses the telephone closer to his ear in order more distinctly, or rather to avoid a peculiar hissing which somewhat mars the effect. Every wire connecting the switchboard at one of the floors of another, produced a jarring sound. Still the music or conversation transmitted from the stage could be easily heard by the whole of the company, and the applause of the audience was distinctly heard as the rising or dropping of the curtain; certain musical instruments, particularly when playing simultaneously with others, produced a jarring noise, as for example, the lower notes of a violoncello and the low notes of brass instruments. A chorus could, however, be thoroughly enjoyed, and was most effective in the transmission of a performance of this kind, necessarily is, however, that the listener does not see the actors, though he hears the words, and, therefore, frequently does not understand where the laugh comes in. The effect might be best compared to listening to a conversazione at a theatrical performance from a position behind the stage, and a theatrical form it by a light wooden partition. A little reflection at telephones of different descriptions, switches all and orders, and an Edison loud-speaking telephone, were at show in one of the rooms, and at some future date, we understand, the latter instrument will be placed in circuit, so that an audience may enjoy the performance without even so much as holding a pair of telephones up to their ears. The latter are, it should be mentioned, the ordinary well-known Bell telephones. Altogether the evening was a most enjoyable one, and the United Telephone Company deserve great credit for the liberal spirit in which they endeavour to popularise the capabilities of the telephone system.

THE SPEAKING CONDENSER.

In a former Note we announced that M. Dussaud had succeeded in making the "singing condenser" of Varley act as a telephonic receiver of speech. Since his first experiment he has brought the apparatus into a more practical form. It consists of a transmitting circuit consisting of a microphone, a battery of four Leclanché cells, and the primary of a small induction coil, having about 0.5 ohms resistance. The receiving circuit is composed of the line wire, a receiving condenser of condensers, and a battery of from six to twenty Leclanché cells, according to the number of receiving condensers employed. The microphone is of a peculiar construction. Two metal plates enclosed in a ring of wood and forming a box, are connected in the circuit. Each plate has attached to its inner centre a small button of carbon, and between these two buttons is a little spindle of carbon held there by a brass wire crossing the interior of the box between the two plates, and capable (by the degree of tension given to it) of increasing or lessening the pressure of the microphonic contact between the two ends of the spindle and the buttons. All condensers will serve as receivers provided a battery be employed in the receiving circuit to keep them charged; but M. Dussaud prefers those having a thickness not over six centimetres, and made of thirty or thirty-six sheets of tinfoil separated by sheets of ordinary or of parafined paper. A thin ring of wood or ebonite placed round each surface gives solidity to the pole. One side is fitted with a gutta-percha cup-piece, or two condensers hung from a head-piece may be fixed upon each ear of the observer. When loud speaking is required, twelve condensers are placed in an open trough about three inches apart, and by this arrangement speech may be heard over a radius of five or six yards when a battery of thirty cells is used in the receiving circuit.

CABLE FOR TELEPHONIC CIRCUIT.

AN English patent has been taken out for a type of telephonic cable designed by Messrs. J. Holmes and E. T. Greenfield, of Brooklyn, New York, to eliminate the effects of inductive electric conductors running close together. The arrangement is novel, and is worthy of reference, and worthy of some notice. It is said, however, scientifically, that the intensity of the induced current in a conductor ranged upon the parallelism between the conductors, and that such a current is generated and the primary is broken, or such a current goes feebler as the parallelism of the lines is destroyed, and becomes inappreciable when the lines cross each other at right angles. It is then proposed to utilise for a telephonic line a metallic circuit or conductor wire of which shall be made to cross and recross repeatedly the main wire of the circuit, the expansion and contraction of the line will not be disturbed by induction from a neighbouring wire through which an electric current is passing. One practical objection to this construction is that it requires double the length of wire, and is connected with a construction which uses so much connection, and also is attended with a vastly increased resistance. However, it proposes the protection of a single line from the above inversion provides a more simple and less expensive mode of utilising the general fact above noted, and is perfectly adapted to any number of lines arranged in proximity to each other, and following through a general direction; and it consists simply in causing the wires of the cable to cross and recross at so that they will repeatedly cross and recross at short intervals, each line wire in succession, and consequently no metallic return wire is used. The most convenient manner of securing this relative arrangement of the wires is to braid them together into a cable, for which purpose they must be insulated, to prevent actual contact of the conducting surfaces. By braiding the wires each one of the system will be carried alternately over every one of the others, and if the wires are fully close, as with machinery, the construction will be uniform throughout the cable, occurring at regular intervals, and the curves rising to uniform heights from the axial line of the cable, which regularity of construction will produce the most complete neutralisation of induction. Each wire is made to act as a support to its neighbours, and while the wires thus serve to support each other, the whole cable can be as readily mounted on poles, or otherwise supported or submerged, after the manner of a single wire. A cable constructed according to this plan may be composed of three conductors braided together; but, manifestly, the same principle would apply to any larger number of wires which could be conveniently braided up into a single cable. If two wires only were to be used they might be braided into a cable by means of a third strand a cord of any non-conducting material, or they might be served by serving, or in any other suitable way, to a cable of tape or any other suitable support. In this case two wires are attached to the insulating strip in such a way as to cross and recross each other at short intervals and with regular curves. According to this construction, when conductors are arranged as above described, no induced current is formed in any one of them by the passage of an electric current through any of the others, or if formed it is so far modified by the action of the others as to be practically not to interfere with the working of any of the lines in the cable, and the cable can, accordingly, would be free of them with reference to any other line now by but not included in the same cable.

APPLICATION OF THE TELEPHONE TO THE MEASUREMENT OF THE TORSION OR TRANSVERSE SHEARING STRAIN OF SHAFTS, &c.

THE Société Internationale des Électriciens, in a paper read by Le Lieutenant Electricien Sebert, has described a method of measuring the torsion or transverse shearing strain of shafts, &c., by means of the telephone. The apparatus consists of M. Carlo Ganz's system of two electro-magnetic transmitters to two stationary electro-magnets, and resting in each case opposite to the poles of the latter on the shaft revolves. The electric waves being electrified through a telephone, so that the currents in the two coils tend in opposite directions, no sound is produced by the instrument when the apparatus is properly adjusted and the shaft is not under torsion; but it will be seen, however, that the slightest effort will disturb the equilibrium by throwing the armatures into different positions, varieties of induced currents, which affect the telephone, being thereby produced. The sentences of the sound emitted by the instrument depend upon the number of armatures and the velocity of rotation; but the intensity of it is stated, depends upon the angular displacement of the armatures, or the torsion of the shaft. This may be accurately ascertained by allotting one of the sets of armatures to the end of the shaft, as in the figure, where we call L the length of the shaft between the two sets of armatures, and α the angular displacement of the latter in circular degrees the torsion x for unit length will be $x = \frac{\alpha}{360} \frac{1}{L}$. If x, be the torsion of the shaft when the machine does no work, the expression $\frac{x}{x'}$ will be the ratio between the force necessary to overcome friction, &c., and that actually transmitted to the shaft. The force necessary to produce a given torsion may be measured by a dynamometer, having a lever of length R, to which one end of the shaft is fixed. If a force of P kilos. produces the torsion x on the length of shaft L, the torsion of unit length will be $x = \frac{P}{L}$. If we know the angular velocity and the number n of revolutions of the shaft in unit time, we have all the elements necessary for calculating the work done. For, since the force P, the moment of which is P R, produces a torsion x, the force necessary to overcome friction is $P \frac{x'}{x}$, and the force corresponding to the torsion x, measured by the kilojoules by displacing the armatures will be $P \frac{x'}{x}$. The force P being applied through a lever of length H, the total work transmitted through the shaft will be $P 2 \pi H n \frac{x'}{x}$. That absorbed by friction, &c., will be expressed by $P 2 \pi H n \frac{x'}{x}$; the useful work will be $P 2 \pi H n \frac{x - x'}{x}$; and, lastly, the ratio of the effective to the total work, or the duty of the machine, will be $\frac{x - x'}{x}$.

LE PREMIER CHERCHEUR D'OR

Le *Progrès* de San Francisco rappelle l'histoire de la découverte de l'or en Californie, découverte qui a produit une si grande révolution dans le monde économique, et il l'accompagne d'un mot qui a conservé le pouvoir d'éveiller des images ardentes, chaleureuses, et actuellement, même en Europe. Après avoir parcouru d'immenses richesses, il est banal dans la gouvelle. Son nom est Jean Sutter.

Né en 1803, dans le duché de Bade, Sutter entra au service dans la garde suisse de Charles X. En 1834, il quittait la France et se rendait à New-York, pour fonder aux États-Unis une colonie de vignerons. Il passa ensuite dans le Missouri, le Nouveau-Mexique, travailla pour le compte de la Compagnie des fourrures dirigée par les Astors, parcourut les îles Sandwich et l'Alaska. Mais il ne trouva nulle part, lorsqu'il traversait San Francisco, il sollicita et obtint du gouverneur de l'État une concession gratuite de trente lieues de terrain dans la vallée du Sacramento, sur les bords de l'Amérer la Fourche, et à cheval auprès d'un Sacramento Gu, c'était en 1839. Jean Sutter se mit résolument au travail avec ses Blancs et tout Indiens; il se construisit une maison sur un monticule d'où il commandait tout le pays. En 1847, la conquête et l'achat de la Californie par les États-Unis ne le déposséderent pas, et en 1848 l'ancien garde suisse se trouvait à la tête d'une exploitation agricole empressée à la culture des céréales et à l'élevage des bestiaux. Il avait construit des moulins, des scieries, des ateliers de toutes sortes; ses chevaux et ses bestiaux se comptaient par milliers.

Enfin, au printemps de 1848, en faisant marcher pour la première fois la machine d'une scierie mécanique sur la Fourche, un de ses ouvriers découvrait dans le sable une paillette d'or. Sutter s'efforça de tenir la découverte secrète; mais en quelques semaines elle était connue à San Francisco, et bientôt des milliers de diggers ou chercheurs d'or, Indiens et Européens, accourant sur les bords de la Fourche; les soldats, les matelots désertaient pour exploiter ce nouvel Eldorado. Sutter ne devait pas profiter des richesses incroyables que les nouveaux venus allaient détecter. Après de nouvelles vicissitudes, il quitta définitivement la Californie, et s'établissait, dit le *Progrès*, âgé de près de soixante-dix-huit ans, il habite une chaumière dans le petit village, moitié de Lititz, à six lieues de Philadelphie.

LES COMMUNICATIONS TÉLÉPHONIQUES

A PARIS

SYSTÈME EDISON

Deux Compagnies se disputent à Paris le service des communications téléphoniques, dont les lecteurs de *la Nature* connaissent déjà les principes généraux par l'article que nous avons publié dans le numéro du 28 février 1880 sur l'un des systèmes actuellement employés en Amérique. Nous décrirons aujourd'hui les appareils de la Compagnie Edison, réservant pour un article ultérieur ceux de la Compagnie Gower.

Le transmetteur est un téléphone à charbon système Edison, représenté en coupe figure 1, et en perspective, figé 2, son support, figure 2.

Il est fondé sur les variations de résistance électrique qu'éprouve une pastille de charbon lorsqu'elle subit des pressions variables. Ce charbon, pour donner de bons résultats, demande une préparation toute spéciale. Il est obtenu en brûlant du pétrole dans des lampes à longue mèche; il se dépose sur les parois de la chambre de combustion une sorte de noir de fumée qui est ensuite légèrement comprimé dans un moule qui lui donne la forme et les dimensions d'une pièce de un franc en argent. La pastille ainsi préparée est placée entre deux disques de platine dont l'un est fixé sur la boîte métallique qui soutient la plaque vibrante; l'autre disque porte un petit bouton d'ivoire qui vient s'appuyer contre cette plaque, du réglé la pression en vissant plus ou moins la plaque sur le support. Les deux disques formant donc les deux conducteurs d'une boîte ronde et aplatie dont la périphérie est formée par un anneau d'ébonite fixé sur le disque visé dans le support. Un fil de platine amène le courant sur la face antérieure du disque placé du côté de la plaque, ce courant traverse la pastille de charbon et sort par la partie métallique du support. En parlant devant l'embouchure, même à 20 centimètres de distance, les vibrations se transmettent à la pastille, se traduisent par des variations de pression et par suite par des variations de résistance électrique.

Le courant de la pile, après avoir traversé le transmetteur, n'est pas envoyé sur la ligne pour actionner le récepteur, mais il traverse le gros fil on fil *inducteur* d'une petite bobine d'induction (fig. 3) sans condensateur ni trembleur, et va à la pile. Ce circuit est donc constitué par la pile, le transmetteur et le fil inducteur de la bobine. Le fil induit de la bobine est relié à la terre par l'une de ses extrémités, son autre extrémité correspond avec la ligne. Au poste récepteur, l'un des fils de la bobine du téléphone récepteur — un téléphone magnétique système Bell, par exemple — correspond avec le fil de la ligne et l'autre extrémité de la bobine avec la terre. Tel est l'ensemble complet de la communication. On envoie donc dans la ligne, non pas le courant de la pile, mais le courant induit dans le fil fin de la bobine par les variations d'intensité du courant inducteur, lorsque la parole émise devant le transmetteur modifie les résistances de la pastille de charbon.

L'idée d'employer les courants *induits* et non pas le courant direct remonte aux recherches de M. Gray sur les téléphones musicaux, bien avant l'invention du téléphone parlant. M. Edison est le premier — en Amérique — qui ait eu l'idée de l'employer au téléphone à pile, idée qui était aussi venue à MM. Pollard et Garnier avant qu'ils n'aient eu connaissance des expériences antérieures de Gray et d'Edison.

L'emploi de la bobine d'induction présente plusieurs avantages. Le circuit formé par la pile, le fil inducteur et le transmetteur est très-court, et par suite sa résistance est très-faible. Il en résulte que le courant qui le traverse est très-intense, et que les variations d'intensité produites par les vibrations de la pastille de charbon sont très-grandes. Le courant induit, qui traverse la ligne, est donc très-énergique, et il peut actionner le récepteur à de grandes distances. Le circuit de la ligne, au contraire, est très-long, et sa résistance est très-grande; il en résulte que le courant induit qui le traverse est très-faible, et que les variations d'intensité produites par les vibrations de la pastille de charbon sont très-petites. Mais, comme le courant induit est très-intense, ces petites variations suffisent encore pour actionner le récepteur à de grandes distances.

transmetteur et le fil inducteur de la bobine présente une faible résistance. Il en résulte que les variations de résistance de la pastille de charbon se traduisent par des variations assez grandes dans l'intensité, et par suite les courants induits dans le fil fin sont eux-mêmes fonction de ces variations d'intensité du circuit primaire. Si l'on mettait le parleur à charbon dans le circuit de la ligne et que cette ligne fût un peu longue, les variations de résistance de la pastille de charbon seraient insuffisantes par rapport à la résistance totale du circuit, et par suite le téléphone récepteur serait à peine influencé. C'est ce qui explique pourquoi on ne peut faire de la microphonie directe à de grandes distances. D'autre part, les courants induits ayant une plus grande tension que les courants directs, peuvent être transmis à de plus grandes distances, sans que la résistance de la ligne diminue beaucoup leur intensité. L'emploi de la bobine d'induction a donné un artifice ingénieux que nécessaire remarquable, mais il est assez incommode, bond et coûteux; on lui a, pour ces motifs, substitué le *pangraveur*, dans lequel tous ces inconvénients sont supprimés.

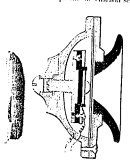

Fig. 1. Coupe du transmetteur à charbon d'Edison.

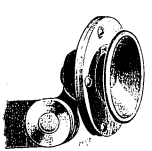

Fig. 2. Transmetteur à charbon d'Edison.

Il est maintenant facile de comprendre comment le poste central peut converser avec chaque abonné en les reliant entre eux; le diagramme (fig. 6) représente le montage au moment où les deux abonnés 27 et 56 sont en conversation.

La ligne L' est reliée directement à la ligne L, en plaçant une cheville en 2; cette cheville établit une communication par l'intermédiaire des plaques métalliques C et C'. Il y a donc trois circuits distincts :

1° Le circuit du transmetteur de l'abonné 27, formé par sa pile P', le fil inducteur de la bobine B' et le parleur T';

2° Le circuit du transmetteur de l'abonné 56, formé par sa pile P'', le fil inducteur de la bobine B'' et le parleur T'';

(Ces deux circuits sont représentés en gros traits sur le diagramme.)

3° Le circuit de ligne relié à la terre par ses deux extrémités et traversant les deux récepteurs R', R'', les fils induits des bobines B', B'' et les signaux avertisseurs A', A''. Ces signaux avertisseurs sont toujours dans le circuit, et en voici la raison : Lorsque la conversation entre les abonnés 27 et 56 est terminée, en accrochant le téléphone en place, un commutateur *automatique*, manœuvré par le fait même de la suspension du téléphone, place la commutateur automatique

l'importance relative qu'on attache aux communications avec l'un ou l'autre des correspondants, il sera facile de *faire attendre* M. C ou, au contraire, d'interrompre la conversation avec M. A pour donner audience immédiate à M. C. Tous certains cas, au contraire, MM. A, B et C pourront s'entretenir en même temps, comme s'ils étaient réunis dans la même pièce; il suffira pour cela que le poste central établisse les communications demandées par les intéressés.

Ce montage à triple communication présente donc des avantages de même à faire oublier le petit inconvénient que présentent les indiscrétions possibles, mais peu probables, du poste central.

Les communications téléphoniques par le système Edison donnent des résultats très satisfaisants lorsque les lignes ne sont pas trop nombreuses et trop rapprochées des lignes télégraphiques, qui produisent, dans ce cas, des courants d'induction parfois assez gênants. Il demande seulement un entretien de la pile et un certain réglage du transmetteur, organe un peu délicat, à Bruxelles, on a remplacé le parleur à charbon d'Edison par le transmetteur microphonique de M. Blake, qui donne d'excellents résultats sans nécessiter des réglages aussi fréquents.

Dans un prochain article, nous examinerons le système Gower, dans lequel l'appel et la conversation se font par des organes exclusivement électromagnétiques.

E. HOSPITALIER.

CORRESPONDANCE

SUR UN SINISTRE AÉRIEN

Marseille, 17 août 1880.

Monsieur,

M. Charles Brest a fait à Marseille, le premier de ce mois, sa première ascension avec le ballon *Stanislas*, parti à cinq heures du Prado, par un temps très calme, il franchissait vers cinq heures et demie la chaîne des montagnes de l'Estaque et atteignait en peu de temps les plaines de Pesquelès, près d'Aix.

Le dimanche suivant, 8 août, malgré un vent violent du nord-ouest, M. Charles Brest s'élevait pour la deuxième fois avec le *Stanislas* et disparaissait bientôt à l'horizon, passait par le mistral vers la haute mer.

Une dépêche de Berre indique que le 9 août on a recueilli dans une anse, entre Rona et Port, près d'Ajaccio, un ballon avec une nacelle et accessoires. Dans la nuit du 8 au 9, grosse mer et vent grand frais sur cette partie de la côte.

Voici d'autre part, le récit publié par le *Petit Marseillais* et dû au capitaine du *Segonde*, qui, dans sa traversée de Marseille à Palerme, a vu, en mer, le *Stanislas* dans une situation des plus critiques.

« Dans la soirée de dimanche 8 août, dit le capitaine du *Segonde*, entre sept et huit heures du soir, notre bateau se trouvait en face du détroit de Bonifacio, vers le 42e degré de latitude et le 7e de longitude, lorsque nous aperçûmes de bas, venant vers nous, un ballon aux allures bizarres dans la nacelle. Le vent soufflait assez fort, venant du nord-ouest et poussait le ballon naturellement vers le sud-est, avec une vitesse d'au moins 25 milles à l'heure.

« Le ballon courait presque à fleur d'eau, suivant les ondulations des vagues et disparaissant à moitié dans le creux de l'une à l'autre. Il ne tarda pas de nous atteindre, mais à ce moment il s'éleva à perpendiculairement à hauteur de mât, nous dépassa et disparut derrière l'horizon avec une rapidité vertigineuse. Les passagers du *Segonde* eut eu tout le loisir d'observer la nacelle, dans laquelle on voyait un accumulateur bissant sur son échelle à coude, sans doute pour échapper aux coups de vague auxquels la nacelle était exposée et nous avons tous pensé qu'il allait atterrir en Corse. »

L'ensemble de ces renseignements vous apprendra qu'il faut ajouter à la liste déjà si longue des victimes de l'aéronation, le nom de M. Charles Brest.

Veuillez agréer, etc.

UN LECTEUR ASSIDU.

CHRONIQUE

L'éruption du volcan Furgo dans le Guatemala. — On nous apprend de Panama que le volcan Furgo, près d'Antigua (Guatemala), qui était inactif depuis plusieurs années, a fait soudain éruption le 29 juin 1880 à trois heures du matin. Les passagers du paquebot Wilmington, de la ligne du Pacifique, ont vu ce magnifique spectacle d'une distance de 50 milles à vol d'oiseau. Du plus haut pic du Furgo, des colonnes de flammes s'élancaient à 5000 pieds, illuminant une vaste étendue d'espace à l'est et au sud, tandis qu'au nord et à l'ouest leur éclat obscurcit par d'immenses nuées de poussière et de fumée. La première grande colonne de feu, dit un témoin oculaire, s'est élevée à 5000 pieds de haut pour le paraître, lancant des matériaux d'environ 5 pieds cubes; celles d'une pièce d'artillerie. Une demi-heure après, on a vu descendre brûlant deux torrents de lave. L'un au sud, vers la ville d'Antigua, et l'autre à l'ouest, vers la mer, des masses de matières en fusion consumaient tout sur leur passage, détruisant des forêts, combinant des eaux d'un et remplissant l'atmosphère de nuages de fumée et de vapeur. Une rue considérable s'est manifestée subitement dans la rivière de Guacalde, qui prend sa source sur le versant occidental de la montagne.

Tremblement de terre dans la Turquie d'Asie. — Une violente secousse de tremblement de terre s'est fait sentir à Smyrne dans la matinée du 29 juillet 1880. Les oscillations, qui se déplacèrent du nord au sud, ont duré douze secondes. Si elles avaient continué quelques secondes de plus, on aurait eu à déplorer une catastrophe aussi terrible qu'en 1776 à cette époque. Quinze personnes furent ensevelies sous les ruines de la ville. A cinq heures, tous les habitants étaient dans les rues. Un Turc a été tué dans son arabeie pendant qu'il récitait les prières du matin. Dans la rue Saint-Georges, une jeune fille et un jeune garçon ont été ensevelis sous les ruines d'une maison; on les en a retirés avec beaucoup de difficulté, mais encore vivants, quoique grièvement blessés.

Les dommages causés aux monuments publics et aux propriétés privées sont considérables et doivent s'élever à plusieurs millions de piastres.

2218. "Transmitters for telephones." R. M. Lockwood and S. H. Bartlett, of New York. Dated June 15, '64. The effectiveness of these transmitters depends not upon the mechanical vibration of a diaphragm but upon what is termed molecular movement, transmitted from molecule to molecule of a non-resonant material, which for a body remains stationary while waves and the molecules which control the volume, pitch, and vocalness of sound transmitted to and through the wires. A microphone of any suitable character is provided which transmitting-wires, and is either wholly or partly embedded in cork, light wood, or other non-resonant material.

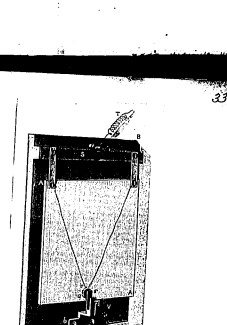
Fig. 1 represents the transmitter in section.

The microphone is represented as composed of two bars, a a, arranged in or about in the same plane, with their inner ends approaching each other but out of actual contact, as shown. These bars are preferably of carbon of the kind well known to electricians, but they may be of any suitable conducting material, such as metal, which, however, as far as experiments have extended, has been found inferior to the carbon in its results. The adjacent ends of the bars, a a, have semi-cylindrical notches cut in them opposite each other, forming a circular opening between the bars for the reception of a pin, b, on the lower face of a small button or disc, b, of carbon or other conducting material similar to that of which the bars, a a, are composed, said button resting by gravity on the inner ends of the bars.

DE LOCHT'S PANTELEPHONE.

Leon de Locht, Mining Engineer and Professor at the College of Mining, Mont-St-Martin, Liége, Belgium, after several years' experimenting, has succeeded in overcoming the defects of the best telephones at present in use. After the invention of Graham Bell, Ader, Edison, Hughes, Blake, Gower, Crossley, Preece, Varley, and others, which have been brought to perfection in various countries, has thought of a new principle which he calls the pantelephone. The pantelephone is a microphonic transmitter of a new construction, and receiver which differs at a first view from all that are in use. It is capable to transmitting without broken at forty-five feet from the apparatus of a distance of several miles through the medium of receiving telephones. The pantelephone, which is extremely simple, is composed essentially of a movable plate carrying a contact-piece, and a screw against a disc of carbon or metal—silver or platinum.

In connection with the accompanying cut, the plate is seen figured at b, b. It may be of aluminium, sheet iron, steel, or any suitable metal. In this instance, whatever that is capable of being formed into plates of large superficial area, while at the same time possessing the requisite amount of lightness. It is preferable that the form should be square or oblong, and, when made of metal, two or three inches in width, and from two to three feet in length, as inflexible as possible, and not liable to bend out of shape through the influence of heat, moisture, or humidity. It is surrounded by two small vertical bolts and springs, S S, from a support, S, which is perfectly straight and stands out from the face of plate B B, forming the framework of the apparatus. The bolts pass through the lower end of the plate b, forming or soldered a small carbon disc, c, which, when the apparatus is in use, is pressed by a screw, a, against a small piece of silver or platinum fastened to the end of a short and somewhat inflexible spring, c, the latter being fixed by means of a screw, c, to the copper support s s. By means of a thumb-screw, T, passing through the support the contact of the carbon, c, with the piece, d, may be regulated at pleasure.



The pantelephone is placed in the circuit of a voltaic pile in such a way, for example, as in the current entering at E proceeds to the support S, thence through the spring r to the contact between c and d, the carbon c, and through the plate b b to the springs S S, and leaves the apparatus at T.

The microphone and receiver are of ordinary construction, by means of which the invention is enabled to re-produce the utterances as to insure the greatest distinctness and the best possible results. Various arrangements may be employed, too, to diminish or avoid all noises which might arise from tremors of the wires, or from the shaking of the wall to which the apparatus is attached. It is claimed that the pantelephone is capable of being regulated, in all limits to get out of any sound; moreover, that the expense attending the introduction of the system is insignificant, since the apparatus under proper conditions requires for its working only the electromotive force of a single voltaic couple. The instrument transmits all sounds, articulate or inarticulate, with equal facility, through the medium of either solids or the air. It is declared in a key (which may be set to music) several octaves in depth in such a way that its reproductions to accurate vibrations is in no way impaired.—*Scientific American.*

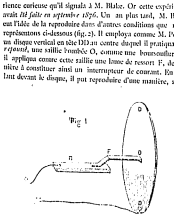
THE TELEPHONE IN POLITICS.—The President of the French Republic has established in his study a telephone apparatus, enabling him to have instantaneous communication with the Presidents of the Senate and Chamber and all the Ministers. *Scientific American*, Sept. 13, 1880

In a letter to the *Operator*, Mr. T. D. Lockwood discusses the right of Mr. Bellmer to the credit for having been the first to invent, an instrument identical in principle with the microphone of Professor Hughes. He applied on April 14th, 1877. Mr. Bellmer filed a caveat in the patent office on the 27th of April, 1877. Mr. Bellmer filed an application in the patent office for a patent on his invention on the 27th day of April, 1877. He described in his caveat of April 14th, 1877. But October, 1877, Mr. Hughes commenced his experiments; privately exhibited his microphone in January, 1878; and gave his perfected invention to the public in May, 1878.

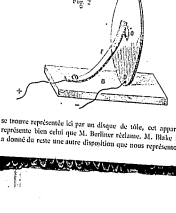
Journals and Periodicals

Le microphone Berliner.

En présentant avec laquelle M. Berliner exécutait la priorité de l'invention du microphone, et la complaisance de certains journaux allemands pour accueillir cette réclamation, nous forcent de revenir un peu sur ce système, et en même temps de faire connaître les appareils de ce genre exposés en 1876 et 1877 par MM. Pelrce et Blake. D'après des renseignements qui ont été donnés en 1878 à M. du Moncel par M. Blake, alors à Paris, M. Pelrce en faisant des expériences à la Providence avec les appareils de Hell, fut très-étonné d'entendre la parole avec un transmetteur téléphonique à pile composé d'un disque de tôle 1D (fig. 1) placé verticalement et aimantant un morceau de fer rouillé R placé horizontalement, par l'intermédiaire d'un ressort F, fortant sur ce morceau de fer, et fixé au centre O du disque. Sous l'influence des vibrations du disque, le ressort produisait de petites frottements qui suffisaient pour fournir, par instants, la reproduction de la parole. Toutefois ces résultats n'étant pas été suffisants pour lui faire croire à des applications utiles, M. Pelrce s'est contenté de les considérer comme une expérience curieuse qu'il signala à M. Blake. Or cette expérience avait été faite en septembre 1876. Un an plus tard, M. Blake en était l'idée de la reproduire dans d'autres conditions que nous représentons ci-dessous (fig. 2). Il employa comme M. Pelrce un disque vertical en tôle 1D au centre duquel il pratiqua, en *e*, un petit trou, et qu'il appliqua contre cette saillie une lame de ressort F, de matière à constituer ainsi un interrupteur de courant. En parlant devant le disque, il put reproduire d'une manière, sinon



parfaite du moins suffisante, la parole à travers un téléphone introduit dans un circuit voltaïque, mis en rapport avec ces deux parties de l'appareil. Sauf la lame de charbon qui



se trouve représentée ici par un disque de tôle, cet appareil représente bien celui que M. Berliner réclame. M. Blake lui a donné de cette une autre disposition que nous représentons

fig. 3. Ce sont deux disques de tôle DD, D'D' superposés horizontalement et munis à leur centre de la saillie bombée dont nous avons parlé. Ces disques sont en contact par cette saillie. Les bords des deux disques sont d'ailleurs séparés par des calottes plus assez minces pour maintenir leur parallélisme tenus vernis de parler avant de se prononcer d'une manière si catégorique. Cela dit en passant, nous allons examiner maintenant le nouveau transmetteur de M. Berliner qu'on nous donne comme une merveille, et qui n'est qu'une dérivation des transmetteurs Blake, Edison et Fernandez Janez.

Les figures 1, 2, 0 et 3 ci-contre représentent cet appareil dont la coupe, fig. 1, représente les détails principaux, c'est l'embouchure téléphonique ; *fg* le diaphragme en fer battu soutenu sur ses bords par une enveloppe de caoutchouc élastique. Une lame flexible d'argent *k*, fortement pressée contre cette enveloppe de caoutchouc par une vis *l* porte vissée en *i*, une sorte de cartouche métallique *i*, qui renferme l'un des contacts microphoniques, constitué par un petit cylindre de graphite. Le courant arrivé à ce contact par la vis *l*, qui est isolée de la masse de l'appareil par un taquet d'ébonite *m*, fixé sur le couvercle en fer de l'appareil. Une large lame d'argent *fp*, fixée en *m*, et emboîtant avec isolement la cartouche *i*, permet de serrer plus ou moins fortement la cartouche contre le diaphragme, au moyen d'une vis *r*, et porte articulée obliquement une lame *g* terminée par un petit cylindre métallique *r* qui renferme le second contact de graphite, logé est arrondi par sa partie extérieure. Derrière ce système est disposé, une traverse de fer *n* et une bobine d'induction *t* sur laquelle agit le courant du microphone, et dont le fil induit communique avec la ligne téléphonique. L'appareil est naturellement suspendu verticalement.

Discoveries in the Telephone

To the Editor of The Telegraphic Journal.

Sir,—While working with a Gower-Bell telephone and a Crossley transmitter and Bell receiver in circuit it was observed that when speaking on the "Gower" the sounds always proceeded from the Bell receiver, and when speaking on the Crossley transmitter from the "Gower." This very materially added to the distinctness.

Missing the Bell receiver when speaking on the Gower, at the Gower when speaking on the Crossley, gradually from the ear, when a distance of three-quarters of an inch intervened the sound became continuously more round to the other telephone, and when the distance was increased to an inch and a half the sound passed entirely into the other telephone.

On connecting up a single galvanometer, the best at hand, in circuit with the Gower, and blowing with sufficient force to produce a clear sound on the whistle, the needle was deflected through 40 divisions. Increasing the blowing force until a deep sound was produced, the needle returned to zero, and passed through 20 divisions in the opposite direction.

The effects obtained when the blowing was at the distant station were similar but less marked, the deflections being 15 and 7 divisions respectively.

The figures given are the averages of several trials.

I am, Sir,
Yours faithfully,
Edinburgh. F. MACRAE KEITH.

Edison's Telephone.—We understand that the "grimler" telephone is not giving satisfaction, and that in many instances the Edison receiver is being substituted for the receiver, in consequence of complaints from renters.

The Government and the Edison Telephone Company.

The important and long-anticipated struggle between the Government and the Edison Telephone Company was commenced on Monday last at the sittings in Banco in the Queen's Bench Division, before Baron Pollock and Justice Stephen, the Attorney-General being for appellant, and the Edison Telephone Company for respondent. The action is in the name of the ex-parte

The defendants' witnesses 'denied the similarity of the telegraph and telephone, 'pointing out the difference. Professors Tyndall and Stokes supported this view. The former said in cross- examination that, from a purely scientific point of view, in any legal proceedings, on questions affecting the application of patents to the uses of life, having always steadfastly declined to do so. But, as he had explained, the principle and illustrated the action of the telephone by Mr. Graham Bell and Mr. Edison in the Lecture Theatre of the Royal Institution, he was anxious that his silence should not be misinterpreted, and he had, therefore, on the present occasion, to express the opinions contained in his affidavit. The difference between the telegraph and the telephone was one of kind and not of degree. Professor Gladstone and Professor Jenkin testified to the same effect. The telephone, according to them, is a totally distinct invention from vocal telegraphy with a needle pointing to letters on a dial, &c., being set in motion by sound. Dr. Henning was the only witness whose evidence was final. He pointed out the difference between the system of Bell and that of Edison, and explained that, while the latter's power of hearing the human voice could not, in his view, be called a telegraph.

Mr. Justice Stephen said some of the definitions given were more difficult to understand than the thing defined, though they had given much trouble to their authors, who were men of great eminence. But what the Court had to do was to ascertain whether Bell had invented a new and useful thing, different from other things, but to construe the words of Bills Acts of Parliament.

Various other affidavits were then read. For the defendants those of Baron Reuter, Mr. Symington, Lord Aldworth by Mr. Gowen and Sir Charles Bright; and for Bell, Sir Joseph, and Mr. Hopkinson. For the other side further affidavits by Mr. Preece was read on behalf of Mr. Tierney Wilmott, the defendant's manager, speaking at Glasgow of Graham Bell's telephone, said, "Everybody is in the greatest of all the marvels of the electric telegraph due to a countryman of their own—Professor Graham Bell."

During the reading of the affidavits Mr. Justice Stephen again drew the attention of counsel to the fact that although the Court was required to hear the opinions of scientific persons upon the meaning of the word telegraph, and the distinction which existed between it and the telephone, and between a telephone and a telegraph, the real question which the Court would have to decide would be not whether Bell should be put upon the word telegraph in three Acts of Parliament.

The construction of the various affidavits, or of such matters of opinion as were considered relevant to the case, the Solicitor-General, continuing his address to the Court, observed that it would be necessary for him to enter into any considerable amount of detail. He had explained the definition of the word telegraph, as employed in the Act of 1869, to be any communication, by any means, whether it was that opposed to the system of a needle or a dial. Electricity was at the passing of the Acts the only agent known for the purpose of enabling the word telegraph to be used. But if 1869 the word "electric" was first introduced, and a telegraph was defined to be any apparatus for transmitting intelligence by means of the agent, no mention of wire being made. It was said to be a misfortune that what passes along the telephone was not a message; but the Act spoke broadly of "other communications," and any intelligence transmitted from one person to another, by any means, was admitted if this telephone was not different in kind, but in degree, it certainly could not be a telegraph. Was it a telegraph within the monopoly; and he submitted that the affidavits of Professors Tyndall and Stokes, on this point, were extremely valuable. It would not depose, and in the technical degree; but he considered it very important that the latter, which had been taken before a vocal telegraphy, and in this sense Morse's "consider" was a telephone. It was contended that their invention was founded on different principles from that of Bell's telephone; but their own were based on different principles, and that Bell's telephone had been in existence before the Act of 1869. It was not within the Act, but the other one would not. He, therefore, called for the defendants, also spoke of the distinction between Edison's and Bell's telephone, and no doubt such distinction existed. As to whether the defendant's came within the monopoly, as to whether the defendant's case within the monopoly, as to whether the defendant's case within the monopoly, as to whether the defendant's case

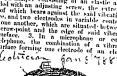
38

Electrician June 29, 1881

21

230746. Microphone.—(Emile Berliner, Boston, Mass.)—(Filed March 31, 1880.)—(No model.)—Patented in England, May 5, 1880; in Belgium Jan. 9, 1880; and in Italy Feb. 15, 1880.

Claim.—1. A microphone or contact-telephone in which one electrode is left free to move in position by being suspended from or attached to a permanent magnet for the purpose set forth. 2. In a microphone or contact-telephone, the combination of a stationary electrode, a diaphragm consisting of an elastic metal provided with an adjusting screw, the extreme point of which is opposite the said vibrating surface, and two electrodes in variable contact with one another, which are supported between the said screw-point and the edge of said vibrating surface. 3. In a microphone or contact-telephone, the combination of a vibrating surface forming one electrode of an electric

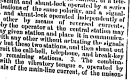


2.1

tric current, a pendulous weight forming the other electrode, and a device for changing the inclination of said pendulous weight, substantially as and for the purposes set forth. 4. In a microphone or contact-telephone, the combination of the diaphragm B, the block P, adjustable weight G, plate H, forming an armature-magnet, E, electric plate I, and adjusting-screw J, substantially as and for the purposes set forth. 5. In a telephonic apparatus, a magnet forming an electrical circuit, and electrodes on its face in contact, substantially as and for the purposes set forth.

234772. Switch for Telephone Lines.—(Charles B. Hoadley, New York, N.Y.)—Filed March 15, 1880.—(No model.)

Claim.—1. In a series of telephones upon the same main circuit, connected with a central station, the combination, with each of the telephones, of a shunt or cut-off, substantially as set forth over the main circuit, and a talking device for each of said shunts or cut-outs, substantially as set forth, consisting of a talking by a current in one direction over said main circuit, and for unlocking by a reversed current, whereby any given number of telephones may be placed in communication, and all the other telephones left in or cut out of the circuit by an operator at the central station, except those at stations where the shunt or circuit is locked. 2. The combination, with the



2.

telephone and signal at each station, of a telephonic shunt and shunt-lock operated by a series of pulsations of the same polarity, and a signal-shunt and shunt-lock operated by a pulsation of the opposite polarity, substantially as and for the purpose set forth, whereby the operator at the central station may call any telephone and place it in communication with any other without actuating the signals of any but those to which the shunt and then shunt and of the remaining stations, and break-key thus, with the vibratory tongue. 3. The combination of the main-line current, as operated by reversals of the current, with the telephone-shunt and its cut-off shunt, operated also by said tongues and controlled by a current over the main line, substantially as described. 4. The combination, with the vibratory tongue as operated by reversals of the current, of the telephonic apparatus controlled by said tongue, and the telephone-shunt and its operating devices controlled by a current over the main line, substantially as described. 5. The combination, with a single polarized magnet and its vibratory tongue, armature, the unison device, and cut-off shunt controlled by said armature, of a local telephone-shunt and the devices operated by said magnet for actuating said cut-off and telephone-shunt, substantially as described. 6. The combination, with the telephone switch-lever I, carrying the spring arm g, having a contact-point, and the spring f, in electrical contact therewith, of the metal segment m, having its ends insulated from each other when the switch-lever is in the position one of said ends will be in contact with one spring and the telephone switched out of the main circuit, and when the said lever is swung outward the other end of said segment will be in contact with another spring, and the telephone switched into the main circuit, substantially as described.

The Lilly Mechanical News 1881.

WHY THE TELEPHONE OPERATES.

A correspondent of the Cleveland Trade Review, signing himself "An Experimenter," writes as follows:

"Millions of people use the telephone without inquiring as to its principle, and none of the inventors of this mode of communication (for according to evidence there were several) or any of the adepts, have done anything to enlighten the public on the question. We have the fact that the speaking telephones than the Bell are coming into operation which do not depend on electric induction, but on the communicative properties of the air itself. This circumstance confirms my theory.

"Most people are aware that the sound from scratching with a pin upon a piece of dry timber at one end can be heard distinctly at the other end. This results, I take it, from the fibrous character of the wood—a distinance of contact between particles. I conclude that it is the fibrous character of the atmosphere to which we are indebted for telephonic communication. The atmosphere, when pure, is composed of two gases, with the admixture of a small proportion of aqueous vapor and carbonic acid.

"Now, as the atmosphere is admitted to be a body, may we not suppose that it is constituted like other elastic bodies, though it cannot, like these that are solid, be brought within the sphere of microscopical investigation, and that this aqueous vapor is distributed throughout the atmosphere in the form of an infinitely minute and symmetrically reticulated fibrous tissue, susceptible of tension and attenuation, like that known to exist in animal and vegetable substances?

"By such a supposed distribution of the aqueous vapor, an independent vehicle of sound is at once supplied, and the gaseous elements of the atmosphere are left to perform their wonderful and important duties in the economy of the creation undisturbed. The supposition which I have hazarded, will also satisfactorily account for the greater facility with which sound is transmitted in the lower regions of the atmosphere, where the relative proportion of the aqueous vapor to that of the gaseous elements is greater than in its higher regions."

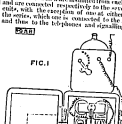
J. T. GENT AND CO.'S MICROPHONE TRANSMITTER.

THE patentees inclose an instrument in a d. mast walnut case, to the lever of which they attach, leaving a slight space between, a

diaphragm of wood; to this diaphragm they affix thin plates of metallically-prepared material, the plates nearing but not touching each other.

These attach to lever brackets, having spindles on which are loosely-hung metal arms, each arm carrying a plug or pencil of prepared material, these again resting on plates affixed to diaphragms. They prefer to use from 12 to 16 of these suspended arms, arranged in series of 2 or 4, so that the current of electricity to traverse the whole must pass over successive sets. Each arm is adjustable, and may be placed horizontally or vertically. The object of using a row of plates is that the whole of the vibrations of diaphragm may be utilised, and the redundancy current be correspondingly more powerful. The



plates at one end are connected to battery, and at the other end to a coil in the case.

Any form of telephonic receiver may be used with this transmitter, and they use flexible tubes to protect wires from injury, thus obviating one objection to the use of wire conductors between transmitter and receiver. The usual automatic switches and call-bell form part of the apparatus. The transmitter and use of tubes for purpose or use are patented.

each circuit any number of stations, each station being provided with an apparatus, which, when an audible signal is given at any station, will give visual station there, substantially as described. The receiving one circuit with signal bell, each of which is fully described. The switch board receiving each of the external circuits, for use, telephones, keys, and signalling apparatus, with one of the ends of the coils of the electro-magnets of the system from external sources together. It consists of a suitable frame-work containing a series of spindles and are connected respectively with the external circuits, with the exception of two at the extreme end of the series, which are connected together, and thus form the telephones and signalling appa-

1. 1880. Improvements in Telephonic Apparatus and Systems. *By John Henry Johnson,*—(A communication by *George Lee Anthony, of Boston, and Thomas Augustus Watson, of Everett, in the State of Massachusetts, United States of America.*)

In the system there are a series of telephonic signalling apparatus, one at central station, and one at

tuses at the central station. Immediately behind the upright bars and at right angles to them are a series of parallel horizontal metallic rods, also insulated from each other, which serve to electrically connect two or more of the upright bars together by means of metallic connectors, which connectors can be slid on the upright bars, and when released spring into contact with the horizontal rods. Each of the horizontal rods connects with a spindle, and each spindle has which is connected to the electro-magnet of a suitable vibrator, which lies full a number plate when the electro magnet of the annunciator is excited or otherwise. Connection and from said electric magnet connection is made with the battery. Each spindle is in addition in exchange system is also provided with a switch-lever, pressure of one two stations can communicate with one another telephonically a person at any other station is prevented from overhearing the conversation without notifying the stations talking with one another. This result is accomplished by means of a rocking switch, which in this system is placed at each station. When a telephonic signal is given at any station, and successfully passes through the signal bell of each station to the next station, and the telephone when not in use is not in circuit; but when it is desired to communicate by telephone with a station on either side, by the intervention the station

surveillant de la surface, le mécanisme du ventilateur et les portions des divers postes. Il conviendrait que ces derniers fussent astreints à noter, avant leur descente, la pression barométrique, et à la comparer avec les observations du poste précédent. Le mécanicien, ou le chef de place, devrait également, à certains moments de la journée, observer le baromètre, et, dans le cas où il constaterait une baisse rapide, en prévenir les surveillants du fond, qui auraient à prendre des mesures en conséquence. En même temps, la marche du ventilateur serait activée. Ces mesures ont d'ailleurs déjà été introduites dans la pratique par les directions de plusieurs mines à grisou. La température devrait aussi être observée : dans ce but, il serait utile d'établir à la surface des thermomètres à maxima et à minima. »

Je me tiens compte des recommandations qui précèdent n'eût entraîné une lourde responsabilité, dont les conséquences pourraient, dans certains cas, à notre avis, provoquer les rigueurs de la loi.

Chaque fois qu'une chute barométrique aussi prononcée que celle du 17 de ce mois serait constatée[1], toutes les fosses à grisou devraient être évacuées pendant au moins quelques heures. Le travail ne reprendrait qu'avec la hausse du baromètre; la ventilation serait en outre rendue beaucoup plus active et des recommandations spéciales seraient faites aux mineurs. On nous répondra peut-être que ce système offrirait certains inconvénients dans la pratique; mais nous ferons observer que ces inconvénients sont peu de chose lorsque la vie d'un grand nombre d'hommes se trouve en jeu.

Les mesures de précaution que nous prenons ici pour les mines sont, dans un autre ordre d'idées, les mêmes que celles dont tous les capitaines de navires sont moralement obligés de leur conseiller. Leur existence en dépend souvent, du reste. Le vaisseau qui attend le signal du départ et est parti retenu au port par l'annonce d'une tempête prochaine. Ce retard à se mettre en route lui est toujours préjudiciable, mais il vaut mieux souffrir ce contre-temps que de s'exposer à périr corps et biens, pour avoir fait il dès avis météorologiques précis de leur exigence, ou même du navire tout entier.

Les responsabilités sont les mêmes pour le commandant d'un navire et le directeur d'une mine. L'existence des hommes placés sous leurs ordres est intimement liée à leur prévoyance, à leur sang-froid et à l'observation des règles qui se rapportent à l'exercice de leurs fonctions.

Il est à espérer que la météorologie, à laquelle la navigation est déjà redevable de beaucoup de bienfaits, pourra, dans un avenir prochain, rendre des services non moins importants à l'industrie houillère. Elle ne sera certainement pas une panacée à tous les malheurs qui arrivent dans les mines, mais on peut affirmer qu'elle servira à en diminuer notablement le nombre. Elle acquerrait par là un nouveau titre à la reconnaissance de l'humanité.

A. LAMASTRE.

[1] Depuis plus d'un an, l'Observatoire royal de Bruxelles a pris à tâche de signaler aux mines, par voie télégraphique, les baisses barométriques anormales. Malheureusement ces avis restent d'ordinaire sans effet, et il est important de pousser le tube de 15 centimètres.

APPAREIL AVERTISSEUR DES GELÉES

Les cultivateurs prennent constamment un appareil capable de les prévenir en faisant marcher automatiquement une sonnerie électrique dès que la gelée se ferait sentir pendant la nuit. Il suffit de tendre près de terre un fil de fer isolé de dix à quinze mètres de longueur; de telle façon qu'une de ses extrémités soit fixe et que l'autre soit libre. Si la température s'abaisse, le fil se contracte et diminue de longueur; le fil peut être disposé de telle façon que les deux contacts correspondant à la température de 0 degré, ou extrêmité libre termine en crochet établisse un contact et ferme le circuit d'une pile, de manière à faire fonctionner une sonnerie. Il va sans dire que nous n'indiquons ici que le principe d'un système qui peut être établi de plusieurs manières différentes. Un ingénieur physicien a même proposé de compléter cet appareil, en faisant communiquer l'extrémité libre du fil de fer avec un bras de levier qu'il arriverait à boucher ou ouvrir avec la température de 0 degré. Le contact ferait basculer un poids sur une mauvaise qui mettrait le feu à des matières combustibles. Les matières en brûlant produiraient un nuage de fumée destiné à prévenir les cultivateurs des effets du refroidissement nocturne. Il y a dans ces idées très originale qu'il serait intéressant de mettre en pratique.

LES TÉLÉPHONES SPÉCIAUX.

La plupart des téléphones connus se composent toujours d'un transmetteur, tantôt magnétique, tantôt microphonique, d'une ligne et d'un récepteur dans lequel on retrouve toujours comme parties essentielles :

1° Une plaque vibrante;
2° Un moyen aimanté ou un électro-aimant;
3° Une hélice traversée par les courants ondulatoires émis par le transmetteur.

Aucun de ces organes *essentiels* d'un téléphone n'existe dans l'*indispensable* à son fonctionnement, mais il y a plus, on a pu entendre et la parole *sans récepteur*, ou du moins sans récepteur apparent, et entendre le photophone de B-ll nous a montré qu'on pourrait transmettre la parole à distance *sans fil conducteur*.

Ce sont les singuliers appareils qui réalisent ces conditions que nous avons cru pouvoir grouper sous le titre de *téléphones spéciaux*, à défaut

dinaux; les matériaux solides consistent en débris volcaniques (pyroxène et feldspaths triclinique) et en pyrite.

Champignons parasites des vignes. — M. Maxime Cornu, dans une note analysée par M. Dumas, montre comment la théorie des germes s'applique à l'histoire des champignons épiphytes. Il s'occupe spécialement des parasites de la vigne. L'auteur remarque que l'oïdium et l'anthracnose tuent souvent des grappes qui, mêlées ensuite dans le fumier, ne sauraient se conserver. Mais il ajoute qu'il est loin d'en être de même pour le péronospore, et il tire de ce fait la conclusion que tout traitement de vigne contaminée par ce dernier, loin d'être introduit dans un compost, devra être détruit par le feu avec le plus grand soin.

Électricité. — Le décès de M. Lévêque avait laissé vacante une place de correspondant dans la section de physique; l'Académie y pourvoit aujourd'hui. La liste de présentation portait : en première ligne, M. Abria, à Bordeaux; en deuxième ligne *ex æquo* et par ordre alphabétique : MM. Cossa, à Montpellier, Violle, à Lyon, et Terquem, à Lille. Les votants étant au nombre de 49, M. Abria est élu par 45 suffrages; trois se portent sur M. Violle, 2 sur M. Terquem et 1 sur M. Cossa.

Le vénéré a été réellement trompé par un comité secret dans lequel ont été élus les sept experts de Commissions de paix. Cependant, nous devons enregistrer, outre deux très longues communications de M. Chevreul et de M. Tresca; une note de M. Raudot sur une pile *imputrescible* qui extrairait de l'eau plus d'hydrogène que celle-ci n'en contient! (16 volumes pour 1 volume d'oxygène); — une réclamation de priorité formulée par M. Buzer contre M. de Rondelet, relativement à la loi d'extinction des liquides; — les offres de service de M. Lefèvre, capitaine de frégate, qui se met à la disposition de l'Académie pour observer le prochain passage de Vénus; — la description d'un avertisseur pour les incendies, par M. Barbier-Dreuil; — un mémoire de M. Bitte sur l'action mutuelle de l'acide chlorhydrique et des chlorures métalliques; — des expériences de M. Chapuis sur le spectre d'absorption de l'ozone; — enfin des recherches médicales et statistiques sur la ville de Cette par M. Louis Amat.

STANISLAS MEUNIER.

NOUVEAU MICROPHONE

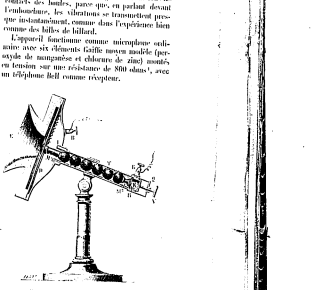
DE M. ROTHEY, DE PARIS

Ce microphone, à contacts multiples, représenté dans la figure ci-contre, se compose d'une rondelle charbon R, fixée à l'extrémité d'un tube de verre T d'un centimètre de diamètre, fixé lui-même sur un pied à genou, ce qui permet de faire prendre à l'ensemble de l'appareil toutes les inclinaisons.

L'embouchure porte une plaque d'ébonite de 1 millimètre d'épaisseur, sur laquelle est fixée une masse de cuivre M qui pénètre un peu dans le tube du verre. Dans ce tube, se trouvent six boules de charbon du comme d'un diamètre un peu plus petit, de façon à pouvoir s'y mouvoir très librement.

Le microphone est complété par une seconde masse de cuivre M' s'appuyant sur le haut d'une cuisse ronne K, par l'intermédiaire d'un petit ressort en spirale non représenté sur la figure. La vis V fixée sur l'écrou O sert à régler la pression de la masse M contre les boules. Les variations de résistance du microphone se produisent également sur tous les contacts des boules, parce que, en parlant devant l'embouchure, les vibrations se transmettent presque instantanément, comme dans l'expérience bien connue des billes de billard.

L'appareil fonctionne comme microphone ordinaire avec six éléments Gaiffe mouvé modèle (peroxyde de manganèse et chlorure de zinc) montés en tension sur une résistance de 800 ohms[1], avec un téléphone Bell comme récepteur.



Microphone de M. le docteur Raudot.

En employant des courants *induits* et un téléphone récepteur à 11 fil fin, condition nécessaire avec les courants induits, la distance peut être considérablement augmentée et atteindre, avec des résistances artificielles, jusqu'à 250 000 ohms.

Nous avons constaté à des expériences faites avec ce microphone, et nous avons constaté qu'il transmet très nettement la voix, sans altérer son timbre et sans craquements.

[1] Comme valeur *pratique*, une résistance de 1 ohm repréente celle d'un fil de cuivre pur de 1 millimètre de diamètre et de 19,5 de longueur, ou environ 10 mètres de fil de cuivre de cinquième d'un égal diamètre, ou bien encore 97 m. très de fil de fer de 4 millimètres de diamètre (fil télégraphique ordinaire).

Le Propriétaire-Gérant : G. TISSANDIER.

Imprimerie A. Lahure, rue de Fleurus, 9, à Paris.

THE TELEPHONE.—Mr. Rolls, of the South-Western Railway Telegraphs, has lately been carrying out some experiments with the Gower-Bell loud-speaking telephone which have proved remarkably successful, as the first plans the instrument was tried over sections of varying lengths as a means of verbal communication between signal cabins, a noteworthy point in the experiments being that the block wire itself was the only connection between the distant points, Mr. Rolls placing the telephones in multiple circuit with the block instruments at each end, between line and earth, in such a manner as in no wise to affect the block working; in fact, while listening at the telephone a train passing the distant cabin could be heard simultaneously with the receipt at the sending-signals upon the block instrument indicating the train's departure, the movement of the levers placing signals on behind the train five miles away could also be distinctly heard. Conversation was carried on with the utmost ease by inexperienced persons, and all sounds were remarkably clear, although several through postal wires would be powerful currents are on the same set of posts. This form of telephone having proved so successful, was subsequently tried as a long circuit speaking instrument between Yeovil and Exeter, a distance of forty-nine miles, upon the same set of poles as before; and despite the usual effects of induction, the voice was as remarkably predominant and as clearly and distinctly heard as in the previous experiment over a short section. Further trials indicated that the distances mentioned might be at least doubled.

THE TELEPHONE FOR DIVING OPERATIONS.—*L'Electricité* states that M. Dubois has introduced the use of the telephone in connection with the operations of the bed of the bay of Naples. By this means the lieutenant overheard are able to communicate with each other as quickly and intelligibly as could be desired.

A novel microphone, made by M. Bondet in Paris (*La Nature*, No. 394), has the general shape of a telephone as a support. It comprises a mouthpiece, in which is an ebonite plate in which, with a short piece of copper connecting from its middle a short way into a glass tube in which are six little balls of retort carbon in a row; a second piece of copper following the tube, ending in a small cup-shaped piece of carbon, which is in contact by means of a screw with the carbon balls. This cup can be raised or lowered by means of a milled head, with an Gimbal in tension, by a fulcrum and chain, is also mounted voice very distinctly without altering its timbre and without the disturbing sounds being rendered.

LONG DISTANCE TELEPHONE SYSTEM OF DR. HERZ.

A new system of telephony, invented by Dr. Herz, is attracting a great deal of attention among electricians in Europe, on account of the surprising distances through which telephonic communication has been maintained by it. The first announcement of the invention in the papers of September stated that conversation had been carried on through the cable connecting Brest and Penzance, a thing generally considered impossible, on account of the comparatively sluggish action of the electric current in submerged cables. The experiment proved sufficiently successful to encourage Dr. Herz to push forward his investigations, and, according to foreign advices, he has been rewarded by being enabled to carry on conversation through an actual distance of over six hundred miles over circuits having no special adaptation to telephonic communication.

Dr. Herz has apparently solved two difficult problems: that of increasing the amplitude of electrical vibrations, and that of neutralizing currents foreign to the telephonic circuit. The first he accomplishes by a microphonic transmitter with multiple contacts, and a system of derived currents; the second by interrupting the line and intercepting conductors or diffusers. We have received an extended illustrated description of this interesting invention, written by Th. Du Moncel, which will be published in full in SUPPLEMENT 274.

A SPEAKING CONDENSER.

IT is well known that the capacity or condenser of tinfoil sheets when connected to the terminals of the coils of the secondary circuit of an induction coil will produce musical notes when the primary circuit is excited by a battery and a Bell's electric vibrating telephone with intermittent contacts. The note to be heard is determined by the number of the pauses, whose vibrating telephone makes and breaks the primary circuit, in accordance with the vibrations of the coils, and the corresponding induced currents acting upon the condenser. The transmitter set into this vibrating telephone, which is audible as a humming sound, when, as Professor Hughes has called it, the "singing condenser" is introduced, was likewise, by Mr. C. F. Varley, used carefully investigated by Mr. C. F. Varley, and other French experiments, in connection with the application to telephony by Mr. Edison, who has succeeded in making it reproduce articulate speech after the manner of the Bell telephone receiver. M. Dussaud found that when a carbon microphone was placed in the primary circuit of an induction coil, instead of a free interrupting clicking of a vibrating and the striking of a bell could be imperfectly heard, but speech appeared quite inaudible. Following up this promising step, however, by including in the circuit of the secondary coil, with the condenser M. Dussaud found that speech was then delivered with great distinctness. For articulation the sensibility is simply inverted between one end of the secondary circuit and one pole of the condenser. Upon the terminals of Ruhmkorff coil, under the simple influence of the induced currents of the secondary circuit, articulate speech sounds, were found to reproduce with visibility the most delicate articulations when the condenser was made with sufficient capacity. With a condenser of 2 microfarads the best results were obtained from a condenser of this capacity. With a ten-centimetre induction coil, one metre of wire, and thirty-six layers of tinfoil. Leclanché cell in the primary circuit, gives pure progress now being made in Glasgow. It is also worthy of remark that Messrs. Graham have just secured the right to the exclusive use of the Gower-Bell telephone over an area extending to thirty miles round Glasgow, an area which embraces many towns and districts of commercial and manufacturing importance. But perhaps the most important fact in connection with the enterprise in which Messrs. Graham are engaged is that the firm has been granted a license from the Postmaster-General, in response to an application which they made to the Post Office authorities prior to (not after) the decision given by the Judges of the Court of Exchequer in the Telephone case. We have not learned what the exact terms of the license are, nor are we certain that the formal document has yet been handed over to Messrs. Graham; but at the very fact that they have been granted a license is quite sufficient to show how the legal proceedings initiated by Mr. Martin's-le-Grand regard the immediate future of telephonic telegraphy. We may now confidently expect that licensed telephonic exchanges will be established in other parts of the kingdom, unless the Post Office people think that they can overwhelm all the work that may arise until the new system of speech-communication between persons at a distance shall have attained much more formidable proportions than at present confronts us in some quarters. It is scarcely expected that in the meantime any more licensed exchanges will be allowed in Glasgow, and it is an step in advance to know that, by securing a legal position for themselves, Messrs. Graham have inspired much confidence in the minds of their exchange-subscribers, both actual and prospective.

BELGIUM.—In September last an International Congress of Commerce and Industry was held in Brussels, and in the Scientific Section papers were read on electrical subjects, such as "Telephonic Communication," "Electric Light," &c. A brief report of the Congress is given in Mr. Kennedy's report to Earl Granville. He says:—"M. Bede read an interesting report on telegraphic communication, explaining the battery telephones for which the Reiss and Gray apparatus are used, and the telephone without battery, of which Bell's system is the prototype. Two apparatus with batteries have, he said, been taken up—viz., Edison's and Blake's. M. Bede, without speaking more in favour of the one than the other, simply affirmed that numerous systems are in existence, and capable of meeting all the wants of the public. He went on to examine the question of telephonic communications in cities, and from one town to another. He considered it important that the connection between the central offices and telephonic lines should be perfected and examined, the advantages and disadvantages of above and under ground telephonic wires. He thought that the State should not monopolise telephonic communication, but should leave its working to private enterprise, and not fear its competing with the telegraph or Post Office. M. de Locht Labye, an engineer, explained to the meeting a pantelephone of his own invention. In his opinion local telephones are, and must be, undertakings of public interest, or, in other words, each person, subscriber or not, should be able to use it. On this condition only could the State allow the highways to be used. He was strongly in favour of a concession being given to one company in each district, as the best means of promoting the interests of a service incapable of division. He quoted the examples of London and Paris, where, after numerous and cumbersome trials of competition, companies amalgamated; and, in conclusion, he suggested that each concession should be put up to auction. M. Bede expressed a contrary opinion to that of M. de Locht Labye as to each concession being put up to auction; he thought it should be left entirely to private enterprise; he added that the Department of Public Works was antagonistic to the proposal, and, with every respect for the Telegraph Department, he still thought that his new system would best succeed under private companies. M. Hubert considered that there should be but one company per district, so as to avoid disputes; but that a monopoly could not belong to Government. In answer to M. Bede, he would say that telephonic connections exist already, and that there had been no complaints made against any of the offices so connected; he thought that the Government would manage matters better than a private company. M. Bonguie remarked that in France the State alone has the right of laying wires; and that this circumstance is a great drawback to telephone development. M. Bede thought that no comparison could be drawn between telegraphic and telephonic apparatus; therefore the staff of the State would not serve for the last-named undertaking. M. Desguin considered that only one branch should exist in each town unless the companies were amalgamated; otherwise the subscribers to one would be isolated from others, and the public would consequently be deprived of advantages. As regards the stimulus of competition, it would be replaced by the interest of companies to increase the number of their subscribers and to perfect their apparatus. He thought that the intervention of Government would be more desirable than in postal and telegraphic matters, as the telephone requires no intermediaries are of general interest, desires that a law may be speedily voted on the granting of concessions."

A SPEAKING CONDENSER.

IT is well known, that the capacity or condenser of tinfoil sheets when connected to the terminals of the coils of the secondary circuit of an induction coil will produce musical notes when the primary circuit is excited by a battery and a Bell's electric vibrating telephone with intermittent contacts. The note to be heard is determined by the number of the pauses, whose vibrating telephone makes and breaks the primary circuit, in accordance with the vibrations of the coils, and the corresponding induced currents acting upon the condenser. The transmitter set into this vibrating telephone, which is audible as a humming sound, when, as Professor Hughes has called it, the "singing condenser" is introduced, was likewise, by Mr. C. F. Varley, used carefully investigated by Mr. C. F. Varley, and other French experiments, in connection with the application to telephony by Mr. Edison, who has succeeded in making it reproduce articulate speech after the manner of the Bell telephone receiver. M. Dussaud found that when a carbon microphone was placed in the primary circuit of an induction coil, instead of a free interrupting clicking of a vibrating and the striking of a bell could be imperfectly heard, but speech appeared quite inaudible. Following up this promising step, however, by including in the circuit of the secondary circuit and one pole of the condenser M. Dussaud found that speech was then delivered with great distinctness. For articulation the sensibility is simply inverted between one end of the secondary circuit and one pole of the condenser. Upon the terminals of Ruhmkorff coil, under the simple influence of the induced currents of the secondary circuit, articulate speech sounds, were found to reproduce with visibility the most delicate articulations when the condenser was made with sufficient capacity. With a condenser of 2 microfarads the best results were obtained from a condenser of this capacity. With a ten-centimetre induction coil, one metre of wire, and thirty-six layers of tinfoil. Leclanché cell in the primary circuit, gives pure musical sells can be amplified by one-litmus-cadmia cell, for articulation the sensibility battery in the secondary circuit should be of battery in the primary circuit, as has been told, but that the voice is feeble, but when ten cells in the secondary, a voice continuous cell, and two cells in the primary, the voice is as loud as that of a good Bell telephone; and with fifteen Bunsen cells in the secondary, the sounds were brightened and speech could be heard with the ear held a yard from the receiving instrument. This is a practical result of some importance. M. Dussaud has yet further improved in response to an application which they made to the Post Office authorities prior to (not after) the decision given by the Judges of the Court of Exchequer in the Telephone case. We have not learned what the exact terms of the license are, nor are we certain that the formal document has yet been handed over to Messrs. Graham; but at the very fact that they have been granted a license is quite sufficient to show how the legal proceedings initiated by Mr. Martin's-le-Grand regard the immediate future of telephonic telegraphy. We may now confidently expect that licensed telephonic exchanges will be established in other parts of the kingdom, unless the Post Office people think that they can overwhelm all the work that may arise until the new system of speech-communication between persons at a distance shall have attained much more formidable proportions than at present confronts us in some quarters. It is scarcely expected that in the meantime any more licensed exchanges will be allowed in Glasgow, and it is an step in advance to know that, by securing a legal position for themselves, Messrs. Graham have inspired much confidence in the minds of their exchange-subscribers, both actual and prospective.

Electrician March 19 1881

SOMETHING FOR THE AMERICANS.—The celerity in switching, for which praise is given to the Glasgow Telephonic Exchange, is said to be in a measure due to the plan of the mirrors in the panelling of the switch-boards, a device which effectually prevents the eyes of the young lady operators from wandering off the boards for more than two seconds together all the time they are on duty. Falling discs are consequently instantly seen and attended to.

LONG DISTANCE TELEPHONE SYSTEM OF DR. HERZ.

A new system of telephony, invented by Dr. Herz, is attracting a great deal of attention among electricians in Europe, on account of the surprising distances through which telephonic communication has been maintained by it. The first announcement of the invention in the papers of September last stated that conversation had been carried on through the cable connecting Brest and Pontanezen, a thing generally considered impossible, on account of the comparatively sluggish action of the electric current in submerged cables. The experiment proved sufficiently successful to encourage Dr. Herz to push forward his investigations, and, according to foreign advices, he has been rewarded by being enabled to carry on conversation through an actual distance of over six hundred miles over circuits having no special adaptation to telephonic communication.

Dr. Herz has apparently solved two difficult problems: that of increasing the amplitude of electrical vibrations, and of neutralizing currents foreign to the telephonic circuit. The first he accomplishes by a microphonic transmitter with multiple contacts, and a system of derived currents; the second by interrupting the line and interposing condensers or diffusers. We have received an extended illustrated description of this interesting invention, written by Th. Du Moncel, which will be published in full in SUPPLEMENT 274.

Deutsche Illustr. Ztg. 16. 1881.

THE DEVELOPMENT OF THE ELECTRIC TELEPHONE.

The telephone was introduced as a practical business medium in May, 1878. There are now 300 companies, or districts, in the United States. This increase has not been more rapid than the improvements in the telephone apparatus and appliances. Instead of the original box, which, if attached to a wire connected with numerous other boxes, made all receivers of each and every message audible, there are now central exchanges in the cities and at the terminal points of railroads. Each box is now only known to those engaged in it. By latly improved devices at the exchange offices, delays or blunders in giving communication seem to be only the result of stupidity or carelessness on the part of one of the employé's whose duty is to connect the wires. One is expected to do this duty within fifteen seconds after the call. By neat systems of checks, dereliction may be traced to the offender. A very late invention is an elevated tube for telegraph and telephone wires, designed to do away with the unsightly poles on the streets and the awkward features on the house-top, and to prevent the interruption of service by the breaking and crossing of lines. Electric street lights and clocks, fire alarms, ambulance and police calls, letter boxes and drinking fountains, can be attached to this contrivance and the pillars that support it. Experiments in laying telephone wires underground have so far proven successful for only a distance of between five and six miles.

Opening an account with a telegraph office, may from his office telegraph by telephone to any part of the world, besides effecting, if a branch telegraph office has to be used instead, a saving in receiving the message of at least thirty minutes.

Naturally, the minds of inventors and operators were turned to the local fields of telephone development, although occasional experiments have been undertaken and made in long distances. Through literality, or from circumstances beyond control, the fifteen-mile limit has been extended by the Western Union, and an eastern telephone company has opened speaking communication between Boston and the cities of Lynn, Worcester and Springfield, the latter city being about one hundred distant. Among the experiments conducted under the patronage of the French government on the telegraphic lines of the state, one of the most extraordinary was the transmission of a speech on a single wire from Tours to Brest, passing through Paris, the length of which exceeded 800 miles. A prominent inventor and the manager of a telephone exchange in New York cities that, from knowledge gained from experiments, long distance communication can be satisfactorily made from New York to Albany by the use of a single wire. It may be here observed that telephone wires are exceedingly sensitive to induction, and the crossing of two wires renders sound unintelligible in transmission through them. In this connection it is announced that in England trials have demonstrated the practicability of the submarine telephone.

Mining & Scientific Press, April 16, 1881.

DANGER OF LIGHTNING FROM TELEPHONE CONNECTIONS.—The Cantonal government of Zurich, having been applied to by a telephone company for permission to fix the supports of insulators on the tops of certain public buildings, applied to Prof. Kleiner for an opinion. The following is a summary of the chief points in his report:

1. The danger of lightning in houses over which telephone wires are stretched is not increased, but lessened, if the total conductivity of a wire is approximately equal to that of a lightning conductor. This condition is not always fulfilled under existing arrangements. It may be insured by very simple arrangements, such as the introduction of a special wire for the conduction of lightning wherever the number of wires of two millimeters in thickness running in the same direction is less than 60. This should be insisted upon in all cases. Single connections running along the houses should be stronger than at present—at least as strong as telegraph wires.

2. As the properties of a telephonic plexus for attracting and conducting lightning extend over far wider tracts than those of a lightning rod, a strict regulation of their make and condition is necessary.

The use of telephones should be suspended during thunderstorms.—*New Zurich Zeitung.*

Journ. Soc. Tel. Eng. 11. 1881.

Speech by Telephone.
From the London Times.

PARIS, AUG. 27.—I have several times had opportunities of exhibiting the telephone to the military inmates of the exhibition, but one which will be the chief attraction to a large class of visitors will be that which gives some account of the microphone and microphones which are to be seen there.

I must describe the very interesting auxiliary of these instruments. It is none other than the well-known Edison phonograph, which, during the pleasant of the day light after night noting extended companies in the Gallery and at the Telephone Exchange, has been busily at work. In the latter office there are a number of pairs of telephones. The phonograph is placed in the office and ran to the telephones. The format is the more interesting for the fact that the voices and words of the performers are of the first importance. You enter the room in groups or, perhaps, ten at a time, and the phonograph is set in motion and a pair of telephones, which is in connection with it, are worn over. Each of these is connected with another placed in the room of the Duke, one to the right and the other to the left of the presenter, and the Duke's ears are applied to the receivers. Attention of the phonograph is connected with the telephones at our right and, one to his left. Then while the singer turns our right or left, the sounds increase or diminish, being equal or not, even when they advance or recede. The same increase or diminish in both, and the effect is one which it is impossible more accurately to describe. It is difficult to believe that the performance is not taken place in the room, and that the singer is not before the audience. Perfect silence reigns (two words should be used, for there is no silence in Paris), while the glorious voices of the finest singers of the day are heard as if unaccompanied in the middle of a large room by the silence, across which have rushed the sounds of the orchestra of a mile. The orchestral accompaniment is somewhat weak, owing to the arrangements of the instruments, but the voices are perfect and more clear, falling entirely into the music by movement and action; and in no part of the room is the slightest sense lost with greater [illegible] silence and with the most charming and perfect ease in this splendid room in the Palais d'Industrie.

The successful exercise to which the different talents have been put during the past week is astonishing. Perfect silence reigns (two words stand round, with their hands holding to their ears, listening to the voices, and when they express expression of satisfaction, of coldness, or rapture, on their faces; they look at each other and express themselves with their eyes; but when the performance has been received and they hear the clapping of the hands of the unseen audience they let down their telephones and irregularly join their applause uttered to that which has reached them in the room, unable to contain themselves from the expression of their delight.

Scientific American, July 16th 1881.

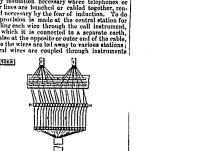
There are few defects, but these are of serious importance. The arrangement is a little too much complicated; a rocking motion is sometimes heard in the receivers, which comes from the microphones, and the whole apparatus is too delicate to be performed by the instruments and is to be heard with undue loudness. These defects are, however, of secondary importance, and as the general lines and the highest aim are correct, the invention is said hereof through all their most delicate changes as they occur and almost with all [illegible] as at the theatre itself.

As [illegible] to the arrangements of the circuits in some detail, I need only say that likewise that at the Théâtre Français is extremely simple, consisting of a single wire, carried overhead, and the double arrangement of microphones [illegible] and receivers attached to them. If and to see, the [illegible] to notice.

The Electrician, July 16th 1881.

5068. IMPROVEMENTS RELATING TO TELEPHONIC AND OTHER SYSTEMS OF ELECTRICAL COMMUNICATION. *J. P. Culverhouse and J. C. Swain.—9th December, 1880.* 6d.

The object of this invention is to avoid the battery connection necessary where telephones or other instruments are used in a circuit, and is declared necessary by the four of induction. To do this provision is made at the central station for coupling each wire through the call instrument, with which it is connected to a separate earth; and also at the receiving or outer end of the cable, where the wires are led away to various stations; several wires are coupled through instruments



to separate and independent earth plates having no metallic connection with one another. The instruments at the central station is also arranged that the bells may be rung through the earth, and that they may also be coupled to an independent earth plate, preferably through a resistance coil. In the figure F F are cables of wires from different stations; G are lightning protectors; H are electro-magnet call instrument receivers; I, wires from each apparatus to one or other of the bars A of the commutator; C C are the separate earth connections; K K are the separate and independent earth plates.

4402. IMPROVEMENTS IN TELEPHONES. *S. Pitt.—Dated 23rd November, 1880.—[A communication from C. de Sollieck.]* 2d.

The inventor claims the mouthpiece of the transmitting telephone by pasting or connecting over it a diaphragm of paper. The vibrations are thus developed, and the entrance of dust, and rusting of the plate by moisture of the breath, is avoided.

The National Scientific Journal, Aug. 1st 1881.

MOLECULAR SOUNDS.—The passage of an intermittent current through iron or other wire gives rise to sounds of a very peculiar and characteristic nature. Page, in 1837, first noticed these sounds on the magnetization of wires in a coil. De la Rive published a chapter in his "Treatise on Electricity" (1853) on this subject, and he proved that not only were sounds produced by the magnetization of an iron wire in an inducing coil, but that sounds were equally obtained by the passage direct of the current through the wire. Gaugid, 1841, and Du Moncel, 1878-81, all have maintained the molecular character of these sounds. Reis made use of them in his, the first electric telephone ihvented, and these sounds have been, since the apparition of Bell's telephone, often brought forward as embodying a new form of telephone. These sounds, however, for a flexible source of electricity, are far too weak for any applied purposes, but they are most useful and interesting where we wish to observe the molecular action which takes place in a conducting wire. I have thus made use of these sounds as an independent method of research.

The apparatus was the same as in the last chapter, except no telephone was used. The intermittent electric current was connected by means of a switch key, either with the coil inducing longitudinal magnetism in the wire, or could be thrown instantly through the wire itself, thus rapid observations could be made of any difference of tone or force by these two methods; a reversing key also allowed when the wire stood, a constant current of either polarity to pass through the wire under observation.

Iron, of all metals that I have yet tried, gave by far the loudest tones, though by means of the microphone I have been able to hear them in all metals; but iron requires the microphone to make its sounds audible, for I demonstrated at the reading of my paper, March 23rd, that these sounds with two kilobmonts rolls were clearly audible at a distance. A fine soft iron wire (No. 28) is best for loud sounds to be obtained by the direct passage of the current, but large wires (1 millim.) are required for equally loud tones from the inducing coil. By threading any suitable wire between these sizes, we can obtain equal sounds from the longitudinal magnetism or direct current. The wire requires to be well annealed; in fact, as in all preceding experiments, the sounds are fully doubled by heating the wire to nearly red heat. There are many interesting questions that these molecular sounds can aid in resolving, but as I wish to confine the experiments to the subject of the two preceding chapters, I will relate only a few which I believe bear on the subject.

On sending an intermittent electric current through a fine soft iron wire, we hear a peculiar musical ring, the cadence of which is due to that of the rheotome, but whose musical note or pitch is independent both of the diameter of the wire and the note which would be given by a mechanical vibration of the wire itself. I have not yet found what relation the note bears to the diameter of the wire; in fact, I believe it has none, as the greatest variation in different sizes and different conditions has never exceeded one octave, all these tones being in our ordinary treble clef, or near 870 single vibrations per second, whilst the mechanical vibration due to its length, diameter and strain vary many octaves.

I believe the pitch of the tone depends entirely upon molecular strain, and I found a remarkable difference between the molecular strain caused by longitudinal magnetism and the transversal or ring magnetism produced by the passage of a current, for if we pass the current through the coil, inducing magnetism in the wire, and then gradually increase the longitudinal mechanical strain by tightening the wire, the pitch of the note is raised some three or four tones (the note of the mechanical transversal vibrations being raised perhaps several octaves); but if we tighten the wire during the passage of an electric current through it, its pitch falls some two or three notes, and its highest notes are those obtained when the wire is quite loose. A similar but reverse action takes place as regards torsion; for if the wire is magnetized by the coil, we obtain an almost complete zero of sound by simply moving the torsion index 45° on either side, and as this was the degree which gave silence in the previous experiments for the same wire, it was no doubt due to the same rotation of its polarized molecules; if we now pass a constant current through the wire whilst the intermittent one is upon the coil, we hear augmented sounds not in pitch, but loudness, and if we give torsion of 45° to one side we have silence, or nearly so, whilst the other side it gives increased tones which become silence by reversing the battery. If, whilst the wire by torsion has been brought to zero, we decrease or increase the mechanical longitudinal strain, then at once the polarized molecules are rotated, giving loud sounds; and we further remark that when the wire is loosened, and we again tighten it, we gradually approach a zero, and on increasing the strain the sounds return; thus we can rotate the molecules by a compound strain of torsion and longitudinal strain.

If we wish to notice the influence of a constant current passing through the wire under the influence of the intermittent current in the coil, we find if the wire is free from torsion that on passing the current the tones are diminished or increased according to the direction of the current; the tones thus have an entirely distinctive character, for whilst preserving the same musical pitch as before, the tones are peculiar, metallic, and clear, similar to when a glass is struck, whilst the tones due to longitudinal magnetism are dull and wanting in metallic timbre. If we now turn the index of torsion upon one side, we have a zero of sound with or without the current; but the opposite direction gives increased tones whilst current is passing through the wire, but zero when not. Here again a peculiarity of timbre can be noticed, as although we have loud tones only to the action of the current through the wire, the timbre is no longer metallic, but similar to that previously given out by the influence of the coil; evidently then the metallic ring could only be due to the angular polarization of the molecules, and when these were rotated by torsion the tones were equally changed in its action upon the wire.

I have already shown that a permanent magnet brought near the wire could rotate its polarization, and it equally can produce sound or silence in these molecular sounds showing that the wire is of a zero of torsion, and a constant current sent through the wire as in the last experiment). We find that either pole of the natural magnet has equal effect in slightly diminishing the sound by an equal but opposite rotation from the line of its maximum effects; but if the wire is brought nearly to zero by torsion, then on approaching one pole of the natural magnet we produce a complete silence, but the opposite pole at once rotates the molecule to its maximum loudness, and on taking away the magnet we have comparative silence as before.

Bending the wire to nearly red heat by a spirit lamp increases the tones of longitudinal magnetism induced by the coil some 25 per cent., but it has a much more marked increase on the tones produced by the direct passage of the current where they have more than 100 per cent. increase; and if we pass the intermittent current through the coil, and constant through the wire, we find no direct rotation of the molecules by heat, although an apparent rotation takes place if we, by the required torsion, first place the wire at its zero. Then on the application of heat faint sounds are heard, which become again almost silent on cooling; are these obtained when the wire is quite loose. A similar

Tempered steel gave exceedingly faint tones, requiring the use of the microphone; but on magnetizing with a constant current, inducing spiral magnetism, the sounds became audible, some 15° micrometre, against 73° for iron; thus the molecular rigidity of steel as observed by previous methods was fully verified.

I have, I believe, demonstrated by retinal experiments which are easy to repeat, that—

1. An electric current polarizes its conductor, and that its molecular magnetism can be reconverted into an electric current by simple torsion of its wire.

2. That it is by the rotation of its molecular polarity alone that an electric current is generated by torsion.

3. That the path of an electric current through an iron or steel wire is that of a spiral.

4. That the direction of this spiral depends on the polarity of the current, or that of its magnetism.

5. That a natural magnet can be produced, having its molecular arrangement of a spiral form, and consequently reversed electric currents would both have a similar spiral in passing through it.

6. That we can rotate the polarized molecules by torsion or a compound strain of longitudinal and transversal.

7. That the rotation or movements of the molecules give out clear, audible sounds.

8. That these sounds can be increased or decreased to zero by means that alone have produced rotation.

9. That by three independent methods the same effects are produced, and that they are not due to a simple change or weakening of polarity, as when rotation has been incomplete a more mechanical vibration line at once reduced the maximum effect.

10. That heat, magnetism, constant electric currents, mechanical strains and vibrations have all some effect on the result.—*Prof. D. E. Hughes.*

England, Northumberland, Shipley, 4th of January, 1881.

[FIELD.]—Telephone Transmitters.—Imply to "J. H. G." It is not a question in doctrine the modulate, or rather control, the I ought to call it, for working the "call," but in practice it is referring to the instrument described on p. 92, first description only applies to the one described on p. 93, which, being all steel with the automatic interrupter, would be only required for short distances because to work to work it. The following description applies to the instrument illustrated on p. 92. Take a piece of soft iron tube, say, 10in. long, 2in. wide, file out the teeth along one of its longer sides, and bore one hole in each end, then fasten it with a couple of screws to the top or side of the piece A, so that the teeth will project beyond the wood. Attach this to the wire B which connects the carbon C to the primary wire of the coil; then to the two additional wire D, the binding post on the opposite side to that is fix one connected to the spring E, and to this wire rub along the serrated lower piece, and the "call" will be made, as described in my former letter, provided the carbon pieces C C are sensitive, as they should be at all times when the instrument is not in use.—JOHN C. FIELD.

Correspondence.

The Bell Telephone.—The Decision of Judge Lowell.

To the Editor of the Scientific American:

In a number of your late issues you have had some interesting articles on Judge Lowell's late decision in the Bell telephone suit against certain parties for alleged infringement. I have read the opinion of the court in the above case (published in SCIENTIFIC AMERICAN of August 27,) with much care, and decline to say a few words upon the same, as I view said opinion as not justified before an intelligent host of American inventors, thinkers, and writers. To be granted two suits by such decisions brings our patent system into disrepute, as affording monopolies the power to control entire fields of useful invention. By careful examination of the field in dispute I realize that the device of the Bell monopoly is to gain, by decisions of courts, the only right to use electricity to convey intelligence by vocal sounds. There is no right over apparatus, no right over the means employed to vary the current; the monopoly simply asks to have the current set aside for their use, whether said current is *undulated, vibrated, intermitted, pulsated, or disturbed.*

Now let us quote the most astounding part of said decision: "But Bell discovered a new art, that of transmitting speech by electricity, and has a right to hold the *broadest claims* for it which can be permitted in my case." It is a fact well known that many others in the same line of experiment, before Bell's patent of 1876, were in sight and in the *hearing* of the desired result. They were all using a current, and were trying different plans of using said current, and had succeeded in a partial manner by *disturbing* a current of electricity. Mr. Bell found a more effective way of using the same current. Just as well give McCormick the only *right* to cut grass and grain because he did it better than any who worked before him.

By all means give Mr. Bell his every due—give him credit for being a persistent worker, and give him all he has invented; but it seems very incorrect to confer on him the only right to use a vibrated or undulated current. Look at the facts—Reiss, Gray, Edison, and others, *prior* to Bell's patent of 1876, were working hard and strenuously with this old, *disturbed, varied, and vibrated* current, getting groans, music, and words out of it, and now all the hosts of electricians of our country are to see another step in and take away their old current.

What I desire is that each inventor shall fully be entitled to use what he invents and brings forward, and no more.

As the Bell telephone stands to-day it looks as if it is next to impossible to obtain the permanent magnet, the induction coil, and current, but if some inventor can find a means of using electricity and its e-stablished powers in the transmission of vocal sounds, *in a manner and by apparatus not pretended by any one else*, that an established public sentiment and a high and honorable court of last resort should protect all alike. How will Mr. Reiss over in the old country, and in our own land of right and liberty how will Elisha Gray feel when that little current, so subtle, so unmanageable, had finally been taken from him? How will my old friend Dolbear feel, too, after *merging* the current, away back yonder, years ago? In fact, what will be the wonder and surprise of the hundreds of intelligent professors who have in years and years been using intermittent currents and getting sounds and songs, when they learn that they are forbidden to undulate a current in any endeavors to make a machine which will talk at the other end of the line?

I hope to hear others speak out and give their views on this subject.

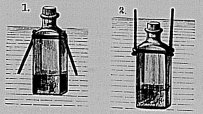
Yours OVER GRAVITY.

Do axis Mes vats for Invention of the Telephone by "Carlos Gilbert"

A Life Saving Lesson in Physics.

It is a well-known fact that any person of average structure and lung capacity will float securely in water if care is taken to keep the hands and arms submerged and the lungs full of air. Yet in most cases people who are not swimmers immediately raise their hands above their head and scream the moment they find themselves in deep water. The folly of such action can be impressively illustrated by means of a half empty bottle and a couple of nails; and the experiment should be repeated in every household until all the members —particularly the women and children—realize that the only chance for safety in deep water lies in keeping the hands under and the mouth shut.

Any short-necked, square-shouldered bottle will answer, and the nails can be easily kept in place by a rubber band



or a string. First, ballast the bottle with sand, so that it will just float with the nails pointing downward, as shown in Fig. 1; then by turning the arms upward, as shown in Fig. 2, the bottle will be either forced under water at once or will be tipped over so that the water will pour into the open mouth, and down it will go. To children the experiment is a very impressive one and the moral of it is easily understood.

The vital value of this precaution was strikingly illustrated near Accomac C. H., Virginia, a few days ago. A niece of the Hon. John Neely, while bathing, was swept off into the ocean by a strong current and soon disappeared in the high breakers. As she could not swim her companions gave her up for lost. Two young fishermen who were employed some distance away thought they set out with a small boat in search of her, and soon, when a mile or more from shore, found her floating on the water. She had been drifting nearly an hour and was greatly exhausted, but soon recovered. Unable to swim she had pluckily floated, thereby making her rescue possible.

A NEW USE FOR THE INDUCTION BALANCE.

BY GEO. M. HOPKINS.

The form of induction balance devised by Professor Hughes, of London, already has several interesting and useful applications, and a new use for it is now suggested by the recent tragedy at Washington. It seems essential to locate the bullet in the body of the President.

The induction balance is a most delicate electrical instrument for detecting the presence of metals, and a modified form of it could be easily applied to this purpose with a reasonable expectation of success. This instrument consists of two short glass cylinders, around each of which are wound two parallel coils of fine insulated copper wire. One coil of each pair is included in a battery circuit in which there is

Fig. 1.—THE INDUCTION BALANCE USED AS A BULLET FINDER.

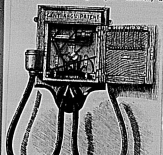
Scientific American Supplement No. 287

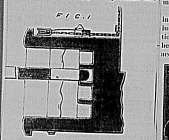
J. T. GENT AND CO.'S MICROPHONE TRANSMITTER.

THE patentees inclose an instrument in a neat walnut case, to the lever of which they attach, leaving a slight space between, a



diaphragm of wood; to this diaphragm they affix thin plates of specially-prepared material, the plates resting but not touching each other.

These attach to lever brackets, having spindles on which are loosely-hung metal arms, each arm carrying a plug or pencil of prepared coal, and these again resting on plates affixed to diaphragm. They can be set to vibrate from 12 to 16 of these prepared arms, arranged in series of 2 or 4, so that a current of electricity is traverse the whole of these arms at once or successive sets. Each arm is adjustable, and may be placed horizontally or vertically. The object of using a row of plates is that the vibrations of the vibrations of diaphragm may be multiplied, and the undulatory current be correspondingly more powerful. The



plates at one end are connected to battery, and at the other end to a coil in the case.

Any form of telephonic receiver may be used with this transmitter, and they use flexible tubes to protect wires from injury, thus obviating one objection to the use of wire conductors between transmitter and receiver. The usual automatic switches and call-bell form part of the apparatus. The transmitter and use of tubes for purpose named are patented.

The National Telephone Exchange Association.

The third semi-annual convention of this association was held in Saratoga, the second week in September. There were present, at the first session 230 delegates, of whom 100 represented telephone companies. Among the prominent delegates were:

G. L. Wiley, assistant general superintendent of the Metropolitan Telephone and Telegraph Company; W. A. Childs and Francis Shaw, of the Law Telegraph Company; Henry W. Pope, of the Staten Island Telephone Company; Henry Metzger, general manager of the Pittsburg Telephone Company; William Sargent, the general superintendent and electrician of the Bell Telephone Company, of Philadelphia; Mr. Goodyear, representing L. Tillgthson. C. H. Hotchkiss, John A. Hocking, Walsburn & Moen, and other firms were represented. Among the subjects for discussion were these: The latest improvements in all the instruments used; underground wires; wire construction and kinds of wires; also a report on electrical disturbances interfering with the telephone service.

IMPROVEMENT IN TELEPHONES.

The engraving shows an improved telephone transmitter and receiver recently patented by Mr. J. A. Lakin, of Westfield, Mass. This instrument is especially for use in railroad offices, and other places wherein much local noise disturbs the successful operation of the common telephone now in general use. This instrument consists of a square box, in which are placed both a transmitting and a receiving diaphragm. From the receiving diaphragm chamber two sound tubes extend to be received one in each ear. They are kept in place by a small spiral spring, tending to draw the tubes together, and thus keep the small rubber caps on the ends of the sound tubes in place in the ear. These cups shut out all extraneous sounds and confine the sounds of the receiving telephone, so that their full effect is felt on the ear.

The lower part of the box, as seen in the drawing, contains the transmitter, which is made very sensitive. It is claimed that this instrument will talk two hundred miles or more.

Pressing the button, as shown in the cut, brings the battery into circuit with the transmitter. The inventor of this instrument has given much time and study to the construction of telephones, beginning as early as 1869, although, as he informs us, most of his attention has been given to acoustics.

LAKIN'S TRANSMITTING AND RECEIVING ELECTRIC TELEPHONE.

For further information address J. A. Lakin, Westfield,

Home Department.

The Induction Balance as a Bullet-Finder.

Considerable interest has been felt in the proposal made by several gentlemen well known in the scientific world to locate the position of the bullet that struck down the President, by delicate electrical apparatus. The form of induction balance devised by Prof. Hughes, as exceedingly delicate electrical instrument for detecting the presence of metallic substances, has been suggested for this purpose, and it appears probable that it could be used in many cases with success.

This instrument consists of two short glass cylinders, around each of which are wound two parallel coils of fine insulated copper wire. One coil of each pair is included in a battery circuit, in which there is a clock microphone. The other pair is placed in a closed circuit with a receiving telephone. The two glass cylinders, with their enclosing coils, may be widely separated. The induction set up in the secondary or telephone circuit is balanced by the reversal of one of the secondary coils, and so adjusted that the induction in one of the secondary coils exactly balances or neutralizes the induction in the other, so that when the ear is applied to the receiving telephone no sound is heard. If, however, a fragment of metal, no matter how minute, is placed in one of the glass cylinders, its presence destroys the electrical balance, and the fact is indicated by the loud ticking of the clock on the microphone. The same result will be observed if the coil is placed in the neighborhood of a piece of metal.

Mr. George M. Hopkins, to whom the idea occurred of using this instrument as a bullet-finder, in some trial the experiment of testing the effect of a leaden ball in the instrument, placing the bullet at different distances, and repeating it from the coil by installing substances. The experiment, however, failed at first to give satisfactory results, and for the reason that the metal head produces the least effect on the instrument, and requires a very strong current to obtain suitable results. As a strong current burned the carbon of the microphone, it was found necessary to use a current interrupter operated by a clock which interrupted the current at regular intervals. With this current breaking, Mr. Hopkins announces that he has obtained results that surpassed his expectations, as he was able, with a set of coils that were by no means sensitive, to locate the leaden ball with the coils raised a vertical distance of nearly two inches.

Encouraged by these results, Mr. Hopkins states, as stated, Mr. Hopkins wrote to the President's private secretary, suggesting that his apparatus might be used successfully in locating the position and depth of the bullet in the President's body, requesting the position of which the physicians in attendance upon him may known to entertain diverse opinions, and which a sudden crisis in the patient's condition may render highly important to verify. The instrument was sent to Washington by request, but at the time of this writing it had not been used.

Mr. Hopkins states positively that if the missile were of iron or steel, there would be no difficulty experienced in locating it at a depth of even four or five inches; but being of lead, he thinks it doubtful if it would disturb the electrical balance if it is located at a greater depth than two inches from the surface of the body.

Fig. 2 shows the apparatus properly connected and in the act of being used to locate a bullet. The diagram, Fig. 1, shows the arrangement of battery, microphone, and primary and secondary circuit wires. The induction balance in use in connection with the coil-less telephones patented by Mr. Edison. The number of the apparatus is A,1,13, and it contains twenty-five figures and six alphas. The two figures given herewith will, however, serve to explain the new invention, which is clearly capable of many modifications. According to the one mode of carrying out this invention, a current battery is caused to circulate through the telephone, and a weight is employed, with a pendulum-arm passing through it, and resting upon the carbon button. Rod-springs bearing upon the weight, and attached to the carbon button, serve to hold the weight in position. The amount of initial pressure may be regulated by the screw. The circuit wires are connected to the primary coil of an inductorium with the battery in circuit. Owing to the inertia of the weight, and its not being able to follow very rapid movements of the diaphragm, there results a difference of pressure between the screw and the carbon. The screw may also be tipped with a point, so that the initial pressure of the carbon upon the weight, or upon a piece of any proper metal placed between the carbon and screw, hold round, oblong, oval, or in any configuration as long as it is a weight. It may be a hollow sphere, cube, or any other shape, and be filled with mercury or any other heavy substance. The springs may be bent or warped, and may be bent in any shape between the weight and disc upon the diaphragm.

Fig. 1.—Diagram Showing Circuits of the Induction Balance.

In some cases two pieces of carbon or other finely-divided conducting matter are secured to the diaphragm, each carbon being connected to the circuit. When in a state of rest the two coils are in contact with each other. The amount of initial pressure being regulated by the bowing outwardly of the diaphragm by a spring of adjustable curved metal upon a screw, or two flat carbons may be employed screwed to the diaphragm and adjusted so that the ends are in contact, the bowing outwardly and inwardly of the diaphragm regulating the position tending to increase or decrease the initial pressure.

According to another modification an inertia transmitter is constructed, consisting of a diaphragm having a rubber fixture thereon, a flat or other spring serving to hold the weight in position, and an adjusting screw whose office is to rest upon a carbon disk. A double inertia transmitter may be constructed having two carbons connected together, hence the difference of pressure takes place at two points of contact, as in the device first described and in the two latter inertia transmitters the carbons may be their cups permanently, or they may be loose; the latter is preferable.

According to another modification, an inertia transmitter is constructed, consisting of a diaphragm having a rubber fixture thereon, a flat or other spring serving to hold the weight in position, and an adjusting screw whose office is to rest upon a carbon disk. A double inertia transmitter may be constructed having two carbons connected together, hence the difference of pressure takes place at two points of contact, as in the device first described and in the two latter inertia transmitters the carbons may be their cups permanently, or they may be loose; the latter is preferable.

According to another modification, an inertia telephone is constructed in the following manner:—A diaphragm, carbon button, and rubber or other fixture employed, with a helix or helix of iron, and is secured to a spring which may be made adjustable. A permanent magnet is also provided, which may be made to approach or recede from the weight, and so regulate and decrease the initial pressure on the carbon. One of these transmitters may be screwed to the diaphragm, which in its turn may be poised in a frame, and a weight secured to the center of inertia constituted of carbon filings, or any suitable quantity of mercury, both in a tube with an opening. Rubber fixed to one of the wires secures the whole being secured to the diaphragm. In another form, supports are secured to the rubber piece, which is secured to the diaphragm; the carbon rests on the platinoid surface of a screw, which serves also to connect the rubber piece with the diaphragm. A weight is provided, which may be made of a pointed shape, and a spring which serves to give to the weight an initial pressure and hold it in position; a screw may be connected from the spring to the point of the weight, and thereby made adjustable. A diaphragm, with the inertia-transmitting devices upon it, may be secured in a wooden case by stringer elastics. A further variation of this type of transmitter consists of an upright attached to the diaphragm, the upper end of the which upright is platinoid and rests upon a carbon disk, which is in an adjustable cup. The movements of the diaphragm increases and decreases the pressure upon the carbon. In this transmitter may consist of a diaphragm and a weight, the latter being held in position by the instrument of a diaphragm by means of a bowed piece which connects the lever with the diaphragm. The carbon button applied with which the spring rests suitably suspended. Close the circuit, the pressure is regulated by the movement of the diaphragm. A double lever may be employed, the carbon being between the two; the bowed piece serves to separate both levers simultaneously, and they carry their carbon button with them. The block connected to the diaphragm may receive a hard carbon rod against which the springs rest; they are berylled, any outward movement of the diaphragm tending to increase the pressure. A carbon which may be used in lieu of the rod, and between double springs.

According to a further modification, an inertia telephone is constructed with two carbons resting on a flat bed-piece, and resting on the carbons a weighted which is kept upon them by springs and adjusting screws, the weight and bed-piece forming the instrument, or decreasing the tension of the spring. Or the diaphragm may have a block to which is secured a carbon, while on the latter rests two springs, the forward movement of the diaphragm increasing the pressure at both points of contact. Or a cup may be employed with carbon rod in it, while upon the carbon rests a lever, the initial pressure of which may be varied by an electro-magnet, which may be the primary coil of the inductorium or disconnected therefrom, or may be a permanent magnet, or even a spiral or flat spring may be used, or if the diaphragm is held in the right position its own weight may be used. Another modification consists of an upright, to the bend of which is the carbon; on this rests a lever, to the end of which is secured a weight which passes the rod around which it is held by a spring to yield, the rod serving to hold the weight in position; by these means the initial pressure of the carbons is regulated. Or the carbon connected with a diaphragm may be acted upon by a pendulous spring with carbon disc upon its extremity resting against the carbon, the tension being also employed. According to a further modification of inertia transmitter, weights are secured to a lever pivoted from an arm which connects with a diaphragm; the carbons on the lever rests upon a carbon button in a cup upon the diaphragm; one of the weights is adjustable so as to adjust the initial pressure. Or four weights may be used secured to the underside of block upon the diaphragm; the current enters by the first spring, thence passes through the carbon tips to the carbon tips of the second chain, and from thence to the fourth and last spring.

According to another part of this invention a receiver is constructed upon the electro-motive principle in the following manner:—It consists of a diaphragm, a small cylinder or cup of wood or other suitable material impregnated with phosphate of soda or other proper chemical, to produce the electro-motive action, and a spring connecting the diaphragm with the disc tipped with platinum or gold. The shaft of the disc is raised by a worm and worm-wheel, or by inertia telephone may be secured to a strip of elastic material instead of a diaphragm. In a bevel gear may be employed, springs which are tipped with rubber or other soft substance. The magnetograph receiver may be arranged as a transmitter, the armature resting on a diaphragm; a spring connecting the armature with the chalk; the chalk in this case is made to rest upon a carbon disk. In a magnetograph receiver of an induction coil having a high resistance, a battery is provided; a metal-to-metal receiver may be used or a receiver as constructed as follows:—When the milliter. The action is as follows:—When the diaphragm is vibrated by the voice it acts to widen the spring, this instantly deprecates the point of contact between it and the chalk, thus increasing the flow of current from the battery; the instant the spring ceases to rest it pinches it and weakens the current from the battery. The magnetograph may also be arranged to transmit direct from one to the other without the intervention of an induction-coil, the armature of which they can by raising a lever to make receivers or telephones in circuit with the battery, the tension of the spring from the diaphragm upon the armature by depressing it; they are also provided with a handle and limiting screw are also used. A spring is further provided, also a roller, which serves to hold the lever when it is drawn up or down; both instruments are similar in construction. When receiving, the pressure is put on the spring resting upon the chalk and it is raised, but when transmitting, the pressure on the spring is light and the chalk is not raised.

The telephone may further be constructed so that each sound wave is made of an aggregation of smaller waves. A lever is provided suitably pivoted, and one its fulcrums is used for connecting it with the diaphragm, the other with the lever resting slightly upon it. Each of these is divided containing an electro-magnet, which is connected to one pole of the circuit, while the lever is connected to the other post; the armature of the diaphragm serves to recti-

English Mechanic & World of Science, July 29 1881

EDISON'S NEW TELEPHONES.

In the sun-and illustrations are shown two forms of telephone recently patented by Mr. T. A. Edison as improvements in his carbon telephones patented in the United States on the 4th of May, 1878, and 11 subsequent dates, the latest given herewith will, however, serve to explain the new invention, which is clearly capable of many modifications. According to one mode of carrying out this invention, a current battery is caused to circulate through the telephone, and a weight is employed, with a pendulum-arm passing through it, and resting upon the carbon button. Rod-springs bearing upon the weight, and attached to the carbon button, serve to hold the weight in position. The amount of initial pressure may be regulated by the screw. The circuit wires are connected to the primary coil of an inductorium with the battery in circuit. Owing to the inertia of the weight, and its not being able to follow very rapid movements of the diaphragm, there results a difference of pressure between the screw and the carbon. The screw may also be tipped with a point, so that the initial pressure of the carbon upon the weight, or upon a piece of any proper metal placed between the carbon and screw, hold round, oblong, oval, or in any configuration as long as it is a weight. It may be a hollow sphere, cube, or any other shape, and be filled with mercury or any other heavy substance. The springs may be bent or warped, and may be bent in any shape between the weight and disc upon the diaphragm.

In some cases two pieces of carbon or other finely-divided conducting matter are secured to the diaphragm, each carbon being connected to the circuit. When in a state of rest the two coils are in contact with each other. The amount of initial pressure being regulated by the bowing outwardly of the diaphragm by a spring of adjustable curved metal upon a screw, or two flat carbons may be employed screwed to the diaphragm and adjusted so that the ends are in contact, the bowing outwardly and inwardly of the diaphragm regulating the position tending to increase or decrease the initial pressure.

According to another modification an inertia transmitter is constructed, consisting of a diaphragm having a rubber fixture thereon, a flat or other spring serving to hold the weight in position, and an adjusting screw whose office is to rest upon a carbon disk. A double inertia transmitter may be constructed having two carbons connected together, hence the difference of pressure takes place at two points of contact, as in the device first described and in the two latter inertia transmitters the carbons may be their cups permanently, or they may be loose; the latter is preferable.

According to another modification, an inertia telephone is constructed in the following manner:—A diaphragm, carbon button, and rubber or other fixture employed, with a helix or helix of iron, and is secured to a spring which may be made adjustable. A permanent magnet is also provided, which may be made to approach or recede from the weight, and so regulate and decrease the initial pressure on the carbon. One of these transmitters may be screwed to the diaphragm, which in its turn may be poised in a frame, and a weight secured to the center of inertia constituted of carbon filings, or any suitable quantity of mercury, both in a tube with an opening. Rubber fixed to one of the wires secures the whole being secured to the diaphragm. In another form, supports are secured to the rubber piece, which is secured to the diaphragm; the carbon rests on the platinoid surface of a screw, which serves also to connect the rubber piece with the diaphragm. A weight is provided, which may be made of a pointed shape, and a spring which serves to give to the weight an initial pressure and hold it in position; a screw may be connected from the spring to the point of the weight, and thereby made adjustable. A diaphragm, with the inertia-transmitting devices upon it, may be secured in a wooden case by stringer elastics. A further variation of this type of transmitter consists of an upright attached to the diaphragm, the upper end of the which upright is platinoid and rests upon a carbon disk, which is in an adjustable cup. The movements of the diaphragm increases and decreases the pressure upon the carbon. In this transmitter may consist of a diaphragm and a weight, the latter being held in position by the instrument of a diaphragm by means of a bowed piece which connects the lever with the diaphragm. The carbon button applied with which the spring rests suitably suspended. Close the circuit, the pressure is regulated by the movement of the diaphragm. A double lever may be employed, the carbon being between the two; the bowed piece serves to separate both levers simultaneously, and they carry their carbon button with them. The block connected to the diaphragm may receive a hard carbon rod against which the springs rest; they are berylled, any outward movement of the diaphragm tending to increase the pressure. A carbon which may be used in lieu of the rod, and between double springs.

According to a further modification, an inertia telephone is constructed with two carbons resting on a flat bed-piece, and resting on the carbons a weighted which is kept upon them by springs and adjusting screws, the weight and bed-piece forming the instrument, or decreasing the tension of the spring. Or the diaphragm may have a block to which is secured a carbon, while on the latter rests two springs, the forward movement of the diaphragm increasing the pressure at both points of contact. Or a cup may be employed with a carbon rod in it, while upon the carbon rests a lever, the initial pressure of which may be varied by an electro-magnet, which may be the primary coil of the inductorium or disconnected therefrom, or may be a permanent magnet, or even a spiral or flat spring may be used, or if the diaphragm is held in the right position its own weight may be used. Another modification consists of an upright, to the bend of which is the carbon; on this rests a lever, to the end of which is secured a weight which passes the rod around which it is held by a spring to yield, the rod serving to hold the weight in position; by these means the initial pressure of the carbons is regulated. Or the carbon connected with a diaphragm may be acted upon by a pendulous spring with carbon disc upon its extremity resting against the carbon, the tension being also employed. According to a further modification of inertia transmitter, weights are secured to a lever pivoted from an arm which connects with a diaphragm; the carbons on the lever rests upon a carbon button in a cup upon the diaphragm; one of the weights is adjustable so as to adjust the initial pressure. Or four weights may be used secured to the underside of block upon the diaphragm; the current enters by the first spring, thence passes through the carbon tips to the carbon tips of the second chain, and from thence to the fourth and last spring.

According to another part of this invention a receiver is constructed upon the electro-motive principle in the following manner:—It consists of a diaphragm, a small cylinder or cup of wood or other suitable material impregnated with phosphate of soda or other proper chemical, to produce the electro-motive action, and a spring connecting the diaphragm with the disc tipped with platinum or gold. The shaft of the disc is raised by a worm and worm-wheel, or by inertia telephone may be secured to a strip of elastic material instead of a diaphragm. In a bevel gear may be employed, springs which are tipped with rubber or other soft substance. The magnetograph receiver may be arranged as a transmitter, the armature resting on a diaphragm; a spring connecting the armature with the chalk; the chalk in this case is made to rest upon a carbon disk. In a magnetograph receiver of an induction coil having a high resistance, a battery is provided; a metal-to-metal receiver may be used or a receiver as constructed as follows:—When the milliter. The action is as follows:—When the diaphragm is vibrated by the voice it acts to widen the spring, this instantly deprecates the point of contact between it and the chalk, thus increasing the flow of current from the battery; the instant the spring ceases to rest it pinches it and weakens the current from the battery. The magnetograph may also be arranged to transmit direct from one to the other without the intervention of an induction-coil, the armature of which they can by raising a lever to make receivers or telephones in circuit with the battery, the tension of the spring from the diaphragm upon the armature by depressing it; they are also provided with a handle and limiting screw are also used. A spring is further provided, also a roller, which serves to hold the lever when it is drawn up or down; both instruments are similar in construction. When receiving, the pressure is put on the spring resting upon the chalk and it is raised, but when transmitting, the pressure on the spring is light and the chalk is not raised.

The telephone may further be constructed so that each sound wave is made of an aggregation of smaller waves. A lever is provided suitably pivoted, and one its fulcrums is used for connecting it with the diaphragm, the other with the lever resting slightly upon it. Each of these is divided containing an electro-magnet, which is connected to one pole of the circuit, while the lever is connected to the other post; the armature of the diaphragm serves to recti-

procate the lever or spring over the surface of the disc. A push button is provided to open the receiver circuit when transmitting. When the lever and spring are adjusted for receiving, thus preventing the tertiary or battery coils of the induction-coil from interfering each other's currents.

When the lever and spring are adjusted for receiving, the current is carried through the primary coil; when down, the carbon transmitter is caused to be in circuit and the tertiary coil is made to be in the line with a condenser, the latter to prevent the circulation of earth currents through the coil and thus disturbing them. The tertiary coils are thus disposed with, which, batteries or discs of finely-divided conducting matter may be made of any known substance which conducts electricity, or which can be powdered, may be moulded by itself, or mixed with one or more other conducting or non-conducting substances to form the tension-diaphragm may be used.

VALPARAISO, 25 DE MAYO 1881.—LA PATRIA.—1

LA

COMPAÑIA CHILENA

DE

Teléfonos de Edison.

VALPARAISO.

LEGALIZACION DE SOCIEDAD.

Por decreto del señor juez de comercio fecha 19 del corriente, se ha mandado publicar por el término de diez dias la sociedad que consta de las escrituras siguientes:

ESTATUTOS DE LA SOCIEDAD.

En la ciudad de Valparaiso, República de Chile, a quince de diciembre de mil ochocientos ochenta, ante mí Francisco Pastene, notario público y testigos que suscriben, comparecieron los señores don José D. Huelsaide, don Pedro A. Mc Kellar, don Santiago Martin por sí y como socios i mandatarios de la sociedad que jira con la razon social de Martin y Mac Neil, segun se acredita mas adelante, y don Lucius H. Foote, todos mayores de edad y de este domicilio, siendo los cuatro primeros comerciantes y el último Cónsul de los Estados Unidos de Norte América en Valparaiso, a quienes doi fé conozco y dijeron: que en conformidad a la escritura otorgada en esta ciudad con fecha veintidos de noviembre corriente año ante el notario que suscribe i la presente, son dueños de la Empresa de Telefonos de Edison que funciona en Valparaiso y asimismo de el privilejio exclusivo concedido por el Supremo Gobierno a don Tomas A. Edison y que al presente, habiéndose completado el espíritu necesario para el mejor desarrollo del privilejio enclusivo y esplotacion del teléfono en Valparaiso, y queriendo independizar esos negocios de sus respectivas personas, venian en constituir una sociedad anónima con arreglo a los siguientes estatutos:

TITULO PRIMERO.

Constitucion y objeto de la sociedad.

Art. 1.° Se establece en Valparaiso una sociedad anónima que se denominará Compañia Chilena de Teléfonos de Edison, y cuyo objeto es la esplotacion en Chile del Teléfono de Edison del sistema central de Teléfonos, y de todas las invenciones y modificaciones que en estas materias se realicen. La sociedad podrá establecer agencias para la esplotacion directa del teléfono como la que tiene en Valparaiso o bien asignar el derecho a establecerlas en las ciudades que crea mas conveniente, y celebrar en uno u otro caso cualquier contrato relativo a esplotacion comercial en la Chile, con o otras que mas que se relacionen con el objeto principal de la empresa, i jiros conexos.

Art. 2.° La sociedad se constituye por el término de diez años, pudiendo prorogarse por otro período igual si así lo acordare un número de accionistas que represente el 60 por ciento del capital social con que jira la sociedad, a la fecha de la espiracion del término.

Art. 3.° Si en el trascurso del tiempo se hicieren modificaciones al teléfono de Edison o invenciones que sean preferibles al sistema de este invento, la sociedad podrá usarlas si juzgare conveniente, sin necesidad de variar el objeto indicado en el artículo 1.° en el sentido de hacerse dueño de los nuevos inventos y de aprovechar las modificaciones que salva el teléfono.

Art. 4.° La sociedad constituye domicilio en Valparaiso, no obstante que pueda establecer empresas particulares en algunas otras ciudades de la república.

TITULO SEGUNDO.

Capital social.

Art. 5.° El capital social es la suma de doce mil pesos, representado por cien fracciones acciones de quinientos pesos cada una.

La sociedad, un punto jeneral, podrá acordar un aumento del capital social y la emision de mayor número de acciones si así conviniere al desarrollo de las operaciones sociales.

Art. 6.° El espresado capital queda desde luego asentado en la forma siguiente:

Don José D. Huelsaide, doscientas acciones.

Don Santiago Martin, cincuenta acciones.

Don Lucius H. Foote, cincuenta acciones.

Don Pedro A. Mc Kellar, cincuenta acciones.

Y los señores Martin y Mac Neil cincuenta acciones. Total: cien acciones.

Los dichosnios acciones suscritas por el señor Huelsaide se entenderán un tercio a favor de don Tomas A. Edison y que al presente, siendo los mismos primeros comerciantes y el último Cónsul de los Estados Unidos de Norte América en Valparaiso, a quienes doi fé conozco y dijeron: que en conformidad a la escritura otorgada en esta ciudad con fecha veintidos de noviembre corriente año ante el notario que suscribe i la presente, son dueños de la Empresa de Teléfonos de Edison que funciona en Valparaiso y asimismo del privilejio exclusivo concedido por el Supremo Gobierno a don Tomas A. Edison y que al presente, habiéndose completado el espíritu necesario para el mejor desarrollo del privilejio ex

que ha sido nombrado por el accionista, por cuyo motivo cesará en el servicio de la Compañía.

El Directorio no podrá entrar en sesion ordinaria ó extraordinaria sin la concurrencia de tres propietarios. Si no fuese posible reunir con número por ausencia ó inhabilidad de alguno de ellos, se completará llamando á los suplentes, y si aun así no se pudiere completar número, se dará cumplimiento á lo prescrito en el inciso siguiente: Segundo: Reemplazar al director ausente ó que se halle inhabilitado por mas de un mes, nombrando interinamente en su lugar á uno de los accionistas: Tercero: Velar por la buena direccion y administracion de la Compañía; y Cuarto: Presentar en las juntas jenerales ordinarias el balance, estado y memoria de que trata el artículo veintiocho de estos estatutos.

Art. 30. Queda nombrado un Directorio que funcionará hasta la junta jeneral de enero de mil ochocientos ochenta y cinco, compuesto de los señores Pedro A. Mac Kellar, Lucius H. Foote, Santiago Martin y José D. Husbands, quienes nombrarán en la primera sesion que celebren despues de la apertura de los estantes, al director propietario que falta y los dos suplentes.

Art. 40 de nombres al señor J. D. Husbands, director gerente y firmará así por la sociedad. La sociedad de Martin y Mac Kellar solo celebrará operaciones otorgadas ante el notario don Julio César Escala, con fecha diez y siete de diciembre de mil ochocientos setenta y dos, entre don Santiago Martin y don Guillermo H. Mac Kellar, en la cual se encuentran los artículos siguientes:

1.° La sociedad se establecerá en calle puerto bajo la razon de Martin y Mac Kell. Pero Andrés Soton tendrán derecho de usar el nombre de la casa.—Confirma esto un artículo á que me remito. Los otorgantes y firmaron con los testigos que lo fueron don Manuel T. Feliú y don Benjamin Dodd.—Sigue á esto un papel de un peso.—Hoy fe.—José D. Husbands.—R. Ante mí.—Pedro Alcántara Mac Kellar.—Pedro Martin y Mac Kell, ámbos.—Manuel T. Feliú.—Benjamin Yeomans.—Ante mí *Francisco Pastene*, notario público y de hacienda.—Confirmo con lo escrito arriba de su tenor á que me remito, ante la presente segun dicho.—Valparaiso, abril siete de mil ochocientos ochenta y uno.—*Francisco Pastene*, notario público y de hacienda.—Certifico que la escritura que precede queda anotada en mi protocolo del último de instrumentos del Conservador de Comercio con el número cuarenta y tres á fojas setenta y cuatro. Valparaiso, mayo trece de mil ochocientos ochenta y uno.—*José María Tapia V.*—Notario y Conservador de Comercio.

APROBACION DE ESTATUTOS.

En la ciudad de Valparaiso repúblicas de Chile, á diez de mayo de mil ochocientos ochenta y uno. Ante mí Francisco Pastene, notario público y testigos que suscriben, compareció don José D. Husbands, mayor de edad y de esta domicilio, á quien doi fé conozco y dijo: que en uso de las facultades que le confiere el artículo cuarenta y seis de los Estatutos de la sociedad anónima titulada Compañía Chilena de Teléfonos de Edison, que ha otorgado con fecha quince de diciembre de mil ochocientos setenta y cuatro ante el notario don Julio César Escala, con fecha diez y siete de diciembre de mil ochocientos setenta y dos, entre don Santiago Martin y don Guillermo H. Mac Kell, en la cual se encuentran los artículos siguientes:

1.° La sociedad se establecerá en calle puerto bajo la razon de Martin y Mac Kell. Pero Andrés Soton tendrán derecho de usar el nombre de la casa.—Confirma esto un artículo á que me remito. Los otorgantes y firmaron con los testigos que lo fueron don Manuel T. Feliú y don Benjamin Dodd.—Sigue á esto un papel de un peso.—Hoy fe.—José D. Husbands.—R. Ante mí.—Pedro Alcántara Mac Kellar.—Pedro Martin y Mac Kell, ámbos.—Manuel T. Feliú.—Benjamin Yeomans.—Ante mí *Francisco Pastene*, notario público y de hacienda.—Confirmo con lo escrito arriba de su tenor á que me remito, ante la presente segun dicho.—Valparaiso, abril siete de mil ochocientos ochenta y uno.—*Francisco Pastene*, notario público y de hacienda.—Certifico que la escritura que precede queda anotada en mi protocolo del último de instrumentos del Conservador de Comercio con el número cuarenta y tres á fojas setenta y cuatro. Valparaiso, mayo trece de mil ochocientos ochenta y uno.—*José María Tapia V.*—Notario y Conservador de Comercio.

APROBACION DE ESTATUTOS.

En la ciudad de Valparaiso repúblicas de Chile, á diez de mayo de mil ochocientos ochenta y uno. Ante mí Francisco Pastene, notario público y testigos que suscriben, compareció don José D. Husbands, mayor de edad y de esta domicilio, á quien doi fé conozco y dijo: que en uso de las facultades que le confiere el artículo cuarenta y seis de los Estatutos de la sociedad anónima titulada Compañía Chilena de Teléfonos de Edison, que ha otorgado con fecha quince de diciembre de mil ochocientos setenta, presente para que se reduzca á escritura pública el Supremo Decreto aprobatorio de los Estatutos arriba citados, el cual es del tenor siguiente:

«República de Chile. Intendencia de Valparaiso. Número novecientos veintisiete. Valparaiso, mayo siete de mil ochocientos ochenta y uno. El señor Ministro de Hacienda, con fecha de ayer, me dice lo siguiente:

«Con acuerdo con esta fecha dictado lo que sigue:

Número novecientos veintisiete y nueve. Vista la solicitud precedente, los Estatutos y demas documentos que se acompañan y lo informado por el Fiscal de la Corte Suprema de Justicia, he acordado y decreto:

Apruébanse los Estatutos de la sociedad anónima titulada «Compañía Chilena de Teléfonos de Edison» que constan en la escritura pública otorgada ante el notario de Valparaiso don Francisco Pastene, con fecha quince de diciembre del año próximo pasado, cuyos los artículos nuevos, valorizados y que van agregados.

Art. 1.° Los cuotas se celebrarán á favor de determinada persona y no podrán ser en lo sucesivo por ordenes del ó al tenedor ante en lo. libros de la sociedad.

Art. 28. De las ganancias de la Compañía se rebajará en cada semestre la suma que acuerde la junta jeneral para formar un fondo de reparaciones y seguros subsiros del saldo de esta fondo no pase de cinco mil pesos.

Art. 31. La Compañía quedará disuelta por la pérdida de la mitad del capital social. La disolucion de la Compañía podrá tener lugar antes del plazo señalado á su duracion, si así lo acuerda por mas mayoría de accionistas que represente las tres cuartas partes del capital social, cuyo acuerdo se tomará valer. Ante ella se procederá en otra junta jeneral convocada al efecto y con intervalo de diez menos, si se ejecutará antes de obtener la correspondiente aprobacion del Presidente de la República. La cantidad del privilejio exclusivo no se sacará como pública del capital.

Se aprueban las modificaciones de los artículos 12, 16, 29 y 30 de los artículos espresados en la forma que consta de la escritura otorgada ante el mismo notario don Francisco Pastene, con fecha 4 de abril próximo pasado.

Habiéndose comprobado que la «Compañía Chilena de Teléfonos de Edison» ha cumplido el capital social de diez mil pesos, se le declara legalmente constituida y se fija el dia 20 del presente para que se proceda á sus operaciones.

El Directorio de la espresada Compañía cumplirá con las requisitos prevenidos por el artículo 450 del Código de Comercio.

Tómese razon, comuníquese y publíquese. Lo trascribo á V. S. para los fines consiguientes y en á usted para la mia.—Dios guarde á usted.—*E. Altamirano*.—El Jefe de la Compañía Chilena de Teléfonos de Edison. Conforme con su original.—Valparaiso, mayo trece de mil ochocientos ochenta y uno.—*José María Tapia V.*—Notario y Conservador de Comercio.

Ag.t Gazette. Almonte &c. Sept. 1881.

TELEPHONIC.

A New and Important Invention by Worcester Man.

Ever since the introduction of the telephone into general use, one serious annoyance has presented itself, which will soon be done away with. It is the constant ringing of the call bell of subscribers at central office.

The invention is a device by which call bell, which has been perfected by Mr. James Kotzel of this city. By its use only the subscriber wanted by the central office is called. It does away entirely with the ringing of the bell when a subscriber at central office touches any other subscriber. For all practical purposes there been in constant use on the line of the city. The subscriber during that time had been constantly bowled and has worked every time with perfect satisfactorily to all. The only trouble which was noticed, is the inability of a subscriber to ring without pulling in the instrument that belongs to him. This trouble has to-day been found to be of little moment, as complaint has been on an indicator being put in colored disk is put in sight whenever the bell rings, and which disappears as soon as the circuit is broken.

The arrangement by which the wants are obtained are all to a line 19 or 12 twelve lines, and upon the face of the instrument there is this is the brass rack of an ordinary clock. On the front of the box at the center is a small key, with the number of each station, and a pointer or hand. When a station is desired, No. 6 for instance, the hand is pointed on this dial is placed on the figure 6. A push button is then pressed, and the action starts the electric current down the line, which connects with the other stations in automatic manner, and rings the bell only at station No. 6. As soon as the subscriber at No. 6 takes the telephone to answer it is operated at the central office, he is notified by the bell ringing on the operating table. The central office now has the other subscribers can not call the line is in use by the subscriber at No. 6 until he has finished. The call by the subscriber is the same as before.

The apparatus used is very simple and there is no reason why it should get out of repair any more than any good clock. It works if kept wound up like a clock, and will run from 8 hours to 24 hours without winding. It is so arranged that when the subscriber sends down then a lever will strike the crank to the call bell and it must turn be wound up before the subscriber can call the central office. The machine or clock at the central office will run for a week without winding.

The advantage to the Central Office will be that it will give better service in less time than the present. It does away with the constant ringing and the annoyance of answering. That it will give prompter service is self-evident, as the bell only rings when wanted. An advantage to the public right is that it will not so often client, as the call can be made as long as he long as the subscriber wishes, and can soon be put on be more stations and not on all if it is desired. It has been tested by private parties, and by the Telephone Exchange in this city until now they are so well satisfied that they have equipped one line with it, and their subscribers do not complain.

Sonn, Nov. 11.th 1881.

THE TELEPHONE AS AFFECTED BY SOME METEOROLOGICAL PHENOMENA.—Several continental observers appear to have been lately studying the sounds which may often be heard in a telephone that is connected with a wire stretched, say, between the roofs of two houses, and connected with the water of gas pipes. On the occurrence of lightning, more especially, sounds are heard, and at the time nearest preceding to M. Rossi Thery, of Geneva) as much as 3 secs, whatever the distance of the latter. Even when a thunder was heard, and the discharge must have been at least 25 kilometers off, M. Thery observed these induction effects. The sound was not like that of a Swedish watch rubbed on the box. The telphone affords an easy method of studying the velocity of thunderstorms, and other features of this electrical influence. M. Lalande, who has experimented similarly for some time past, thought to amplify the sounds, and did so by placing two microphones on the plate of the receiving telephone. The arrangement is set up in a quiet room, where all foreign vibrations are guarded against, and the author is able to hear the least sound at a distance of one mètre or more from the second telephone. Again, M. Landerer, at Tortosa, finds currents produced in his telephone-circuit by atmospheric electricity in three different ways. First, the condensation of aqueous vapour results in a sound resulting the cry of tin. A sensitive galvanometer in the circuit is not, or hardly, affected. These sounds are strongest at night. Next, there are the sounds which occur during lightening (and the currents producing which affect a galvanometer considerably). Thirdly, the wind generates currents which do not act on the telephone, but act on the galvanometer strongly. At Tortosa, the very dry west winds produce the greatest oscillations. Telluric or earth currents act both on the galvanometer and on the telephone; they are distinguished from atmospheric currents by the regularity and continuity of their action, during pretty long intervals.—*Times*.

LA

COMPAÑIA CHILENA DE TELÉFONOS DE EDISON

VALPARAISO

Organizada segun leyes de Chile en 1881

AVISA A TODOS AQUELLOS a quienes pudiera interesarles, que habiendo comprado el derecho exclusivo para usar el único Teléfono práctico, como tambien el sistema central relacionado con este, y habiendo tal mismo obtenido del Supremo Gobierno un **PRIVILEJIO ESCLUSIVO** el 29 de abril de 1880, SE HALLA DISPUESTA a entrar en arreglos con cualesquiera personas idóneas para el establecimiento del servicio telefónico en **CUALQUIER PUNTO DE CHILE** y todo cualquier plan que facilite del modo mas eficaz el servicio, ya sea por medio del **SISTEMA CENTRAL** ó por líneas privadas.

Solo esta compañía puede vender derechos exclusivos para territorios dados y proporcionar materiales bajo condiciones convenientes.

Es una práctica será comunicar con 4 ó todos las ciudades, pueblos y personas en una estension territorial de 200 MILLAS, desde un punto dado, y proporcionarles comunicacion instantánea, como tambien de casa en casa, en una ciudad.

Todo propuesta relativa a los servicios indicados deberá dirijirse por escrito al que suscribe, debiendo las de aquellas personas que no sean individualmente conocidas, venir suficientemente garantidas por alguna casa responsable de la localidad a que pertenezcan.

Recibidas dichas propuestas, no dará a conocer a los interesados las condiciones y precios para el referido servicio.

Valparaiso, mayo 21 de 1881

JOSÉ D. HUSBANDS,
director-jerente.

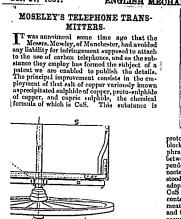
MOSELEY'S TELEPHONE TRANSMITTERS.

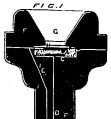
IT was announced some time ago that the Messrs. Mowley, of Manchester, had avoided any liability for infringement supposed to attach to the use of carbon telephones, and so the substance they employ has formed the subject of a patent we are enabled to publish the details. The principal improvement consists in the employment of that salt of copper variously known as precipitated sulphide of copper, proto-sulphide of copper, and cupric sulphide, the chemical formula of which is CuS. This substance is



used either in a compressed or in a pulverulent state.

The proto-sulphide of copper is made to form

FIG. 1.



part of an electric circuit, and is so placed that it may be influenced by the vibrations of a diaphragm when the latter is set in motion by the action of sound waves. The variations in the rapidity and amplitude of the vibrations of the diaphragm produce corresponding variations in the conductivity of the proto-sulphide of copper and therefore in the undulations of the electric "current" in the circuit in which it is inserted. The invention may be applied in various ways, but some typical examples will serve the purpose of explanation.

Fig. 1 is a section showing the method of employing the proto-sulphide of copper in the pulverulent form. A is a cavity formed in a non-conducting material such as wood; B and C are two conductors of electricity, such as platinum or other metal, carbon, or the compressed proto-sulphide of copper, which are attached to the cavity at D, E, communicating respectively with the opposite relaxed tube battery; F is the body of the transmitter; G is an open mouth piece, and H, H diaphragms. The cavity A is loosely filled with the pulverulent proto-sulphide of copper, which, being then in contact with the conductors B, C, forms part of the electric circuit. In Fig. 2, compressed

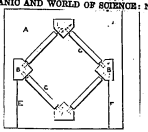


FIG. 2.

proto-sulphide of copper is employed for the blocks B, and the pastils C. A are the diaphragms upon which are mounted the blocks B, and the pastils C, are freely suspended. In this opposite blocks are connected with the wires E, F. It will be understood that a great variety of forms may be adopted both with pulverulent and with solid CuS; but in all cases the patentee makes the contacts with the proto-sulphide of copper by means of a conducting material, between which and the proto-sulphide no chemical reaction can occur under ordinary circumstances, for which purpose he prefers to use platinum.

[FEBRUARY 18, 1882.

The Telereduphone.

M. Mercadier, the eminent French electrician, has ingeniously adapted the photophone of Professor Bell to telegraphy. In the photophone a ray of light is reflected by a mirror, so as to fall upon the sensitive surface of a "selenium cell" joined up in the circuit of a voltaic battery and a speaking telephone. When the light strikes the cell its electric resistance is diminished, and a wave or pulse of current flows through the telephone, causing it to sound. By eclipsing the ray of light a great many times per second, this sound can be caulked into a continuous hum, like that of a tuning fork, and by again occulting the intermittent ray for long and short intervals corresponding to the flashes of a signalling lantern, this hum or drone can be broken up into audible signals. Thus, if the Morse telegraphic code is used, a short occultation, producing a short pause in the note of the telephone, will stand for a "dot," and a long occultation, producing a long pause, will stand for a "dash."

This photo-electric telegraph is realised by M. Mercadier with the help of a gas flame forming the source of light, a mirror, and lenses to direct its rays upon the selenium cell in circuit with a battery and the line wire. The beam is regularly eclipsed by means of a rapidly rotating disk, perforated with a circle of holes, and the telegraphic occultations of the intermittent beam are effected by means of a signalling key, which interposes a dead screen in the track of the light whenever the key is pressed. These apparatus form the transmitter; and the receiver at the other end of the line is, of course, the telephone, which is fitted with a resonator to re-enforce the sound. There is no gain in such an arrangement over the ordinary telegraph now in use; but it has the merit of lending itself to multiple telegraphy. Thus by multiplying the number of transmitters at one end of the line and the number of telephones at the other, several different messages can be sent along the same wire at once. In order to do this it is only necessary to rotate the eclipsing wheels at different speeds, so as to produce notes of different pitch in the receiving telephones, and to fit each resonator so as to enhance a particular note. Then, although the complex current flows through all the telephones in turn, each telephone will only render to the ear of the clerk the particular note for which he listens, and the snakes and breaks of that note will be interposed as dashes and dots. Not only can several messages be sent in one direction along the same wire together, but from opposite ends simultaneously without confusion, and M. Mercadier reckons that with 10 transmitters and 10 receivers at each end of a line he can send 200 dispatches of 30 words each per hour, or 100 words per minute, in either direction. The effects of induction, so troublesome in speaking by telephone, are not experienced in this process, owing to the employment of musical notes and resonators.

ADER'S MAGNIFYING TELEPHONE.

M. Ader showed, at the Electrical Exhibition, a new instrument that possesses the power to magnify reproduced sounds. If a song is hummed in front of the microphones attached to the instrument, the song will be reproduced as a full quartet.

This instrument is formed of four trumpets whose mouthpieces are attached to a vibratory diaphragm (see illustration), but its interior arrangement has been kept secret by the inventor, as it is the only known instrument that is able to increase sounds transmitted through the air.

It is rightly named a microphone, as it does for the ear what the microscope does for the eye.

At present it is only able to reproduce musical sounds, but M. Ader hopes soon to magnify and reproduce articulate speech of the human voice, so that a person whose hearing is defective can hear without placing the instrument to his ear. He may possibly do this, for all telephones commenced by transmitting musical sounds only.

If M. Ader succeeds, instead of the present style of telephone, there may be telephonic offices and rooms where one can sit and talk comfortably to any distance without moving from his chair.—*La Lumière Electrique.*

ADER'S MAGNIFYING TELEPHONE.

Daniel Drawbaugh's Telephones.

The People's Telephone Company has obtained the testimony of about one hundred and thirty witnesses at Harrisburg, Pa., to show that Daniel Drawbaugh, who resides in the adjoining county of Cumberland, invented the first magneto-telephone, and its side of the great case will soon close in this city with the examination of an expert electrician who has tested all of Drawbaugh's inventions. The testimony given thus far goes to show that Drawbaugh invented at least half a dozen speaking telephones before Bell conceived the idea that sound could be transmitted by electricity. Drawbaugh, according to this testimony, began thinking about sound transmission in 1861, and in 1867 invented a machine which carried sound by means of a voltaic battery. In 1871 he made a magneto-electrical instrument which transmitted speech, and which is said to embody all the principles of the Bell telephone of to-day. In 1874 and 1875, it is claimed, he made marked improvements on this invention before Bell had any thought of telephonic communication. Since the Bell telephone went into operation Drawbaugh has invented a machine which he claims, according to tests made, will carry speech at least one thousand miles, and will not be affected by atmospheric influences. This same instrument, he thinks, can be made to transmit sound an indefinite distance. The American Bell Telephone Company, which is resisting the claims of the People's Company will begin taking testimony in a few weeks. In New York, next summer, it will be decided whether Bell or Drawbaugh invented the first magneto telephone.—*Operator.*

Telephones and Electric Lights in Brazil.

The *Rio News* reports a condition of things in Rio Janeiro not at all creditable to certain public officers of the empire. The Director-General of the State Telegraph Department in particular has seen fit to take a position of violent hostility to the introduction of telephones not under his control, and the indications are very strong that his hostility extends also to electric lights, while his methods of manifesting his dislike are not such as public officers customarily resort to.

The *News* says: "Ever since the telephone company of this city—which is unfortunate as to be a foreign enterprise—began to stretch their lines from the central office to the various suburbs, there has been a systematic effort on the part of certain interested parties to impede the work and damage the property. The means usually employed is the cutting of the wires. Regardless of the fact that this is an injury to private parties as well as to the company, this contemptible work has been prosecuted not only without lenidemess, but with the well known approval of influential parties in this city."

After describing at some length the course of the Director-General of the Telegraph Department in this connection, the *News* remarks:

"It is no longer a personal matter; the good faith of the government is at stake. If a privilege to a foreign enterprise is worth one straw in Brazil, then the government is bound to guard and protect it. If, however, a foreigner has no protection for his labor and investments as against the malice of influential per-sonages, then let us know it at once. If matters go on in this way a little while longer—in the confiscation of property, the breach of contracts, the destruction of electrical machines, and the cutting of telephone wires—this country will be satisfied with a reputation which will not only keep enterprise and capital at a distance, but will even drive away those that are now here. It is full time that the steady, thinking portion of this community take those occurrences into consideration, and determine where they are being led."

The destruction of electrical machines referred to occurred during the late National Exposition, the victims being the Edison electric light people, the aim being to prove that system of lighting irregular in its action and untrustworthy.

"It was thought a suspicious circumstance that two armatures in succession should be burned, but when a third was ready to be put in place, an examination of the upright columns of the dynamo developed the fact that a sharp instrument had been inserted beneath the canvas covering at their lower ends, and that the wires had been cut. That the cutting was done by an expert is evident from its location and character. The damage was examined by a committee of the Engineering Club, who are satisfied that the cutting was done willfully and maliciously."

Speaking of this outrage the *News* observes:

"We have heard of no effort on the part of the Associação Industrial, in whose charge the Edison apparatus was at the time of the accident, to ferret out the guilty party; who should make every effort to guarantee fair play, does not seem to have noticed the fact. Fortunately, however, the Edison light has been placed in the Dom Pedro II. railway station, where the public may judge of its merits without interference."

TELEPHONIC MUSICAL PERFORMANCES.—It seems incredible that the musicians on organ stands should serve miles in opposite directions at the same time, so that while the human voice should travel along the wire at the rate of 2 miles a minute, the music from the organ pipes, which can be heard with unaided electrical energy, travels with the steam music, in two hours 24 miles apart. Such, however, appears to be the case at the present time between Woodlands, Norwood, in the residence of Mr. Woodland, and Woodland House, Sydenham, in the residence of Mr. Flood-Page. These houses are 24 miles apart, and connected by a telephone wire which passes through the organ in the concert-room of the Crystal Palace. Every Saturday evening at Mr. Ayre during the past week has Mr. Ayre been present in the Palace, he has also played to his audiences at the Woodlands, who have been sitting in Middlesex House and the Woodlands rent in acknowledgment at the close of the concert. They have heard the Palace organ played, but Mr. Ayre and Mr. Fairy, Mr. Higgs and Mr. Henry Parker, the Palace choir, in fact gentlemen who have been "in the policy" Mrs. Gounard and Mrs. Flood-Page, have been still more astonished to hear simultaneously with the musical interventions which Colonel Gounard and Major Flood-Page, R.A., in his new home occasionally shows them a duet, telephonic wire conveys music and the human voice simultaneously, and without the slightest confusion of sensation, in the same moment in opposite directions. The public will soon have an opportunity of testing this for themselves, as the [Edison-Howard-Tel] Telephone Company of Great Britain, in connection with the Telephone Co.-opany, are about to establish musical telephonic entertainments at the Crystal Palace. Negotiations [illegible] concerned for such purposes, and before the electric exhibition was determined upon, and they will form one of the permanent attractions of the Palace. They have nothing to do with that exhibition, and will continue so long as the visitors are interested enough to support them.

Scientific American.

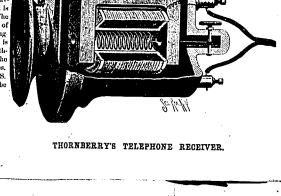
A NEW TELEPHONE RECEIVER.

We illustrate a new telephone receiver, the senses of which be due to the construction of a spiral magnet core under the influence of the currents traversing the bobbin. The spiral core is attached at one end to the diaphragm, and is connected at the other end with an adjusting screw. The spiral core is perfectly free to work in the helix, and the contraction or expansion of the spiral under the influence of the current from the transmitter acts on the diphragm in much the same manner as though it was attracted by a magnet, the results being the same as in Bell's, Gray's, or Phelps' instruments.

A permanent magnet placed outside the bobbin magnetizes the "spiral core" by induction, so that the spiral is very sensitive, thereby making it sensitive to the influence of currents passing in the bobbin. The inventor expects to partially, at least, overcome the influence of induced currents in the receiver, and to obtain more distinct articulation.

The construction of the telephone will be readily understood by reference to the engravings, in which a portion of the instrument is broken away to show the internal parts. The diaphragm is mounted on a mouthpiece of the usual description, and the permanent magnet and bobbin with the inclosed spiral is placed in a small casing attached to the mouthpiece. This instrument is provided with the usual binding posts and flexible connections.

This receiver is the invention of H. S. Thornberry, of Winona, Minn., who may be addressed for further particulars.



THORNBERRY'S TELEPHONE RECEIVER.

THE TELEPHONE.

A company, calling itself the Oriental Telephone Company, has been started with a view to introduce the speaking telephone of Bell and Edison into India, China, Japan, Australia, Fiji, and various scattered dependencies of the British Crown. The chief advantages of the telephone for those countries consists in the fact that it is portable and will answer all kinds of speech. There is word, too, of a National Telephone Company to spread the use of telephones in the provincial towns of the United Kingdom. On the Continent the installation is proceeding rapidly, especially in Germany, where it is under the management of the Telegraph Administration. From France an important advance has been made in Dr. Cornelius Herz, who has succeeded in dispensing with magnetism, and has produced a non-magnetic telephone differing from Ellsworth. His apparatus has been on trial for some time back on the French lines, and was publicly tested lately before M. Cochery, the Minister of Posts and Telegraphs, M. Jules Ferry, Prime Minister, and several well-known scientists. With a single Leclanché cell, Dr. Herz succeeded in transmitting audible speech along a wire from Tours to Bourg, *viâ* Paris, a total distance of over eight hundred miles.

A WONDERFUL TELEPHONE.

The Lancet—March 12.

WHAT A NEW-YORK ELECTRICIAN IS SAID TO HAVE SEEN IN BOSTON.

A very remarkable improvement in the telephone, by means of which vocal messages can be transmitted over the wires thousands, instead of tens and hundreds, of miles, as heretofore, is reported to have been recently demonstrated in Boston, where the main office of the Bell Telephone Company is situated. The report has created some impression among electricians in this City, as it relates to matters involved in all the details, a future for the speaking telephone not second to that of the telegraph itself, indicating, indeed, in the opinion of the most sanguine, a revolution in the whole system of the intercourse with nations by the means of postal correspondence. It appears that Mr. Edward Reynolds, a resident of the Metropolitan Telephone Company of this City, in the capacity of electrician, had occasion, a few months since, to visit Boston in order to confer with the Bell Telephone Company. While there he was shown by Professor Dolbear, of Tufts College, Massachusetts, the workings of an invention by which one voice could be sent distinct from each other to New-York and Philadelphia simultaneously with much other intelligence and subject. It is stated that the same afternoon he started from Boston for this City, and immediately on his arrival here called each for the first time several members of the directory of the above-named telephone company, and requested that the same instruments used in the experiment with the Boston office should be placed in their respective offices. This was accordingly done, and Mr. Reynolds then proceeded to the office of the Metropolitan Company, and there, in the presence of several of the directors, he conversed with the Boston office, and also with the New-York and Philadelphia offices, at the same time, and demonstrated the practicable success. Messages have, it appears, been sent from Boston to New-York and Philadelphia, as from New-York to Philadelphia, Washington, Cincinnati, St. Louis, or even San Francisco, and the invention is said to be perfect in every particular, so that the Metropolitan Telephone Company are now in communication with the Bell Telephone Company with a view to the immediate introduction of this invention, but not ready to divulge. Mr. Reynolds, it is understood, has returned to Boston, and, according to the latest advices, leaves for Europe in a few days, via New-York and London, to make arrangements for the introduction of telephones as here described. In connection with the foregoing it is stated that the sanguine expectations of the directors of the Bell Telephone Company is founded on the practical success of the invention, and the possibility of many others, established on the same principle, being brought into practical use in the course of a few months. Mr. Gilliland states that the principal features of the invention are the transmitting of the human voice by means of a single wire, and the separation of that from the ordinary current of the wire. The latter, he says, is effected by the use of a "secondary circuit," consisting of a delicate arrangement of electro-magnets, which, by means of a "secondary battery," produces a current of electricity of a different character from that used in the ordinary telegraphic service. The invention, he says, is the result of many years' experiments, and is the outcome of the labors of a number of scientific men, who have devoted their attention to the subject. The system is now in use in this City, and in the vicinity of Providence, Rhode Island, and Worcester, Massachusetts, and is working with entire success. It is stated that the next extension will be to Albany, and thence to Buffalo, with which latter city a connection is now in course of construction. Other lines are also in course of construction between Boston and Portland, Maine, and Boston and Lowell, and Boston and Fall River, Massachusetts. It is stated that the Bell Telephone Company have now in operation 30,000 telephones, with 8000 other handsomely fitted up and subscribed for, and

FRENCH TELEPHONES AT THE PARIS EXHIBITION.

THE collection of telephones in the French telegraph annexe at the Exhibition is an interesting one. The accompanying figure represents the "watch" form of Bell telephone as exhibited by M. Bregnet. The outer case, which is of mahogany, is about 3 in. in diameter, so that this form is very convenient for the pocket, and may also be hung up anywhere like a watch. Its novelty lies entirely in its form; the principle, and the several parts of it, being the same as in the ordinary Bell telephone. The permanent bar magnet, instead of being straight, is curved round itself, after the manner of a volute, and the small coil of insulated copper wire is seated upon the central pole. The price of a pair in mahogany cases is 24 francs in France. The price of a pair of "mirror" telephones, which are similar to the watch telephone, but fitted with a straight side handle, like a hand-mirror is 25 francs. The ordinary hand telephones in mahogany and box are 20 francs, and those in ebonite, rose-wood, or nickel-plating, from 40 to 50 francs a pair. A powerful telephone for long lines, formed of a horseshoe magnet, with a brass board and a mouthpiece, costs 102 francs a-piece. Those prices are independent of the "cells" and other fittings.

An improvement effected in the construction of these telephones by M. Alfred Ninuket deserves mention. As formerly made the Bell telephone was by no means constant in its action, and required adjustment. The distinctness of the articulation depends in a high degree on the position of the diaphragm with respect to the pole of the magnet—as far as possible, while leaving sufficient space for it to vibrate in without touching the latter. It was found, however, that differences of temperature affected the vocalisation of the telephone even more than they do the delicate threads of some of our most celebrated singers. The hot breath playing impaired the articulation; and holding the telephone to the face for a few moments has even rendered it dumb altogether. In certain cases heating, on the other hand, improved the speaking. This inconstancy was traced to the expansion and contraction of the diaphragm, which, being clamped all round by the wooden frame of the instrument, could only expand in the middle, so that it became more or less convex there, and, in consequence, receded from or approached the pole of the magnet. To correct this variation, it was necessary to give the magnet a slight longitudinal play, so as to move it nearer to the diaphragm or further from it, as the case might be. M. Ninuket obviates this necessity by leaving the diaphragm free round its edge, not clamping it there between the two parts of the frame; and in order to fix it in its place and prevent its moving about, he overlaps it round its edge by a circular spring made of steel brass wire. This holds the diaphragm down all round, but leaves it free to expand at the edges without buckling in the centre. A telephone of this kind, therefore, requires no adjustment, a point greatly in its favour with the public at large.

M. Ninuket has also effected improvements in Edison's singing call for telephones. This consists essentially in connecting up a small local battery with the telephone, so that on singing against the diaphragm the latter is made to rapidly interrupt the circuit of the battery, and a singing note is heard on the receiving telephone loud enough to call attention. The local battery is connected up for calling by pressing a button in the back of the telephone. This carries a small platinum contact pin forward, within vibrating range of another contact attached to the diaphragm itself. When the call has been responded to, the press button is released, the contact pin springs back, the local circuit is withdrawn, and speaking can be carried on in the telephone in the ordinary way. M. Ninuket gets a considerable improvement in the sound of the call by making the frame of brass instead of wood. A speaking tube covering the diaphragm, with holes in it for the escape of the breath, is also an advantage. The merit of this alarm is that with the exception of the battery it is all comprised within the ordinary telephone itself. The singing note given out by the receiver may be easily heard a distance of 20 yards, with a battery of four two to four cells.

EDISON'S CARBON TELEPHONE.

THE great interest which the discoveries and experiments of Professor Hughes have excited in a branch of physics which he has made his own, and which were first described in this journal,* induces us to bring before our readers some of the experiments in a similar direction made by Mr. Thomas Alva Edison, the eminent scientific adviser to the Western Union Telegraph Company, who, we need hardly remind our readers, is a co-inventor of the quadruplex system of telegraphy and is the inventor of the now well-known electric-pen and of the famous talking phonograph.

Mr. Edison's carbon telephone, which has been referred to in former articles in this journal, is in outward appearance, very similar to the magnet telephone of Professor Graham Bell. Its internal construction, as well as the principle upon which its action depends, are, however, altogether different. Fig. 1 (on next page) represents a longitudinal section through the instrument, in which there is a diaphragm or membrane of thin fernetype iron, which vibrates under the influence of sonorous vibrations exactly in the same way as does the diaphragm of Professor Bell's instrument. Below the diaphragm is a cake of compressed carbon held between two plates of platinum, and attached to a sliding piece passing down the stem of the instrument, by which it can be made to approach or recede from the diaphragm by turning a screw at the lower end of the stem. The motion of the diaphragm is communicated to the upper platinum plate through the intervention of a small piece of india-rubber tubing fastened to the underside of the fernetype disc, and its action is to cause the pressure upon the cake of carbon to vary in

THE TELEPHONE.

THE NEW ENGLAND COMPANY'S INCREASE.—The net increase of telephones by the New England Company in March was 186, making 17,838 instruments in use March 31.

ERIE INCREASE.—The northwestern division of the Erie Telephone Company increased its subscribers 16% in March, and has ordered 80 instruments on account of April. It is estimated that as many as 60 were added in the Northern and Cleveland divisions, making a total increase for March of 225.

THE AMERICAN PORTABLE TELEPHONE CO.—A meeting of this Company was held at their office, 108 Temple Court, on the 10th inst. It was decided to put 10,000 shares of treasury stock on sale at $7.50 per share. Capt. Border made a report of progress in the further utilization of the apparatus, especially for fire department purposes.

THE DRAWBAUGH CLAIMS.—The list of the subscribers to the Bell vs. Drawbaugh case has been given to at Harrisburg, Pa., during the last few days. It is not expected that the case will come to trial in June or July. The Drawbaugh representatives consider that the last evidence materially strengthens their testimony already obtained and makes them impregnable.

AN "ANTI-BELL" TELEPHONE.—The Boston *Herald* says: A new short distance telephone has entered the field—the "Anti Bell"—whose chief merit appears to consist in its phosphor-cop per bronze wire. It disclaims infringing American Bell patents, but maps out its own destiny as a "formidable rival" to that telephone and the system of exchanges generally. It has but this virtue—that it offers telephones and not shares to the public.

THE NEW ENGLAND CO.'S CHARTERS IN BOSTON.—The change of location of the central office is necessitated, says the Boston *Herald*, by the growth of business, as the company is about to introduce the multiple switchboard, which will increase the capacity of the Pearl street office to 4,200 subscribers, exclusive of 1,500 in other parts of the city. The costs of operation will be reduced about 25 per cent. by this change. The expense of the change is not stated.

ALTON, ILL.—The last telephone directory to hand is that of the Alton, Ill., exchange, working under the Central Union Telephone Company, third district. It now has nearly 150 subscribers and about 40 outside connections. Mr. S. H. Brobst is the manager. We note that books of coupon tickets for toll line service are offered at a 10 per cent. discount on all sales up to $20, 15 on from $25 to $45, and 20 on sales from $50 up. The directory is tastefully printed, and contains numerous local "ads."

March 22, 1883.

ELECTRICAL REVIEW.

The Telephone in Moscow.

Our Russian correspondent, located at Moscow, states that the Telephone Exchange in that city had 260 subscribers connected on January 18th. The rates of rental are 250 roubles per annum. The rates are considered very high, or there would otherwise be many more, but even at present rates they are coming in rapidly.

A New Telephone.

Knowledge describes the receiver of a new telephone, which is based upon the principle that when an iron wire or rod is magnetized it suffers a slight increase in length with a compensating decrease in cross section. The inventors claim "the construction of a telephonic receiving instrument consisting of a magnetic wire attached to a sonorous disc or plate, and wound with a primary coil connected to a local battery and with a secondary coil connected to the telephonic line wire, as described." *Knowledge* anticipates very satisfactory results from the new instrument, which, even in its crude form, it says, reproduces sounds with remarkable clearness.

A Long-Distance Telephone.

WASHINGTON, March 16.—Myron L. Baxter, of this city, has been awarded letters patent for a long-distance telephone, which, it is said, recent tests have shown to be capable of overcoming in a remarkable degree the difficulties arising from inductive and other disturbing influences.

M. D'Arsonval, the well-known telephonist, has devised a new form of Bell receiver, which is, for its size and weight, the most powerful yet constructed. The chief modification consists in enclosing the bobbin entirely between the poles of the magnet. This is done by making one pole of the magnet the core of the bobbin, and the other pole as enclosing ring of iron. The inductive plate vibrates over the poles and upper surface of the coil as before. The complete instrument only weighs a little over five ounces and is stated to be as powerful as the heavy Gower-Bell receiver. M. Lecraenky has applied magnets of steel tempered by compression after the manner introduced by M. Clemen dot, and since this mode of tempering does not deform the magnets, a neater article is the result.—*Engineering*.

The Bell Telephone Company in its annual report does not show any great surplus for this year, but no man can set down definitely the present earnings upon Bell Telephone stock, by reason of the unknown quantity of its income upon investments in local exchanges. Earnings of 25 per cent. upon Bell Telephone in 1883 is a moderate estimate. No one can estimate the future value of such a patent. It is the most valuable franchise ever secured to any corporation, and if not interfered with by the courts or the legislatures may pay an income, in time, upon a capitalization of one hundred millions.—*Boston Transcript*.

When some time ago we wrote that the telephone interests of this country would surpass in value the telegraph interests, we were not aware how quickly this would be the case. Despite the fact that the Western Union Telegraph Company has a share capital of $80,000,000, double the capital of the same company some time after the telephone was invented, this $80,000,000 of capital, at its market price of 84, does not equal in value the market price of the Bell Telephone capital, combined with the market value of the sub-companies working under its patents. That the commercial value of telephone, five years after its introduction to the public service, should be greater than the value of the telegraphic system of this country after twenty-five years of operation, no one would have dared to predict until very recently.—*Ex.*

Mr. C. Langdon-Davies in writing to the London *Standard* says of the Van Nyssel-berghe system of electrical communication, "Anything which any telephone can do, and also anything which any telegraphic instrument can do, are, by means of this system, made practicable simultaneously. That is to say, if the system were applied to the telegraphic wires of this country, the whole network would become available for the transmission of telephonic messages, conveying the full force of the voice to long or short distances, without interfering with or receiving interference from the telegraphy, which would be continued precisely as before, on the same wires at the same time." Perhaps if this system were tested by the English postal authorities Mr. Langdon-Davies might have cause to modify his statements to a considerable extent. At present such public communications on the subject of telephony and telegraphy must be taken *cum grano salis*.

THE ELECTRICAL WORLD

The Gillett Long Distance Telephone Apparatus.

In the few years that have marked its growth the art of telephony has already fulfilled most extraordinary promises and realized most wonderful possibilities, and it may justly be masked, even now, among the most valuable of the arts with which electricity has endowed our civilization thus far. Yet it is far from having exhausted its resources and reached the limit of its development. There is a new and almost boundless sphere of usefulness into which it had scarcely thought of entering before now, and where it is destined to play a role of the highest importance—the transmission of articulate speech to long distances. Before its task is completed the telephone must yet fulfill this promise—it must conquer distance. The now indispensable conveniences and facilities which it places at our command for intercommunication between different parts of cities and neighboring towns, must also be made available between cities and towns widely distant from each other. It is, indeed, to this new development, this wider extension of the art that the public is now looking forward with the most interest.

Long distance telephony has been the dream of both scientist and inventor ever since Bell inaugurated the art by demonstrating the possibility of the electrical transmission of speech. But it is only within a comparatively short time that we have begun to approach the realization of this dream. The art of telephony, like all others, "had to crawl before it could walk." When the telephone left the hands of Bell its voice was too weak even for ordinary distances. In order to "cultivate" and strengthen it a certain process of evolution and improvement under the fostering care of the inventor was needed. The microphone transmitter had to be invented, the induction coil and other important accessory devices had to be brought into regulation. It was only after the telephone had succeeded in attaining its natural growth by assimilating these necessary elements that the higher development tending to make its voice reach "our hill and dale" began. At first it was the successive improvements made in the transmitters and receivers intended for ordinary use that enabled the distance of transmission to be gradually increased. But the practical limit to the increase is reached usually within a few hundred miles, with these forms of apparatus. This has since led some inventors to experiment with modified forms of apparatus specially constructed for the purpose of transmitting speech to long distances.

Mr. Webster Gillett, of Ypsilanti, Mich., appears to have been particularly successful in this line of invention. His "long distance" apparatus, the various types of which we take occasion to illustrate herewith, presents features of considerable novelty. The special interest which attaches to this apparatus, from the very fact that it is designed for long distance transmission, is greatly enhanced by the flattering success obtained with it in numerous long distance tests lately made over the wires of the Postal Telegraph Company. Mr. Gillett has been interested in the development of telephony almost from the very first, having obtained patents for improvements as early as 1878. Of late years it may be said that he has made a "specialty" of long distances, for all his efforts have been concentrated on the task of perfecting his apparatus, so as to make it powerful as well as sensitive.

The most important problem to be solved at the outset was to provide a suitable microphone contact, for, as we know, the clearness, the distinctness, the fullness, even, of the articulation, depend greatly upon the manner in which this contact performs its function. In ordinary microphone transmitters all the sound vibrations which make the diaphragm vibrate cause the carbon or metallic pieces between which this delicate contact exists, to move relatively to each other so as to make the contact alternately looser and closer. The resistance to the passage of current through this contact diminishes considerably as the pieces are pressed more closely together; but it increases greatly, on the other hand, when they move away. The difference may amount to several ohms. It results therefrom, that at each sound vibration, the resistance of the local circuit, through the contact and including a battery, and the primary coil of a transmitter, is increased and diminished, thus causing a fluctuation in the current. These fluctuations or "undulations" react upon the secondary wire of the induction coil, and give rise to impulses of current of higher electromotive force that are transmitted over the line. For the perfect transmission of speech each one of these impulses must act individually on the receiver at the other end, and for this they must be well defined.

The problem of long-distance telephony consists precisely in giving to these impulses a sufficiently sharply defined character, for they are expected to withstand a certain amount of retardation in transmission that tends to

THE LABYE TELEPHONE.

The Labye Telephone.

At the Paris Electrical Exhibition of 1881 M. de Locht Labye, of Liége, Belgium, exhibited an ingenious and very efficient telephone transmitter, shown under the name of the pantelephone. The remarkable feature of this transmitter, as described in *Engineering*, was its extreme sensitiveness. It would receive and transmit clearly the vibrations caused by the articulations of a speaker standing with his back to the instrument and thirty yards from it, and it was thoroughly efficient at a distance of four yards in transmitting whispered sentences. The instrument consisted of a single rectangular plate of cork, hung freely from two thin brass or steel strips. To the bottom of the block of cork was fixed a button of hard carbon, held in light contact by a slight inclination of the plate with a piece of platinum. This constituted the whole of the transmitter, which has now been supplemented by the equally ingenious and efficient receiver, which we illustrate on page 445. Considerable interest attaches to this latter instrument. Its articulation is as least as clear as that of the Bell telephone, while its action differs considerably, and the diaphragm common to other telephones is replaced by a thick and mechanically rigid aluminium plate.

Mr. Bell claims as a point of vital importance that, in order that speech may be transmitted and reproduced, a flexible plate should be employed, and this must be put into undulatory movement corresponding to that of the air waves, in order that such undulations may reproduce the air waves, and that to effect this it is necessary that the connecting line between transmitter and receiver should be constantly traversed by a continuous current, the undulations in which produce the vibrations of the diaphragm. On the other hand, M. Labye maintains that in his telephone articulate sounds are reproduced by a series of rapidly succeeding, but absolutely intermittent, blows struck on the aluminium plate, the amplitude and rapidity of these blows depending, of course, on the impulse transmitted through the line, and being rendered audible by an exact reproduction of continuous sounds, the ear not being sufficiently sensitive to mark the intermissions, supposing them to exist. Without dwelling on this theory, we may describe the telephone, which is illustrated by a front view and section, Figs. 1 and 2, and by a perspective view, Fig. 3. To a wooden plate, A, is secured by brass brackets, B B, a powerful horseshoe magnet, N C S. To each pole is attached a small core of soft iron, *d*, surrounded by the coils D D of silk insulated copper wire; these coils are included in the telephonic circuit, the conductors of which are shown at L and T. Opposite the cores of the small electro-magnets D D, which are covered with gold-beater's skin, or some other thin material, are the ends of a bar armature, a a, kept from actual contact with the cores by the film just mentioned. This armature, which is of soft iron and relatively heavy, is rigidly attached in the centre of its length to a bar-f brass, *f g*, which swings on the axis *o*, fixed to the post, *p*, which is made in one with the strap H. The lower end of this lever, which is thus free to oscillate, is traversed by a screw, carrying at one extremity the small hammer H. This hammer rests against the centre of a thick disk of ebonite or other material, M, which is screwed rigidly to a resonator, P, the whole being secured to the base-plate A by means of the metal posts B B. By means of the screw V at the end of the hammer the space between the poles of the magnet and the armature necessary to give the clearest articulation can be very accurately adjusted.

Like the Bell telephone, the instrument we have described can be used either as a transmitter or a receiver. The form, thickness, and practically the material, of the aluminium plate M are indifferent, although the circular shape illustrated is probably the most convenient. Ebonite, hardwood, cork, metal or stone give clearly articulate vibrations, and paper or leather folded to as great a thickness as the range of armature lever will allow may be interposed between the aluminium plate and the hammer without checking the clearness of the transmitted speech. The two parts—the aluminium and the resonator—may be made in one piece, and the more rigidly this organ is fixed the more efficient the telephonic duty appears to be. If, on the other hand, a thin flexible sheet is substituted for the aluminium plate—such as the ordinary Bell diaphragm, disks of mica, aluminium, &c.—the sounds are very considerably reduced, and if the armature lever be connected to the aluminium plate, all audible transmission ceases.

The inventor thus describes the action of the instrument when used a receiver: "The telephonic currents circulating in the bobbins cause the armature to be alternately attracted and repelled. By reason of the reaction of the rigid obstacle against which the armature lever rests, the repulsion alone is effective in producing the first movements of the armature. The latter, in moving away from the pole, momentarily separates the hammer at the end of the lever from the buttress or rigid obstacle. This repulsion is succeeded by the attraction of the armature caused by the following current, and the armature is then pulled back to its original position, and tends to pass beyond this position by reason of the attraction and its own *vis viva* or momentum, but is stopped in this direction by the rigid piece or obstacle against which the hammer strikes. The intensity of the blow or shock consequently results from the combined effect of these two actions, and is in direct ratio to the electro-magnetic forces which produce the repulsion and attraction of the armature. The number of shocks is equal to the number of electrical charges produced in the telephonic circuit."

(2) *Brix's Zeitschrift des deutsch-oesterreichischen Telegraphen Vereins*, 1882, Vol. IX., p. 153. This article is also reprinted in *Hughes's Telegraphisches Journal*, 1883, Bd. 67, XIX., p. 23.

This is a report by Inspector van Legat on Ader's telephone in its developed form. Inspector van Legat says that this instrument was able to reproduce single words uttered as in reading and speaking, though not so distinctly as it reproduced chords and melodies, which latter it transmitted with marvelous fidelity. It even added that the "gestures of the voice, the modulations of interrogation, exclamation, wonder and command attained distinct expression.

So much for Bell's references. Edison's reference is the same as No. 2 of the preceding.

As to the publicity of these documents, permit me to refer you to the shelves of the British Museum and other public libraries.

I do not say that there is not plenty of further evidence, were such needed. But here I am quite content to accept the references given by such unimpeachable authorities as Bell and Edison. When they refer me to papers wherein Reis says, in substance: "I am the inventor of the telephone. My instrument is intended to transmit human speech and all other kinds of sounds that a human ear can hear, and it succeeds in doing so, though I find to my disappointment that it is not yet quite perfect, because, though single words and consonants come through all right, the vowels are not clear"—I am bound to believe, on the authority of Bell and Edison, who give me these references, that Reis's modest claim is just. And I am bound to this belief still more strongly because I find, when I make careful trial of Reis's own telephones, that they will do exactly what he said they were intended to do, namely, transmit human speech at a distance by the agency of the galvanic current.

You have, Mr. Editor, most aptly said that the question is, What was *the kind of sorrow-stained* air attained by Philipp Reis? and I entirely agree with you that this question is not in the least degree affected by whether Philipp Reis is dead or alive. Though himself he is dead, and the task of defending his memory from outrage falls to others, his words still live to testify in the most unmistakable manner to the aim which he set before himself, and to the measure of success which he attained in his invention of the telephone.

Yours, &c.,
SILVANUS P. THOMPSON.

Bristol, March 4, 1883.

P. S.—There is a slight *erratum* in line 12, from bottom of p. 373, where, by mischance, the word which I wrote has been altered from *pe-fect-i to perfect*. Philipp Reis's telephones of 1862 were not perfect, but were perfected instruments, compared with those he showed to the Physical Society in 1861.

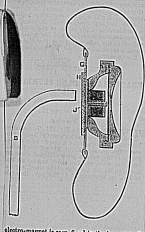
BERLINER'S OPERATOR'S RECEIVING TELEPHONE.

RECEIVING telephones used by operators and others whose chief duties consist in listening to and reporting telephonic messages, require to be made as light as possible, in order to avoid the fatigue of holding up the telephone so constantly constructed. Mr. E. Berliner, of Boston, Mass., has recently patented a device which can be readily strapped to the ear and retained there without discomfort. It inserts in the receiver, and is made to make a receiving telephone which is strapped to the ear, and is so light as not to interfere with the comfort of the operator, and at the same time be efficient in service long continued. The secret is that the practical receiving telephone a certain amount of magnetic strength is required to polarize an electro-magnet, and as this magnet, then, represents a certain weight in steel, for a certain weight to be installed wire and iron which an electro-magnet is substituted for a permanent magnet) it has been found that carrying this weight on one's head interferes with one's comfort and health. It has been tried to substitute steel springs for the ordinary bar steel, and to so adjust as that they will exert pressure only to the sides of the head; but in such steel springs the magnetism is not permanent, and rapidly loses its strength. In his invention, Mr. Berliner discovers that by removing from the receiving tube, phone, and making the former part of the station, a features near the operator's ear, so that the remaining parts of the telephone—viz., the sounding-chamber, electro-magnet, and diaphragm—which are arranged to that are used in the magnetic field. In the figure the core of the



electro-magnet is seen fixed to the iron plate *J G* is another plate forming a holder, and to this plate the strap is attached. A cushion H of soft material is preferably glued to the back of the telephone, in order to prevent any noise in case the operator should strike against the telephone against the magnet N, which is held to a spring by a screw and nut, thus permitting the magnet to yield in case the operator should strike it, while the height can also be adjusted. It is evident from the above description that the requirements sought after in the invention are perfectly met—viz., a receiving telephone of light weight is strapped to the operator's ear, and magnetism of maintained strength is supplied without additional weight to the operator's head or discomfort of any kind. The line wires are connected to the binding posts D D in the usual manner.

THE JAVA EARTHQUAKE AND THE TELEPHONE.

It has been before observed that earthquake and volcanic eruptions have a disturbing effect on telegraph lines, setting up powerful earth currents in them, and rendering communication difficult. Recent advices from Mr. Worsnop, the superintendent of the Oriental Telephone Company at Singapore, also announce the fact that during the recent earthquake of Java and eruptions of the volcano of Krakatoa, the telephone lines in Singapore were unworkable owing to a deafening roar which drowned the voice. Only shouting could be heard on the lines because of the noise, which resembled that of a distant waterfall. On one line, in which a small subterranean cable about a mile in length from Singapore to Johore formed part of the circuit, the roar was mingled with occasional reports like that of a pistol. The volcano of Krakatoa is situated on the island of that name in the Straits of Sunda, between the southern end of Sumatra and the northern end of Java. It is about 600 miles south of Singapore with a corner of Sumatra intervening. The noises in question were heard during the eruption on August 27th last, but can hardly be considered as due to acoustical effects, notwithstanding the violence of the eruption. The cause is perhaps rather to be sought in the disturbance of the terrestrial magnetic field or in the electric state of the atmosphere, by the hurtful explosions. The first signs of the eruption were noticed on August 20, when shocks or earthquakes were felt as far as Batavia, and a fine rain began to fall, mingled with reddish stones. The waters of the straits then began to boil, their temperature rising some 20 degr. C., and great blocks of lava fell on the neighbouring coasts of Java and Sumatra. On the 26th the earthquakes became more pronounced, and at most the Malay-Mere, the largest of the craters, began to break forth into flame. The Gounung-Gunter and the number craters then joined in, until forty-five neighbouring craters were in action. Torrents of sulphurous mud and lava burst out, and at intervals tremendous explosions were heard, followed by showers of stone and ashes. The clouds were heavily charged with electricity, and lightnings played vividly. Next day the shocks and eruptions increased, and were accompanied by tidal waves. The island of Krakatoa entirely disappeared, and the destruction was frightful, as the newspaper reports have already testified.

The Providence Telephone Company.

WHAT EFFICIENT MANAGEMENT HAS ACCOMPLISHED IN THREE YEARS.

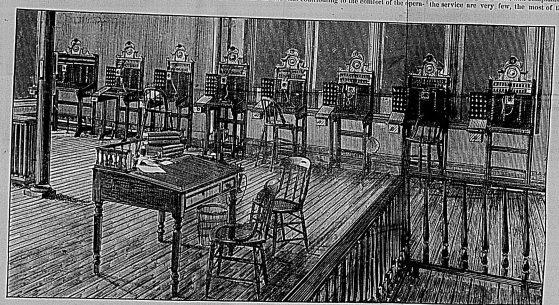
The operating-room of the Providence Telephone Exchange, one side of which we illustrate herewith, was referred to briefly some time since in these columns, but on account of the excellent manner of its construction, and the general management of the business, which has been so remarkably successful, we have thought it important and interesting to our readers to illustrate the description given so fully in our issue to day.

The rapid growth of the telephone business in the territory of the Providence Telephone Company is shown by the following statement of the manner of telephones in use at their various exchanges in the several years which have elapsed since the organization of the present company:

Providence.	Total in all other towns.	Total in Providence and other towns.
Number of telephones rented Aug. 2, 1880	641	802
Number of telephones rented Jan. 1, 1881	857	1,072
Number of telephones rented Jan. 1, 1882	1,661	1,541
Number of telephones rented Jan. 1, 1883	1,482	2,136
Number of telephones rented April 1, 1883	1,725	2,480

The increase of the present year bids fair to continue at the rate of about one hundred per month. The exchanges operated by the Providence company are located as follows: the principal office in Providence City, in which about sixteen hundred subscribers are connected directly with this one room; one branch office in Olneyville, some two miles in the suburbs, where about one hundred residences are connected; Pawtucket, Woonsocket, Attleboro, North Attleboro, Warren, Bristol, Pascoag, and Westerly. The territory within fifteen miles of Providence, which includes all of the above-mentioned places, with the exception of Pascoag and Westerly, is considered as a part of the regular Providence exchange, the offices being worked as branch offices, and nowhere territorial charges made for communication between any of them. As Providence is the business center of this locality, of course the work upon the trunk lines is very large, in some of the offices exceeding the local communications; and the number of communications in the Providence office alone average about nine thousand a day.

The operating-room of the Providence main office was established in the present year of '81, and an entirely novel system of making connections between the switch boards adopted. The peculiar features of which are drawing a portion of the work upon the subscribers by, in most cases, calling them by give their order (wire, doing away with an communication between operators or the necessity of message boys around the room; which system has worked very satisfactorily, as may be judged from the fact that it has not been found necessary to modify it in any way with an increase of the number of subscribers from the hundred, the number at the time the system was adopted, to about seventeen hundred, the same room, which is the number at the present day.



OPERATING ROOM, PROVIDENCE TELEPHONE EXCHANGE. (VIEW OF ONE SIDE ONLY.)

Other novel appliances have been added from time to time, as experience has found them desirable, in the main and branch offices. One important peculiarity is that the central office telephones are invariably looped into the lines under all circumstances, so that no interference is given to the parties conversing if the central office connects into the circuit for any purpose whatever. In the rapid increase of long-distance telephoning this is a very essential feature, and one which will undoubtedly be found indispensable in every large telephone exchange.

Young ladies are employed in the operating rooms, which are provided with many novelties contributing to the comfort of the operators, and speed in making connections from switch to switch. A retiring-room, to be used during meal hours, &c., for the ladies, away from the operating room of the main office, which is furnished elegantly, and adorned with fine pictures and flowers, while upon the tables are found the best periodicals of the day as soon as they are issued. In fact every endeavor has been made by the management of the operating department to render the service rendered by the first-class, and, while holding the operators to a strict performance of their duties, to aid them in all ways which may tend to their comfort and good nature.

The company have about two thousand miles of line in operation, and a number of cables of thirty to fifty wires each, all constructed in the most thorough manner, and are constantly adding to the property in this direction, particularly in the use of cables extend from the central offices within a quarter of a mile. No movement has been made yet in the direction of underground lines, although there has been considerable discussion made both in the city and State governments on the subject. The lines entering the exchanges are of all descriptions known to telephone people,—special wires, two party wires, four party, bi-polar, Bliss clock lines, carrier individual bells, and a few battery lines. A good evidence of the advantage of the system in vogue in this exchange is the fact that these various classes of lines are worked together in harmony, and to the satisfaction of subscribers. Connections average about a half a minute in regular work, and complaints of the service are very few, the most of them resulting from disarrangement of the instruments of the subscribers.

The original capital stock of this company was $75,000, which has been increased to $150,000, as required for the development of the business. The value $50 per share; but few transfers have been made; the price having steadily advanced from $10 in 1881 to over $250 per share, where it now stands firm. Most of the stock is held in Providence, and the president and board of directors are prominent business men of Providence and vicinity.

We attribute the great success attained by this company to the energetic and able management of its general superintendent, Mr. Duxbury, and his assistants Messrs. Gardner and White, who are too well known as old-time telegraphers and electricians to need any praise at our hands.

The officers of the company and board of directors we give herewith: Hon. Henry Howard, president; Henry C. Comstock, vice-president; Charles W. Harnett, secretary and treasurer; J. W. Duxbury, general superintendent; F. H. Gardner, A. C. White, assistant superintendents; Henry Howard, Henry G. Russell, Henry C. Comstock, R. G. Hazard, Jr., Charles Bradley, H. M. Lamed, James H. Chace, H. F. Burrows, C. H. Greene, William H. Pope, directors.

The Blake Transmitter.

reported discussed at the same institution, Subscribers of the stage, the operator could and a careful adjustment showed this position to be a very favorable one for distinct trans- mission, but in some hundreds of later experiments no more satisfactory results were ever been secured. The battery was two cells of gravity, kept on closed circuit until it attained a maximum working strength, and then placed within a few feet of the transmitter. On connecting with the line the effect was most gratifying. The footsteps of the soloists, as they came forward to their places, their parts in the programme, whether in heavy or subdued, the harmony of the co- rus-ses, dividing itself to the ear of a near listener, as with the theatrical experiments, it was found that the suspension of the trans- mitter in any manner which cut off the reinforcement of the vibrations of sonorous bodies weakened the results. Often this would not be noted on exchange lines, which a con- nection with a wire of 20 to 50 miles would instantly detect the lowering of the electro- motive force of the current, or the reduction of the amplitude of the vibrations. A small ornamental bracket, fashioned to correspond with the style of the desk and placed back of the opposite the speaker in front of the Blake, when connected rigidly with the desk and the transmitter, shouted the clearest and most far-reaching tone. Thus disposed, with two cells of gravity battery at hand, the short line from the switch-board grounded on a gas-pipe in the church, has repeatedly been at one time connected satisfactorily with Boston, Salem and Gloucester on the north, and Taunton and Fall River on the south, in- cluding at least six switch-boards and 120 miles of lines, with other grounds at the ex- tremes. Operators at these offices could hardly be made to believe that the speaker was four feet and the choir eighty feet from the transmitter, while in favorable weather they could hear every word spoken in the pulpit from invocation to benediction, and follow all the choral selections from the further end of the church.

It is a lamentable fact that privileges of this kind encourage extreme laziness on Sun- day morning, and probably influence some careless ones to lie on the lounge at home, with telephone at their ears, during the ser- vices of the sanctuary, when they are physi- cally able to lend their bodily presence to the inspiration of its exercises.

When confined to the short wires of a small exchange, the Blake gives, if possible, still more remarkable evidence of its ef- ficiency. As many as fifteen circuits, of three to six subscribers each, have been been attached, to one church, with no great reduc- tion in volume of tone, except on an occa- sional wire of extra resistance. If a change of preachers at the First Congregational Church displeased my hearer, it was an easy matter to signal the office and ask for a connection with the Central Methodist.

The microphone is one of the most remark- able of the many instruments which science has given us. The delicate action of its most perfect and practical representative, the Blake Transmitter, in responding to faint and distant sounds, has often been the theme of remark, and perhaps no illustration will more fully exemplify its varied application than its use in churches and public halls.

It is with no idea of presuming to offer any new suggestion to the veteran telephone man- ager that these few reminiscences are sent to the Review. But if this brief outline of early experiments and later successes should catch the eye of a pioneer in some yet unin- vaded territory, the record of four years ago of sound may stimulate him to interest and instruct his few subscribers, and illustrate in a very attractive way the capabilities of this most marvelous invention, the speaking telephone.

Early in 1879, while Blake's improved mi- crophone was yet very young, the writer secured the first specimen which was loaned from the Boston factory, at 109 Court street, for public-hall experiment. Its power was so little understood that no specific instructions accompanied it beyond the simple matters of battery and line connection. In form it was somewhat longer and larger than the standard pattern afterward adopted, with a heavier induction coil, and its adjusting screw was brought through the base, facilitating ready modification without opening. It is probable that but very few of this variety were ever made, as none appear to have been supplied to the exchanges of that date.

A few experiments showed not only the superior powers of loud and distinct trans- mission now so well known throughout the civilized world, but also the wonderful deli- cacy of action by which faint sound vibra- tions from a distance might be caught up and reproduced miles away. At that time a Tasmian musician was rehearsing a Brockton chorus for the cantata of "Queen Esther," and the idea of obtaining an echo of the hall entertainment at the residences of a dozen subscribers at once suggested itself as pecu- liarly a valuable assistant was secured, in the person of C. E. Austin, of Peterboro, then as now in the employ of L. W. Clarke, the well-known electrician of that city. Though so intimately acquainted with Bell's instruments as to be mentioned by Prescott as one of the pioneers in experiments with receivers, Mr. Austin had never before seen a Blake. After some exhibition, the "trans- mitter was attached to a device known in theatrical men as the "rain-box," in this case suspended midway by an iron axis about twenty feet above the stage, and fastened at an angle of forty-five degrees. The mouth- piece of the little talking machine thus

Thus all reasonable requirements were grat- ified. A gravity battery, if left open on cir- cuit, or closed on a high resistance, lasted for two or three months without renewal, and in many cases the increase of internal resistance has seemed to be far from disadvantageous.

In some few experiments the past year one and occasionally two cups of "prima" battery have been used to advantage, and with their high intensity have been found to show an unexpected constancy. Even when left on closed circuit for three hours, they re- cover in two or three days, and so last for some months. The main difficulty seems to be the rapidification of the current on the car- bon surface, necessitating a frequent use of a fine abrasive, and careful polishing with plumbago, preferably with finely-powdered stove blacking, slightly moistened.

The tone of such instruments, as well as of those constantly used for extra territorial lines, is also deepened and improved by an Edison induction coil, with a secondary re- sistance of about one hundred ohms in place of the regular Blake coil. The recent ex- periments in long-distance transmission indi- cate that practical improvement is to be looked for not alone in new and more power- ful microphones, and perhaps not as much in these as in lines of high conductivity, like the copper wires of the postal telegraph, and in such connections as will secure the strong- est action of our present instruments. The Blake transmitter, with its carbon carefully polished with plumbago, secured either di- rectly or by a wooden bracket to a wooden partition, reinforced by an Edison coil and retained by a deep mercurial cup, will now prove a serviceable instrument on good lines of fifty to one hundred miles, while a less careful arrangement will limit its usefulness to less than one-half the distance.

A word regarding the use of special de- vices for entertainments. E. F. Greenfield, well known as the former superintendent at the Bell Exchange in New York, now with the Edison Electric Illuminating Company, secured very good results in sending music from one transmitter by connecting the primaries of two or more coils in multiple, with one battery and carbon, and attaching two circuits to the secondary of each coil. Thus with two coils, four lines might be connected as two, with grounds only at their remote ends, and without possibility of in- terference.

The article published in your columns some time ago by T. D. Lockwood, refer- ring very kindly to some little tests here, suggested a trial of transmitters for music. A block-walnut board three feet square and one-quarter inch in thickness, was suspended over a piano by heavy electric cords from the ceiling. Three transmitters were fixed near its center, their carbons connected by long spirals to the primaries of three Edison coils a few feet away, and each with two pairs of pilon battery. By a combination of small jacks on the base holding the coils, the secondaries of any or all combined could be coupled instantly in series or in multiple arc, and careful tests showed a decided advant- age in the use of more than one, and the loudest tones were secured by the three in multiple. Unfortunately the twenty-five mile line to Boston was heavily grounded, and the connection with Manager Manson's residence in Chelsea for mutual pleasure failed of complete success, but the results were undoubtedly the best ever attained here.

Now, will not some of your many tele- phone readers follow this long and gossy talk with sketches of their own experi- ments?

OCCASIONAL.

Brockton, Mass., April 28, 1883.

Underground Telephone Wires.—In an article in a late issue of the *Popular Science Monthly*, by Dr. W. W. Jacques, the author says:

"The American Bell Telephone Company has recently constructed two short lines of underground wires in business sections of Boston, and those give us excellent data from which to judge of the extent of the econ- omy, practicability and the expense of putting all wires underground. We have seen and in Paris the retardation and induction are both almost entirely done away with and twisted wires in metallic circuit. It is necessary that all of the wires be in metallic circuit; for, if a metallic circuit be connected with a single-line circuit, the disturbances are not removed. If a subscriber in one city wishes to talk with a subscriber in a neighboring city, both cities must have metallic circuit systems and metallic circuit between the two cities. As the two lines constructed in Boston are short, only about one-quarter of a mile each, it was deemed best to use single- line circuits, hoping that the induction and retardation on so short lines would not be serious. The system is constructed as follows: Eight wrought-iron pipes, 2 inches in diameter, are laid side by side in two rows, about 4 feet below the surface. At each street corner, is built a brick chamber, large enough to admit a man, and with a cover flush with the street. The cables, of which several kinds are in use, run out from the basement of the central office through these pipes and up the side of buildings to roofs, from which they spread out to the subscribers by means of ordinary overhead lines. Conversation over these lines is not so easily carried on as by means of overhead wires, and it is frequently possible to overhear a conversation. This pro- hibits further extension of the single-wire system underground, for tech- nical reasons. The cost of the piping and chambers, in round numbers, $50,000 a mile, and those pipes are intended to accommodate one thou- sand wires. The cost of the cables is from $60 to $100 a mile for each circuit, according to the kind of cable used. In round numbers, we may estimate the total cost for one thousand wires at $100,000 a mile, or $100 a mile per circuit. The cost of piping and chambers would be nearly as great for one hundred circuits as for one thousand, as the cost of cham- bers and the labor of excavating and filling would be the same; and that the cost for one hundred wires may be estimated at $50,000 a mile, or $500 a mile per conductor. The cost per conductor thus increases enor- mously as the number of conductors diminishes, so that it would be clearly impossible to follow out the wires of an exchange system in all their bifurcations."

INVENTION OF THE TELEPHONE.

Counsel for the People's Telephone Company, of New York, filed in the patent office at Washington, on the 25th ult., a brief, giving their side of the application of Daniel Drawbaugh for a patent for a telephone. It contains the following statements: The first telephone patent was granted in 1876, and since then the patents of Gray, Edison and Bell; with the Blake (transmitter), have been consolidated into what is known as the Bell Associated Telephone Company. The stock was originally sold at $50 a share; and afterward was quoted and sold as high as $1,000 a share. The stock has been watered since, and the company is now in the market borrowing money. No dividend has ever been paid. The company has made and is making immense sums of money; but all this and the money it is borrowing has gone into the plant, which rapidly increases in extent and value, and the original stock is probably now worth $1,000 a share or more. It spent a large sum of money, too, in buying patents for improvements on the instruments. This is the only existing telephone in operation. The People's Telephone Company, against which the Bell company brought suit in the United States Circuit Court in New York, is composed of a number of gentlemen who have formed a company and purchased the interest of Mr. Daniel Drawbaugh, of Eberly's Mills, Cumberland County, Pa. Mr. Drawbaugh, as is proved by about 100 living witnesses, neighbors and others, invented the first and in practical operation a speaking telephone between 1865-1-72-73, the result of no acknowledged invention of his in 1865. He was very poor, in debt, with a large and helpless family depending upon him for support, and was, from this cause, unable to patent or cover his invention, or manufacture or introduce it, and is claimed that he never abandoned his claim to his invention to anybody. The men composing the People's Telephone Company bought his claim and some patents that completed the instrument, and made application for Mr. Drawbaugh in 1880 and prosecuted to furnish telephones for about one-third the cost of the Bell telephone. Presuming upon the validity of their claim, they pooled the company's stock; spent about $50,000 and started in the beginning of the work with plenty of capital to go ahead on. The originators were wild with great hopes; but the Bell company caused an injunction and suit. The best of lawyers were engaged on both sides, and the Drawbaugh patent was rejected about two months ago on the grounds that patents had been granted to others, and printed descriptions published by others prior to the date of Drawbaugh's application and that telephones were in use more than two years before Mr. Drawbaugh's application. The hearing proceedings now comes before Judges of to-day, and is presented on three specific points of law: First, the defendants claim that an application is not barred by a patent granted, or description published, more than two years before the application, provided the applicant's invention was prior to the granting or printed publication; second, that the application of the first inventor is not barred by a two years' public use or sale of another man's subsequent invention, without the consent, or allowance of the first inventor, except under such circumstances as to prove a voluntary abandonment of the invention to the public; third, that the Commissioners of Patents cannot lawfully allow anybody to contest the application except by interference proceedings. These points are upheld by high legal authority and pointed judicial decisions, and the belief is that either Drawbaugh will get a patent or the invention be given to the public.

BERLINER'S TELEPHONE TRANSMITTER.

THE principal feature of the invention which has been patented by Mr. E. Berliner of Boston, Mass., is the disposition of the carbon contact surfaces, one being attached to the diaphragm and the other being supported by a metal socket attached to a hinged plate secured to an arm that projects from the back of the mouthpiece downward over the diaphragm. This arrangement of the double purpose of supporting the free carbon electrode, and clamping the diaphragm in its place

against the back of the iron mouthpiece. The diaphragm is bound around the edges with soft rubber, and is separated from the mouthpiece by a ring of the same. The iron mouthpiece is hinged to a casting from which a circular box which contains the induction coil and carries the binding screws for the battery line, and receiving wires. To this frame of the induction coil is attached a plate connected with the battery wire, and carrying a spring having in its free end a screw which presses against a spring connected with the centre of the diaphragm. The spring is of such a degree as well as a conductor through which the current passes to the carbon electrode in the centre of the diaphragm. The terminal current colors at one of the binding screws, passes through the primary wire of the induction coil, through a spring and carbon electrode at the centre of the diaphragm, through the carbon electrode, metallic mouthpiece and the hinge, and passes through a binding screw to the battery. The variation of the current in the secondary circuit occurs at the contact of the two carbon electrodes, the contact being formed by the vibrations of the diaphragm, started to the diaphragm. When the receiver is used as a transmitter, the spring presses the resistant carbon electrode is made harmless by the free resistance in the local current and to amplify the electrical undulations. The terminals of the secondary wire of the induction coil are connected with the two remaining binding screws, which are connected, one with the ground and the other with the line. In connection with this transmitter Berliner connected with this transmitter many of the usual character. It will operate very well, but the well known forms of receiver, and is easily managed and thoroughly efficient. The transmitter has been well introduced, and large numbers of them are, according to the *Scientific American*, in use in this country. They have been adopted in several of the leading German railways, and are extensively used in the German postal service.

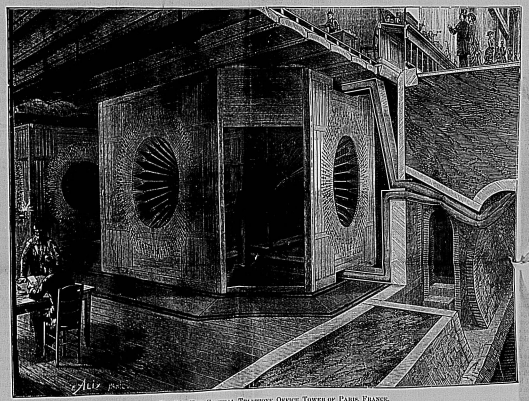
The Telephone Central Office of Paris.

(*Continued.*)

(*Translated for the* REVIEW *from La Lumière Electrique.*)

In our last article we have given an idea of the organization of the Parisian telephone system, and the manner in which it was connected with the different central offices. In this article we shall enter into more details with the same end in view, taking as an example the central office of the Avenue de l'Opera, one-half of the collecting sewer, which runs throughout the whole length of the Avenue de l'Opera under the sidewalks, and the small branch sewer, which, connects the house at No. 27, of that street with that sewer. The walls of the sewer are supposed to be removed in front of the spectator, in order to expose to view the rosace chamber; and above the sewer and the ground covers it one can see the sidewalk of the Avenue de l'Opera, where some pedestrians are represented as passing. One can even distinguish the show-window of the store



(FIG. 2.)—THE CENTRAL TELEPHONE OFFICE TOWER OF PARIS, FRANCE.

There are, as will be observed, two rosace chambers. The first, which is in front, is appropriated to the wires of the subscribers who are in direct communication with the office; the second is appropriated to the auxiliary wires, which, as we stated in our preceding article, connect with all the central offices, which are in this manner placed in communication with each other. The tube which is suspended from the vault of the ceiling of the room is used for the ventilation of the whole office. The wires which to the number of 2,000, end at the office of the Avenue de L'Opera, the most important of all; and for greater clearness in our description we shall follow the wires from the sewer, where they are united in bundles, up to the switches of the central office, where they are distributed, to constitute the private circuits of the different subscribers.

To render our description more clear, we give, in Fig. 1, which represents the rosace chamber of the central office in the Avenue de L'Opera, the section of a portion of the street at the place where the wires enter the office. Thus we see at the right of the figure which forms the entrance to the office, and where are exposed for sale the telephonic apparatus manufactured and sold by the company. The interior of the store, even, may be partly distinguished in the upper part of the figure, above the rosace chamber, which is really one of the cellars of the house. The door, which will be noticed in the branch sewer, corresponds in position to a glazed opening placed in the sidewalk, and consequently allows access to the sewer from the outside, just at the point where the wires enter the office.

Avenue de L'Opera, are enclosed, as we have mentioned, by groups of fourteen in tubes of lead, which of themselves constitute distinct bundles, and these bundles, in entering the office, are separated into the cables of which they are composed in several parallel lines, which correspond to ranges of openings in a large bronze plate, through which all the cables pass by insulators. On leaving these openings the cables are again connected in two large bundles, which enter by two wooden conduits placed at the upper and lower parts of the room in the interior of the rosace chamber. There they are separated, and the lead-covered cables are distributed around circular openings made on the few sides of each chamber, and to which has been given the appellation of rosaces. Being fixed on the interior side of these chambers, each cable is stripped of its lead covering, and the wires which were there enclosed are separated by couples of two, forming seven two-wire lines, which pass through the partition, and are attached exteriorly to double screw-posts placed all around the rosace. To easily distinguish the wires belonging to the same circuit, they are covered with braid of the same color, but each couple is of a different color, so that each cable contains of seven couples of wires of seven different colors, which are always placed in the same order around the rosace.

On a larger circle are placed little plates of horn on which are engraved the names of the subscribers, and on a still larger circle are fixed other tickets showing the number of each cable.

From each screw-post there start two wires covered with gutta-

SCIENCE;

THE PHOTOPHONE.

Mr. Alexander Graham Bell, whose contributions to electric science have been recognized at home and abroad to their fullest value, has written a paper on his latest invention, the Photophone, which we reproduce and abundantly illustrate.

It is a beautiful application of the telephone to the registration of the mechanical action of electricity set in motion by light; but it is not (as the world was led to suppose by some ill informed journalist) a method of transmuting light pulsations into electrical ones, and then changing these back again into light. A beam of light is reflected upon a mirror diaphragm, which is set in motion by the voice or otherwise; the concentrated ray is then reflected so as to affect a piece of selenium in a telephonic circuit, which, by its varying conductivity, acts intermittently on the diaphragm of the telephone, and thus in the usual way reproduces the sound. The instrument is simplicity itself, but the results are of the highest popular and scientific interest.

That it is possible for even the ray of a star to produce a mechanical effect, was demonstrated when Edison used his Tasimeter for measuring the waves of radiant energy of Vega. We thought Bell had solved the problem, upon which Edison was at work when he became interested in the perfection of his electric light, but our hope has not been realized. The subject, however, is one of extreme interest, and it is not strange for the discoverers of the two telephonic systems to be simultaneously engaged in solving the natural corollary to their great propositions. But Edison has an advantage in the pursuit. His employment of the varying electrical conductivity of carbon allows him to introduce any amount of reserve power for mechanical purposes.

It is much to be regretted that Edison can not find leisure from the practical applications of his science to turn his attention to those problems which he is so eminently capable of solving. We vividly recall some experiments in this direction which he carried out during the Spring of 1878, while on a visit to his laboratory at Menlo Park. He allowed a beam of light to fall on the surface of a diaphragm connected with his carbon button, in the hope that by a surface and molecular action, it would be possible to transmit its motion to a receiving diaphragm, where a similar molecular tension would result in the reproduction of the original vibrations. A faint halo is said occasionally to have surrounded the diaphragm. We could not but believe this due to the excited imagination of Mr. Edison, for at the time he was enthusiastically engaged in testing the wondrous capacity of the tasimeter, which he was soon to use in eclipse observations on the Draper expedition.

He also tried to observe the effect of a beam acting on the diaphragm of a phonograph, whose cylinder revolved at enormous speed, hoping a line of phosphorescence might arise from the tinfoil where it came in contact with the needle. Mr. Edison said he employed the direct action of the light (in the last case), in preference to using electricity as a medium for it, because he feared there existed a difference between the vibratory periods of light and electricity, although their velocity was nearly the same. For a similar reason he sought to realize the instantaneous transmission of light by using his motograph, in preference to the magnetic telephone which for this purpose is valueless, owing to the time required to charge and discharge the iron core. But the most interesting of these experiments is to come. He threw a beam of lamp light on a small mirror, fastened to a tuning fork, and reflected a ray upon a strip of hard rubber in the tasimeter, the button of the latter being in circuit with a telephone and battery. On setting the fork in motion, the Lissajous figure caused a movement of the rod, which resulted in the reproduction of the musical note.

But all these pretty experiments are but introductory to the more subtile question, how to translate light through other forms of motion back into light. We wish a hearty rivalry between the two discoverers; for Messrs. Bell and Edison will find the fields of science (like those of trade) yield best fruit when fertilized by competition.

Swiss Telephone Systems.

In the Telephonic Review, which we published in the number of July 14th last of this paper, we have sketched a few of the particulars relating to the state of telephony in Switzerland, and we even went so far as entering into some details on the organization of the lines which are used in that kind of telegraphy. To-day we are going to complete our statement by examining, according to Mr. Bothen's report, the organization of the central offices.

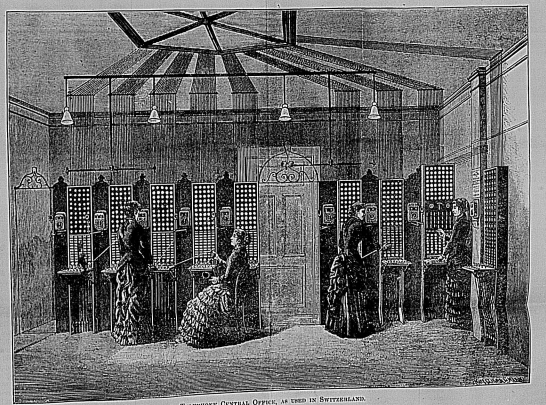
As it has been seen in the article just referred to, the telephone lines in Switzerland are formed of aerial (elevated) wires, which cross over the houses, supported every hundred yards in a suitable way by iron horses. Such horses are placed astride on the apex of the pointed roofs, and generally provided with six horizontal cross-bars of iron, upon which are screwed, from six to eight in number, small insulators, in porcelain, with a single bell. By this system the iron horses simply rest on the roof without any fastening, that permits to remove them in the most easy manner. Such distance of 100 yards is not fixed by any regulations, and, in fact, it often happens to be reduced to thirty yards or prolonged to 900 yards, according to the possibility of selecting convenient resting points.

These horses are made of buttressed corner irons varying in size from 2 to 2½ inches in width and from four to five-sixteenth of an inch thick, and the cross-bars for the insulators are made of T irons, having 1¼ to 2 inches in width, by two three to five-sixteenths of an inch thick. Their weight may be somewhat over 1,000 pounds. The two feet of the two upright bars are consolidated together by means of small cross-ties. The horse, moreover, may be placed in a parallel line, normally or obliquely, with the ridge of the roof according to the direction of the line wires; but a matter of disposition in the placing of the cross-bars on the base irons straddled on the ridge of the roof, and the number of wires which they bear varies from 36 to 60. In order to avoid the breakage of the tiles and slates by these iron horses, pads, made of tarred cloth and filled up with mineral wool, are placed between their feet and the roof; and further, they are maintained in a vertical position by wire strands fastened on the rafters of the roof. The space between the wires on the horses varies, in proportion of the span length, from about 12 to 20 inches, which latter distance corresponds to a span of 200 yards. The size of the horse consequently varies not only according to the number of wires they bear, but also in proportion to the length of the span from one horse to another, and they must always be placed squarely with the direction of the wires in the longer span. The wire adopted is, as has been seen, galvanized cast steel wire, having a diameter of one-sixteenth of an inch; it can bear a traction of 800 to 900 pounds, capable of being strongly twisted, and does not stretch more than two per cent. at the maximum for the highest tractions, but it offers a resistance of 90 to 65 ohms per kilometer (about three-fifths mile).

The setting up of that wire is delicate, because it should not be stretched, and to unroll the same, reels of a special kind must be used. Weldings are made with very soft iron wire, about ¼ of an inch in diameter, and must be placed within 10 yards of the points of support. Finally, the maximum tension to be given to the wires must never be over 80 kilogrammes (about 175 pounds), on account of the rigor of the climate.

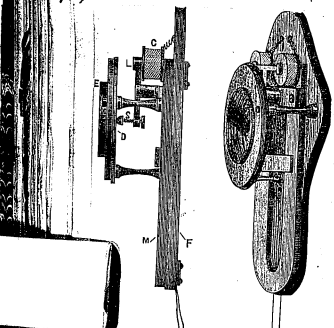
The insulators are made of small porcelain cylinders, thinned in the middle, and presenting at their lower part a fuller-shallow cavity, at the bottom of which an excavation is made, provided with a screw thread, in which the support of the apparatus is fastened.

By means of repeated divisions in the series of the telephonic networks, we arrive at lighter lines with a limited number of wires, and then the points of support become more simple; instead of having two upright bars there is only one, which is fastened on the beams and the wall gables. When lines fall, their place is supplied, with posts like those of the telegraphic lines, but in such cases the insulators become different and take the shape of those which are used on the telegraphic lines and where the distance becomes considerable, the steel wire is replaced with



TELEPHONE CENTRAL OFFICE, AS USED IN SWITZERLAND.

Electrical Review, Sept. 24, 1883.



THE "HAMMER" TELEPHONE.

The "Hammer" Telephone of M. De Locht-Labye.

The London *Electrical Review* says: This telephone constitutes, it is claimed, quite a new and original arrangement for transmitting speech. It can be so, up to the present, almost universally supposed that for the telephonic reproduction of speech the employment of continuous undulatory currents is indispensable. Professor Bell is looked upon as the originator of this theory, and his great influence in the scientific world, and especially his invention of the telephone with stretched membrane or flexible disc as an application of this theory, supported him, and for the time silenced all contradiction.

It is claimed for the De Locht-Labye telephone that it has no flexible organ, no parts susceptible of the undulatory movements which are, as Bell said, for reproduction of the shape of the sound waves of the air.

We will explain, in a few words, the construction of the receiving apparatus, which we have shown in perspective and in sectional elevation in the accompanying sketch. A horseshoe magnet, *M*, has at its poles two little cores of soft iron, on which are placed coils *C*, of insulated copper wire. This magnet is fixed immovably to a wooden frame *F*, which serves as a support to the whole apparatus. In front of the poles of the magnet, and at a very little distance from them, although this distance can very easily be regulated, as we shall soon see, is an armature, consisting of a thick inflexible bar of iron. This bar forms part of a fixed lever, *L*, moving freely on a fixed axle, placed on a little rod of copper, brass, or any other material. As we see, by its position, the armature lever is thus apparently a free reel, and as in itself, in no way of the nature of a flexible disc. It is only fixed to the support by its axis, and is not connected with any membrane or other organ. It is terminated by a little hammer of metal, or some other substance, fixed to the extremity of a regulating screw, *S*. This hammer, in its normal position, rests upon a thick, rigid, inflexible piece of wood, glass, ebonite, or any other material, *B*, of any shape whatever, but which, for the sake of symmetry, has been made cylindrical in the apparatus, and to which is fixed an ear-piece, *E*. We must observe that, as the inventor, who is now in London, has shown us, the ear-piece may form the part which supports the hammer, which shows, he thinks, that in no way is it of the nature of a membrane or flexible disc. The position of the armature lever is determined by the magnetic attraction of the poles of the magnet, the effect of which is counterbalanced by the reaction of the fixed portion supporting the hammer which terminates the lever. By the help of the screw which carries this hammer, we can easily regulate the distance between the poles of the magnet and the armature, so as to obtain the maximum telephonic effect.

These are the essential characteristics of the De Locht-Labye telephone.

Bell, in his original specification (Morgan-Brown patent, June 9, 1877), made the following statement:

"In all previous systems of telegraphy, messages have been received either by means of chemical changes produced by the action of the electrical current, as in the various forms of automatic and autographical telegraphs, or by means of the mechanical movement of a portion of the receiving instrument, operating to produce a visible signal, as in needle telegraphs, a mark upon paper, or other material, as in printing telegraphs, or a sound, as in the Morse system."

He immediately adds:

"Until there and all other plans it has been found difficult, if not impossible, to distinguish between more than four messages transmitted simultaneously over the same circuit, two in each direction," and as Mr. Webster, Q.C., for the United Telephone Company (Limited), said, in his pleading:

"In no single case could it be pretended that Professor Bell intended his instrument to act as reeds."

Now, in the De Locht-Labye telephone, it is claimed that the armature is a free reed. It is arranged in a manner that reminds one of the armature of the Morse telegraph, or, better still, of that of the Hughes printing telegraph, and, nevertheless, the transmission of sounds of all kinds and of speech is effected with complete success.

Numerous experiments have been made by experts with the instrument, of which we give a sketch, and it is declared unanimously that it works at least as well as the Bell telephone, as regards clearness and loudness of sound.

The inventor is convinced that he can make his instruments effect far more, and that, consequently, his results will considerably exceed those of the Bell telephone, so that his telephone can be employed for very long distances.

This, in order to allow the essential points of difference between the De Locht-Labye and Bell telephones, from a mechanical point of view, one might say: That the Bell telephone is characterized by the combination of a magnet, provided with a coil or coils at its ends or poles, and a thin and flexible plate of iron or other metal, surrounded or fixed round its edge, over all the flat circumference near and at right angles to the magnetic pole; whereas the De Locht-Labye telephone is characterized by the combination of a magnet provided with coils at its poles, with a right armature of soft iron or steel, turning freely on a fixed reel or axle, and terminated by a hammer striking against a rigid inflexible body of wood, ebonite, or any other substance. Du Locht-Labye's hammer telephone can work under the same conditions as Bell's flexible disc telephone—*i.e.*, it can be employed in the double function of Bell's transmitter and receiver.

It now remains for us to explain clearly the inventor's idea of the working of the telephone as a transmitter. Every sound wave, on reaching the rigid part, imparts to it a sudden shock, which it transmits instantaneously to the hammer. The latter then separates from the rigid part, and gives rise to a slight movement, the extent of which is in proportion to the intensity of the shock—*i.e.*, to the intensity of the sound. But immediately the magnetic attraction acting continuously and with great force upon the armature, stops the movement of the armature lever, and restores it to its original position so that the movable part can receive a fresh sound shock.

These sudden movements (of the lever) of the armature before the poles of the magnet, engender in the coils covering the poles instantaneous electric currents, equal in number to the movements of the armature, and therefore to the sound shocks. These instantaneous currents, passing through the line, on reaching the end of it, are received by a similar apparatus.

The working of the telephone as receiver is then easily explained. The intermittent instantaneous currents, of variable force and duration, traversing the coils of the telephone, says the inventor, magnetize and demagnetize at each emission. If the magnetizing current is produced first, it is powerless to produce the movement of the armature lever, on account of the reaction of the poles. We leave on which the hammer rests. The demagnetizing current alone is capable of drawing back the armature, and consequently of detaching the hammer from the part on which it rests. The current being instantaneous, the movement is instantly arrested by the continuous action of the magnetic attraction, which restores the armature to its original position, and forces the hammer to strike against the block. It is this shock which produces the sound at the receiver. For each emission of the current there is one shock, and only one. Its force is proportionate to the energy of the current, and therefore to that of the sound shock at the transmitting telephone.

All these movements are sudden, and can in no way possess a duration equal to that of a sound wave or air. The armature and the hammer are, therefore, nearly always in a position of rest, ready to receive new shocks and to transmit them to a distance.

The telephonic transmission of speech, then, according to M. De Locht-Labye, evidently results from a series of shocks, and the bellows from the working of this apparatus that, in order for speech and any kind of sound to be transmitted and reproduced, there must first be an equal number of sound shocks. Little movements of the armature in the transmitter, and consequently of intermittent instantaneous currents of magnetism and demagnetization causing so many sudden movements of the armature at the receiver, and therefore so many blows of the hammer on the fixed part. There must be an exact interval of equal duration between two successive sound shocks, and finally the intensities of all these forces, the transformations of which reproduce the sound, must be in direct proportion to one another.

This is the conclusion to which M. De Locht-Labye's hammer telephone directly leads him.

We think that the description of this apparatus, and the explanations that we have given, may excite some interest, and M. De Locht-Labye has given us permission to state that he will be glad to receive, either through the medium of our journal or directly, any objections or requests for explanation that may suggest themselves, and that it will be both a duty and pleasure to him to answer them. We shall describe in a future number M. De Locht-Labye's "Pantelephone."

Electrical Review, Sept. 20, 1883.

Terrestrial Telephoning.

It is said that M. Hitter, an eminent German philosopher and electrician, in the month of May, 1805, communicated to the Royal Academy of Sciences of Munich the fact of successfully magnetizing pieces of gold by Voltaic electricity. That gold needles or compasses when thus magnetized "obeyed terrestrial magnetic influences for several months, displaying directive qualities," etc. And William Sturgeon, a learned scientist and author of that period, was led to make the following remarkable statement, the truth of which has recently been demonstrated at Washington. Professor Sturgeon says: "This simple process of exciting electric currents, when transferred to the vast apparatus of nature, opens to view the most magnificent theory of terrestrial magnetism that the mind of man can possibly conceive. The sun would thus become the exciting agent, whose uniform tide heat, sweeping the tropical zone, would be productive of an immense westerly circumflowing electrical flood, and convert this terrestrial globe into a grand thermo-electric magnet.

"Thus the earth may be considered as an equivalent to an immense Faraday coil, of which the poles are on one side sufficiently isolated by the waters of the ocean. The action of this pile has produced great chemical changes in the materials of the earth—changes which have differed according to the poles, and of which pile the poles at the other extremity have always such an abundance of electricity as to cause its splendor to appear in magnetic radiations in the vast spaces in the heavens, and usually termed Aurora Borealis."

The foregoing magnetic principle of our earth has remained unchanged for centuries prior to the appearance of human life upon the planet. Then, when comparing the progress of electrical science of the present with the past, the gain has been slow indeed. Professor Morse often spoke of the earth's magnetism, and in his experiments in 1844, suggested a galvanometer attached to plates of metal in the earth, by sending a powerful current of electricity across a stream of water. So, too, will the telephone of to-day receive and transmit signals or sounds of various kinds by powerful batteries connected to the earth without the use of wires, on this terrestrial telephonic principle of the magnetism of the earth and atmosphere.

The principle of the magnet is little understood; and now, when the telephone has only been in operation a few years, and hundreds of thousands of magnets formed and used in all manner of shapes and sizes, is it any wonder that we should be so anxious to learn all about the law of magnetism that permits each magnet installed, whether in the telephone or other electrical device?

February 7, 1884.] ELECTRICAL REVIEW. 7

The American Bell Telephone Company.

Our esteemed contemporary, the *Postal Telegraph and Telephone Gazette* (London), makes the following interesting commentaries on the Bell Telephone Co., showing the English view of our telephone affairs in this country:

"The question of the telephonic centre in the United States after vibrating between Boston and New York, finally settled upon the former place, which might now be aptly termed the vobs and zur of the Union. The telephone interest radiates from Boston to the uttermost parts of the earth. The American Bell Telephone Company, the parent company of the United States, have here their business offices, as have also the principal companies which are operating in the countries to the south of us, Mexico, Central America, South America. When we consider the short space of time since the first telephones were commercially introduced, the progress is telephony has been simply marvelous. Now the number of telephones in actual use in the United States is over 300,000, and a steady stream of them rear from the manufactory to the awaiting subscribers, adding many thousands each month. A few years ago the original company found a difficulty in raising a few hundred dollars for business purposes; now bonds are sold at a premium by the hundred thousand. The various telephone companies operating in the southern foreign countries, obtain all their instruments and apparatus from the American Bell Telephone Company, with which they have contracts to this effect, so that in addition to the large consumption there is a large and constantly increasing export demand. The management to secure, hold, and enlarge its enormous interests has been of a bold, aggressive character, and at the same time is conservative enough—very liberal in its outlay and policy, and yet not wasteful or extravagant. It has been fortified, and the future has not been sacrificed to the present. All the telephones and transmitters are manufactured in this city, by the Western Electric Co., as are also many of the telephonic accessories, such as magneto-bells, switch-boards, &c., although the greater part of the latter are made in the company's manufactories in other cities, only one branch being located here. It is not to be supposed that such an extensive enterprise has been allowed to continue in existence without being questioned or pursued by rivals. No great invention ever flowered in fruit that had not to meet enthusiasts and enemies, but so far the Bell Company has been able to evade or throw off all the shackles which have threatened to blind it. The policy of a *sub rosa* nature has been adopted concerning its affairs—it is quiet while its stock makes large vibrations downward, when a weed, officially, so to its business standing, would restore the equilibrium. It never notices the various questions, allegations, or rumors officiated from time to time, except in the courts, where the answers have been to the public, but has devoted itself wholly to business, to the enlargement of its plant and the earning of dividends for its stockholders. The usual 3 per cent. quarterly dividend has been declared by the American Bell Company, although it is generally understood that their earnings would warrant a higher rate."

The Telephone Problem in England.

The condition of the telephone in that country must be considered an anomalous one, and the *Postal Gazette* says that it is one which will demand the serious attention of the Postmaster-General at no distant period. There is no denying it, that the progress of the telephone is retarded in some measure by the relative position of the postal authorities and the telephone companies. The latter are anxious to develop their systems as rapidly as possible, in order to make the most of the time during which their patents are secured to them. The rules on their part is natural enough, but as it tends to create a formidable feeling in the postal telegraph system, there is naturally a desire on the part of the postal telegraph authorities not to let the telephone grow out of leading strings. The principal patents will run out in about seven years, and we suppose it is thought that if matters can be kept on the present footing for that period, it will be easier and much less expensive for the post-office to take over the telephone. We take it for granted that the latter step will have to be taken, sooner or later, unless the post-office authorities are prepared to see the revenue obtained from the telegraph dwindle down very rapidly. It is no use mincing matters. The telephone will become a very serious competitor to the telegraph, so soon as the ordinary telephonic exchanges in the country are placed in direct telephonic communication by means of trunk wires. It must come to that eventually, and we do not think that the English public will submit to being kept without telephone facilities, which are being provided throughout the neighboring continental countries. We do not pretend to know whether the monopoly held by the Postmaster-General absolutely prevent the connection of the different telephone systems. It appears, however, to be the opinion of the telephone companies that a non-liberal policy might with advantage, both to them and to the public, be pursued in the matter. There are other facilities, such as the connection by telephone of certain trial telephone exchanges with the chief telegraph stations in the same cities, which are already in operation to the ease of the Government employés, but which have not yet been introduced into the telephone exchanges of the companies—as the latter say, because the conditions on which the Post-master General is inclined to grant the connection are too onerous. The question of the establishment of cheap telephone messages, as proposed by Mr. Batten, of the Edison Telephone Company, will also have to be dealt with, and we may expect an unfavorable decision of the matter in this year's session of Parliament. The long, and, we opine, will resolve itself into the following two questions: Is the telephone eventually to be taken over by the post-office and to be worked in connection with the postal telegraph? or are the private companies to continue the *exploitation* of the telephone? If the former is to be the solution of the problem, it will be useless to still further spread the net the only proper policy will be to leave the matter and buy the companies out. If the companies are to continue to provide the telephonic communication, reasonable facilities ought to be given so as to allow the telephone to develop itself as rapidly as in other countries. Of our nearer neighbors, it is notably Belgium which has lately adopted a very progressive policy in this direction. We feel comforted, from the well-known liberal views current out by the Postmaster-General in all his departments, that he will give due weight to public exigencies, and that the public will demand a free and speedy development of the telephone through out the United Kingdom as a most useful instrument for trade, and a great convenience for the entire community.

The Telephone Situation.

Our esteemed contemporary, *Bradstreet's*, comments as follows on matters telephonic:

"The telephone interference case between the Bell Interest, on the one side, and the McDonough Interest, on the other, upon which a decision was rendered by the chief examiner of the Patent Office last summer, promises to reach a final decision soon. It will be remembered that the examiner's decision awarded to Bell priority in the art of telephony, and to McDonough the priority in the construction of the magneto receiver—the one in universal use to-day. On the face of it, the effect of this decision is to give McDonough the right to introduce the use of the magneto receiver by the Bell Company, while McDonough himself is debarred from embarking in the telephone business by the decision awarded to Bell. The net of telephony, to which Bell is adjudged to be entitled, is that of transmitting speech electrically by means of undulating currents. As it is claimed by the Bell Company that the transmission of speech is impossible except by the use of undulatory currents, it would seem that the two contestants are left by this decision in a position in which each can prevent the other from using a complete telephone system which neither can himself employ. It is claimed, however, on the McDonough side, that the examiner's decision, in fixing the date of the McDonough receiver, was also the date of his transmitter, and that, hence the award of priority to Bell for the latter telephony cannot be upheld.

"McDonough, in fact, claims to have constructed both a transmitter and receiver, and to have sent and received articulate speech by means of them prior to Bell. Whether Bell was the first to use an undulatory current for the transmission of speech is evidently of no consequence if instruments were made prior to his which would transmit speech. In view of this state of the case, the decision of the examiner has a greater significance than the McDonough interest thus at first appears; and, if it be sustained by the higher tribunals to which it can be appealed, the control of the telephone will pass from the hands of the American Bell Co. There are three appeals within the finals of the Patent Office—the first from the examiner to the Board of Examiners, the second from this latter to the Commissioner of Patents, and the third and last to the Secretary of the Interior. That the latter is final, so far as the Patent Office is concerned; but that will remain the adjudication of the courts, before which the case can come up as a matter of infringement. The Bell Company has all the merits of delay on appeals, the hearing on which was set for the 11th of January, and the chances of success by the examiner-in-chief of the case now having been before the office for about three years—and the probability of substantial exhaustive, it does not seem probable that a decision will be long delayed. For the same reason, delay will be in favor of appeals, if they are taken, will probably not be decided before 1885, so that the final decision may be reasonably expected in the following year.

"How a final decision in these fundamental patents against the Bell Co., will affect the users of the telephone it is difficult to say. The present telephone system is owned by a number of local companies operating local telephone systems or exchanges, as they are called, which are leased by the Bell Telephone Company, to which they pay royalties for the use of all the telephone patents controlled by it. The Bell Company, or companies is a very large one; their plant is in place, and it almost all ares a paying business is being done. No new company would, therefore, find it a desirable or a profitable thing to attempt to enter into it. It would, therefore, in all probability, take years for the new organization now occupied by the Bell Company, in fact, this is now the programme of the McDonough Company. With such a disposition of the telephone forces, the benefit accruing to the user from a change of ownership would be but slight. The McDonough Company claims to be able to offer to the local companies greater facilities for the transaction of their business in the form of improved and automatic switchboard devices, in place of the apparatus now in use in the exchanges, and to be content with lower royalties than those exacted by the Bell Company.

"From the point of view of the stockholders of the Bell Company, even much more sweeping decisions than are at all likely to be obtained would not be cause for any disquietude. Nothing is more difficult in the commercial world than to wholly dislodge a large financial interest once thoroughly in the possession of the field. Its acquired strength always gives it the ability to compromise with any or all opponents, and, if it cannot remain in control, to at least retain the major part of the advantages of its position. That the Bell Company is no exception. The most that it can lose by the loss of its patents are the royalties now paid it by the local companies. It does not seem to be generally known, or, at least, to be sufficiently taken into account, in estimating the effect of this patent litigation, that the Bell Company is a large holder of the various local stocks—a controlling interest in the majority of them. Whatever the transactions, then, of patent litigation, the Bell Company is still possessed of a very substantial property, of which nothing but the dissolution of the present local companies can despoil it. As indicated above, the probability of this occurring is too small to be taken into consideration.

"McDonough is, however, not the only contestant in the field. There is another, who claims to antedate both McDonough and Bell, and whose claim, if substantiated, may seem at first sight to wholly alter the telephonic situation as above presented. This is Daniel Drawbaugh. He claims to have made a crude, but still a working telephone, as far back as 1867, and it is claimed further that he has since been engaged in perfecting the invention as diligently as his means would allow. It is claimed by his opponents, however, that, admitting his invention of telephone at the time claimed, he abandoned it, as I hence is not entitled to patent protection. The plea of abandonment is set up in the Supreme Court of the District of Columbia, in which the case is pending in the United States Court for the Southern District of New York, and is expected to be decided soon. If Drawbaugh is finally adjudged the inventor of the telephone, the McDonough as well as the Bell patents become worthless, and if it be held that there was abandonment on the part of Drawbaugh, the cannot secure a patent, and the original telephone therefore becomes open and public property.

"It must not be supposed, however, that in this will throw the telephone field open to all and sundry. The telephone field open to all and sundry. The telephone field is but a comparatively simple one. Without the central exchange and at which different subscribers can communicate with each other on a party line basis, the usefulness of the telephone is practically nothing. The value of the telephone entirely. Both the Bell and McDonough and the Bell interests claim to have patents, without infringement upon which a complete telephone exchange can be operated. After the settlement of the question of priority in the invention of the telephone, the contest will very probably be carried into the question of mutual infringement of their devices, unless the contestants in the meantime make a mutually satisfactory adjustment of their claims.

"Whichever comes the most probable upshot of the matter. This will leave the actual distribution of the telephonic forces practically well unchanged, and the question of improved telephonic service at reduced rates will be determined by the business interests of the companies engaged in the business.

"That such an arrangement will result in giving the public a cheaper and more efficient telephone service than the present hardly seems probable. But at the same time, it is by no means certain that this would result from the competition of many companies. In a commercial enterprise of this sort, a comparatively small plant conducted of necessity to particular districts, the duplication of companies, gives no guarantee of cheaper or better service.

"The dividends have to come out of the consumer, and the capital upon which dividends have to be earned is always certain to be larger if distributed among several than if confined to one company."

The Brush Electric Light & Power Company, of Philadelphia, has increased its capital to $1,500,000. Also that Supt. S. A. Duncan, of the Brush Co., of Pittsburgh, Pa., operated during 1883 38 standard Brush lamps (2,000 candle power each) 19 hours daily, using a 1-horse power engine, having the new armature. The circuit was of No. 8 wire.

ELE

On each board there are twenty trunk lines secured when the sun drops and one hundred subscribers' drops. When the boards full The excessive rushes of business which with the operators' keep sometimes occurs in the larger part of the numbers, and the s by one operator only fifty subscribers and ten trunk lines to attend to. One important advan arrangement is that it s The system is at present equipped for six hundred subscribers' lines, and one hundred trunk lines. There are two boards, one with twenty trunk lines between the operators and two hundred subscribers' lines, board and three upon t two six boards, but when the system is com pleted there will be ten. At each end of the system there is a special board containing an upright row of spring jacks, to enable the operator at each end to make connections without reaching across the boards. Care has been taken to make the keyboard circuits reliable and at the same time some special features are in use which avoid a motion for the operator. The two most important requisites in switchboards for large telephone exchanges are speed and economy. It so happens that these two requisites go together; for whatever tends to reduce the amount of work to be done, also enables the operator to do it quickly, and therefore diminishes the cost of the work. The rapidity of speed and economy are met with in a high degree in the multiple switchboard. This system is elaborated from the fundamental idea of having each operator reach all the subscribers' lines in an exchange with one motion for each line, and to enable each operator do all the work involved in effecting the connection of calls wanted by her subscribers. There is no repeating of orders, either by word of mouth or by tickets. The operator to whom a call is made by a certain number of subscribers whose calls she answers. When one of these subscribers is exhausted for connection with any other subscriber, on the exchange, the operator who takes the order makes the connection of the two lines in question, and rings the bell of the subscriber wanted. When the conversation is finished, the same operator who connected them together receives the notice by the subscribers.

ELECTRICAL REVIEW.

RECENT PROGRESS IN TELEPHONY[1]

THE Telephone was first introduced to the British public at the meetings of the British Association. In 1876, at Glasgow, Sir William Thomson startled his hearers by announcing that he had heard, in Philadelphia, Shakespeare quoted though an electric wire, by the aid of the invention of Mr. Graham Bell, which he then pronounced to be "the greatest by far of all the marvels of the electric telegraph." In 1877, at Plymouth, I had the pleasure of showing in actual operation the finally developed instrument now known as the Bell Telephone, which I had just brought over from America; and conversation was easily maintained between Plymouth and Exeter. Five years have elapsed since then, and it is fitting that the British Association should hear of the progress of this astonishing apparatus.

In 1877, it was a scientific toy; it has now grown to be a practical instrument. A £50,000 capital is already embarked in its extension in England, and it is earning a revenue of £60,000. Hitherto it has been practically a monopoly in the hands of a private company, to which the controlling power, and of the Post Office, who, however, have the controlling power, have never exercised. It is often said that competition in any business will have the effect of reducing the charges to the public, but the experience of the past is always and telegraphs recently teaches this lesson. Unless competition tends to lower the rates for a time, but it eventually leads to amalgamation—to the absorption of the weak by the stronger, swollen and watered capital, and, finally to more than twice higher rates to a non-existing public. Competition, however, induces better service, and ultimately, in this respect alone the public gains.

The free traffic in patents, however, leads to jobbery and speculation of the worst type. We have recently seen a number of patents transferred for almost fresh the South Sea Bubble period. The public have wildly rushed into ill-matured schemes for the latest novelties the prizes of gambling promoters, have turned the heads of inventors, have retarded the true progress of the beneficial application of this rare science to the wants of man, and have throughout millions upon imperfect schemes. Much has been said against the monopoly of the Post Office in telegraphy; however, but it may safely be the merit that it has checked the rapacity of company promoters and speculators in this branch of the practical application of electricity, while no one can assert that it has checked the progress of telegraphy. During the last week that the telegraphs in this country were transferred to the State, the total number of telegrams transmitted was 26,000, while in the week ending August 12th it amounted to 724,000. There is no investor who can assert that his chance has not received proper consideration, nor since a real improvements of the Post Office itself are freely adopted by other countries, and American itself—the home of the inventor—has found the advanced system of England worthy of acceptance.

Microphone.—The original telephone receiver of Bell has scarcely been improved upon; it remains in form and construction very nearly the same as that which I exhibited in 1877. The perfection of its working depends upon the truth and perfection of its manufacture. It is now more solid and substantial than it was at first, more powerful magnets are used; but still it is the same simple, unpolished, beautiful instrument that I brought over from America. Mr. Gower has increased its loudness by varying the form of its pole pieces, and using very powerful brass-bound magnets of excellent quality; but experience shows that loudness is always obtained at the expense of clearness of articulation; and, although for many purposes the Gower-Bell may be found valuable, it adapted by the Post Office and is now in contract together all the sections of the British Association stationed through the town of Southampton, at the present time, waiting for distinct articulation appears to be the original Bell.

The Paris Exhibition of last year, so fruitful in electrical novelties, did not bring forth any material improvement in telephonic apparatus. It was noticeable chiefly for its practical application of the telephone, and particularly to the transmission of singing and music to a distance. M. Ader's modification of Bell's receiver is that almost universally used in Paris. It is a very handy, pretty, and convenient form. He utilises a principle which he calls "unreaction." A thick ring of soft iron is inserted between the ear-piece and the diaphragm, and this is said to increase the attractive power of the little horse-shoe magnet upon the vibrating iron diaphragm. A simple experiment confutes all M. Ader's shows that there's some foundation for the fact; when a thin steel spring is adjusted close to the poles of a magnet without being attracted by them, the near approach of a mass of iron to the spring will cause it to be attracted by the magnet.

D'Arsonval has also modified the Bell receiver. He has placed the coil in a powerful magnetic field of annular form, and has thereby concentrated the lines of force upon the induced coil. He brings the whole coil within the influence of the field. The effects are said to be magnified, and the increased loudness is not accompanied by the usual loss of articulation. Speech is reproduced without any change of *timbre*.

Telephone receivers of the Bell type are all based upon the magnetic effects of currents of electricity flowing around magnets or bars of soft iron.

The rapid and rhythmic magnetisation and demagnetisation of a bar of iron or the increment and decrement of the magnetism of a magnet, will produce molecular disturbances, in its own mass, and in any matter which is near it, that lead to the oscillatory motions of sound, and which produce sonorous vibrations that can be made audible to any number of persons, and particularly by that pano-ted by Graham Bell.

Other principles of electricity have also been utilised for telephonic receivers.

For instance, Mr. Edison used the electro-chemical effect. The decomposition of a chemical substance, as paper or on cloth by the passage of currents, through it, produces a modification of the friction of two moving surfaces, which is reproduced sonorous vibrations, and the result is a very loud-speaking apparatus. I myself had the pleasure, in 1880, of submitting to the Royal Society a receiver based on the electro-chemical effects of the current. The passage of a current through water always heats them and therefore produces expansion. If the wire be made fine enough, so that it is heated and cooled almost so rapidly, the expansion and contraction are so quick, that sonorous vibrations are the result. Although I was able to speak through it very clearly, I have not as yet developed this instrument into a practical form. Professor Hughes has recently utilised the electro-static effects of currents. His receiver is even more delicate than that of Bell. Two flat circular discs of metal are rigidly fixed very close to each other in an insulated case of ebonite. When one disc is electrified positively by a charge of electricity, the other is electrified negatively by induction. These opposite electrical charges attract one another with a force with the strength of the signals sent, and the result is that, when telephonic currents are transmitted, certain sonorous vibrations, and, consequently, the reproduction of speech.

Many other forms of telephone receivers have been devised and exhibited, in fact I have recently seen quite a crop of them; but as they involve no new principle, and introduce no particular improvement, having now brought out chiefly to try to avoid existing patents, I pass them over, and proceed to the next branch of my subject.

Our pre-ent Patent Law is, unfortunately, in so disorganised and chaotic a condition, that almost anything is possible, and hence the questionable morality of doing a thing in another way, in order to avoid the incidence of a royalty, is practically encouraged. The possession of a patent is now no guarantee of validity, and it is granted without any investigation, and cannot be upheld without tedious litigation and vexatious expenditure before a technical and scientific tribunal. We therefore cannot hope for any virtue in English inventors or security for their improvements until our law is thoroughly revised. The question before the House of Commons, and, when weekly sages have fully examined the evidence of our legislators, we may hope for some attention to so real and pressing a want.

Transmitters.—The great novelty and peculiarity of Bell's telephone was that the receiver and transmitter were similar and reversible. Some other forms of receiver are of imagining on an iron disc caused it to vibrate in front of a magnet around one pole of which a portion of the electric circuit was wound. These vibrations of a magnetic substance in a magnetic field produced currents of electricity in the coil of wire on the magnet, varying in strength and direction with the sonorous vibrations, which, proceeding along a wire to a distant station, there varied the magnetic strength of a similar magnet so as to vary it from time to time, and at times attractive force on a similar disc, by which it reproduced the experienced it, the sound of the first disc, and thus, reproducing the sonorous vibrations of the air, repeated speech. The currents, however, the polarisation were very feeble; such energy was lost *en route*, and the effect scarcely ever such a practical standard.

Mr. Edison showed last year in Paris and to other receiver, the carbon current. Taking advantage of a peculiar property of carbon which was discovered by him in electrical resistance with the amount of pressure brought to bear upon it, he constructed the vibrating disc which was spoken against to press sideways upon a button of carbon, and thus varied the strength of a current accordingly. of electricity passing through it. This varying current, passing through the primary wire of an induction coil, set up in the secondary circuit coil many powerful currents than the bell instrument in telegraph produced, and caused louder and more articulate speech at the receiving station. Professor Hughes went a step further, and found a combination of materials that were directly related to the sonorous vibrations, which he called a "microphone," and by the idea to proved that the effect of the carbon transmitter of Edison was due to any influence of varying pressure on the mass of the button of carbon, but was a phenomenon of force contact. He found it to extend over last in nature, and he startled the scientific world by introducing the use ducing an instrument which did for minute sounds what the microscope had already done for minute objects. By the light experiment thrown on the theory of the instrument by Hughes, Edison's ing, namely carbon transmitter has been so improved by Blake, Hunnings, *tal of some* Mowday, Ader, and others, that little apparently remains to be done. The telephone as a speaking instrument is now well a, six miles high perfect. It is quite possible to speak to a friend's voice at nine apart. two miles distance. The difficulty of making the telephone a speak by a practical instrument under all circumstances is not due to any and Science defects in the instrument itself, but to disturbing influences distinct was external to it, and consequent on its surroundings. The very by so to perfection and conditions of the apparatus itself are its chief di. essence.

, and, as In the action of the microphone, or carbon-transmitter, is unattain, very little understood: it introduces into a closed electric circuit. In this circuit, though with a current is flowing, a resistance which is business, varying exactly with the sonorous vibrations impinging upon it. so, but in such a manner as to correspond in a way exactly analogous to the delicate varying sound waves. This effect is generally ascribed to be the loose that is a greater or less tendency of electrical contact to become imperfect, under conditions of varying vibration upon each other; but the instruc- there is now little doubt that it is due to a true variation of resistance, tion Phenomena because it has the remarkable property of having its resistance lowered when it is battered upon by sonorous vibrations. This observation was made by Mr. Stroh and Professor Hughes.

The resistance of microphone is very variable: some give 100, while others give 25, and some even 125. The best transmitters that I have worked with (Mowday's) give an average of 37.

Attempts have been made to apply mathematical analysis to the determinations of the best form and arrangement of microphones, but at present the microphone defies mathematics.

Every would lead to the conclusion that a good transmitter should have the lowest possible resistance, but practice does not confirm that idea.

There again asserts that the resistance of the secondary coil of the induction coil should be equal to that of the line it works, but practice proves the very never-so. On a line giving nearly 1,000 resistance, the best effects were produced with a secondary wire of only 30° resistance. The fact is, that the conditions which result in the microphonic action, and the induction in the induction coil, are very complicated, and are not yet sufficiently understood to explain the phenomena they affect within the region of mathematical analysis.

Accessories.—I cannot intend to speak here of the bells, calls, switches, etc., used in carrying out telephonic operations: there has been nothing that is particularly novel introduced, or that was not previously used in telegraphy. In fact, the whole operations carried on in connection with the so-called "exchange" working are simply telegraphic, and are still in a somewhat tentative condition.

Long-distance Speaking.—I have said that the difficulty in speaking is chiefly due to the environment of the wires employed. Were we to erect a wire from Land's End to John o' Groats,

of lightning protectors. The use of double wires diminishes the danger to a minimum. On the Continent and in America, however, telephones are invariably protected by lightning arresters

[1] Paper read at the Southampton meeting of the British Association, Section by the author.

An interesting experiment, which seems to have a bearing on the action of Edison's ferrotic telephone, has been recently described by Herr Koch. When a plate of platinum or palladium is polarised by means of an electric current, the friction of these metals against a plate of moistened glass increases immediately. To measure the friction, Herr Koch uses the mantel in the form of a horizontal button, resting on the bottom of a glass cup, filled with pure or acidulated water. The button serves as pivot to the magnetic needle, which oscillates under the action of the earth; the decrease of the oscillations measures the friction of the pivot. Polarization is produced by the currents of the Daniell element, one pole of which communicates with the glass or button, while the other terminates with a platinum wire entering the water of the cup. The polarization by hydrogen gas produces no effect, but polarization with the pole evaporation is found very effectives. The friction was increased, through this polarization, in the ratio of 3, and sometimes in that of 2 to 4. This increase of friction appears immediately the circuit is closed, and disappears slowly, like the polarization itself, when the circuit is merely opened. It increases with the electromotive force of the polarization by oxygen. Palladium behaves like platinum. Gold (18 carat) gave no effect.

ON CURRENTS PRODUCED BY FRICTION BETWEEN CONDUCTING SUBSTANCES AND ON A NEW FORM OF TELEPHONE RECEIVER.*

In a communication to the Royal Society of Edinburgh of date January 6, 1879, I showed that "electric currents were produced by the mere friction between conducting substances." The existence of these currents can be easily demonstrated either by a telephone or a Thomson galvanometer. I have since found that these currents exist in all pairs of metals which I have yet tried, in the same direction as the thermo-electric current got by heating the junction of the same two metals. They are also approximately at least, subjugate in proportion to the metals rubbed are far apart on the thermo-electric scale—the strongest currents, as far as I have yet observed, being got by rubbing antimony and bismuth together. These observations clearly point to a thermo-electric origin for the currents; but it is possible that they may be due partly to the currents suggested by Sir William Thomson as the cause of friction, and partly, also, to contact forces between films of air or oxide adhering to the surfaces of the metals.

Having ascertained that these friction-currents are of some strength and fairly constant, I proceeded to make several kinds of mechanics for producing currents on this principle. One of them consists of a cylinder of antimony, which can be rotated rapidly, while a plate of bismuth is pressed hard against it by a stiff spring. When this machine is included in the same circuit with a microphone and a Bell telephone, the current got from it is quite sufficient to serve for the transmission of musical sounds and also loud speaking. The transmitter, which I have found most serviceable in my experiments, is made by screwing two small cubes of gas-carbon to a violin, and placing between them a long stick of carbon pointed at both ends, the points being made to rest in conical holes in the carbon cubes. The looseness of the contact is regulated by a finger-screw. This forms an excellent and handy transmitter for all kinds of musical sounds, and also serves very well for transmitting speech.

Seeing that friction between metals clearly produces a current, it seemed natural to inquire if the converse held good—that is, if a current from a battery sent through portions of two metals affected the friction of the one upon the other. I have found that this is in a variety of ways, and the results obtained have no doubt whether to attribute them to variations in the friction, or to sound striking produced by fusion of the portions of contact through which the current passes. The most noticeable effect is produced when one of the rubbing bodies is a mere point, and the other a smooth surface of metal. This form was made a telephone-form of the loud speaking telephone of Mr. Edison, in order to get audible indications of changes of friction produced by the passing of a variable current. It consists of a cylinder of bismuth accurately turned and revolving on centres. The rubber-point is made of a sewing-needle with its point bent at right angles, and its other end attached to the centre of the mica disk of a phonograph-mouthpiece. It is evident that this is only a loose contact, which can be perpetually changed. When this apparatus is included in the circuit with the violin-microphone and three or four Daniell cells, the violin sounds, as was to be expected, are heard proceeding from the loose contact, even when the cylinder is not rotated. They are increased, however, in a remarkable degree by rotating the cylinder slowly, so much so that a tune played on the violin can, with proper care, be distinctly heard all over an ordinary room.

With regard to the explanation of the effect, it is evident that electrolysis can in no sense come into play, as is supposed to be the case in Edison's instruments. I am inclined to look for the explanation rather in the direction of the effects of sound-waves, although the circumstances are considerably different in the two cases. In the rocker we have the best possible union from a mass of hot metal through two points of support to a cold block, whereas, in the other case, the heat is only local to the points of contact, the rest of the metals being comparatively unaffected. The variations in the current produced by the transmitting microphone must

*Abstract of a paper read before the Royal Society of Edinburgh by James Blyth, M. A., F.R.S.E., on May 5, 1880.

ate actions in the mandibles, just as contact of the lips with an external body sets up sucking in the infant. All these movements depend upon what we call instinct—that is to say, organic habits registered in the nervous system of the race. They have arisen by natural selection alone, because those insects which duly performed them survived, and those which did not duly perform them died out. After a considerable span of life spent in feeding and walking about in search of more food, the caterpillar one day found itself compelled by an inner monitor to alter its habits. Why, it knew not; but, just as a tired child sinks into a sleep, the gorged and full-fed caterpillar "moults" into a dormant state."

Of course all this may have been written in jobe. The writer may possibly be laughing at evolutionists. The "inward monitor" of the "gorged and full-fed caterpillar" undoubtedly looks rather suspicious, but one hardly likes to hint at anything so serious. Evolutionists will, I dare say, repudiate such "evolution" as a mere travesty, but it is quite time that half-a-dozen evolutionists who agree on main points should clearly state their belief.

In conclusion, let me ask you as students of nature's processes, whether you have not seen enough to convince you that the revival of the assumption which has been abandoned and reintroduced many times during the last few centuries, that the lifeless is the sole origin of the living—that in fact the non-living and the living are one—is now unjustifiable, and cannot be reasonably entertained. This monstrous fallacy, though taught with the greatest confidence, is based on assumption, and is supported by arbitrarily selected facts, and by not a few misrepresentations and dogmatic assertions. Whenever any form of this false doctrine has been successfully forced into popularity, it has led to the adoption and propagation of the most grievous errors and grotesque conceits.

I am, Sir, yours faithfully,
A. H. SWINTON.

COMET OBSERVATIONS AT PRINCETON.

The weather has been so unfavorable at Princeton, that we have been unable to make any very satisfactory measures upon the spectrum of the comet. On Saturday evening the comet was visible fairly for an hour or so, before it descended into a bank of cloud. On Sunday evening it was beautifully seen for about half an hour, and then was obscured by a fog which still continues.

The spectrum of the nucleus is very bright. It is apparently continuous, though there may be a little special emphasis at the points where the usual carbon bands ought to appear. The spectrum of the coma and of the tail is precisely like that of most comets, showing three bands which coincide sensibly with those given by the flame of a Bunsen gas-burner, presumably due to a hydrocarbon of some sort.

On Saturday evening the nucleus looked much like a star-fish, having five projecting points formed by jets of light proceeding from the central globe to a distance of from four to ten seconds of arc. These jets were not equal in length or brightness, and were not symmetrically disposed with reference to the axis of the comet's tail. Two of them were somewhat curved, they were all diffuse and blunt at the extremity, rather than pointed.

On Saturday, instead of jets, the nucleus had a nearly circular envelope surrounding it, sharply defined from the coma. Its diameter was perhaps 20", but the fog came on before any measures could be made. This disc of light, surrounding the nucleus, was not uniformly bright;—it was more brilliant on the side next the Sun, and there was a curious dark opening in it of oval form some 20" one side of the axes of the tail. We were preparing to study the spectrum of this envelope critically, when we were cut off by the mist.

Although the Comet is now receding from both Sun and Earth, it is rising so much higher in the Northern Sky each night, that if the weather becomes favorable, it may yet be possible to get something more satisfactory; but just at present the rain is pouring and the prospect is rather dreary. C. A. YOUNG.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

LOCUSTS AND SUN SPOTS.

To the Editor of "SCIENCE:"

SIR: Perhaps you will permit me to explain one inapposite word occurring in my communication on the above subject.

When I stated that European migrants come north and east, I should rather have said *north and west*, the set of the migrations, as far as known, is on European areas north and west; and in this direction, butterflies, spiders webs and locusts, whose point of departure has been traced to Southern Asia or Northern Africa, travel periodically; the occurrence being made known to us by their vanguard, so to speak, sweeping over the eastern shore of Great Britain. That this track is not voluntarily chosen by instinct, but rather due to a prevailing south-easterly direction of the winds, rests now-a-days on a great amount of experience.

A. H. SWINTON.

Guildford, Eng., *June*, 1881.

THE BLUE COLOR OF THE SKY.

Prof. Correa having established the fact that the atmosphere of the earth exercises an energetic absorption upon the ultra-violet rays of the spectrum, whose limit varies according to the statement of the atmosphere and the altitude of the sun, Prof. Hartley sought to attribute the limitation to the influence of ozone. His experiments have demonstrated.

1.—That the ozone is a normal constituent of the higher atmosphere, where it is more abundant than on the surface.

2.—That this quantity of atmospheric ozone suffices to limit the spectrum in the ultra-violet region, without considering the absorption caused by the great density of the oxygen and nitrogen.

3.—That the blue tint of the atmosphere is due to the presence of ozone.

In respect of this last point, Prof. Hartley remarks that, if the ozone exists in the high regions of the atmosphere, the light reflected by clouds at a great heighth has a blue appearance because it traverses a gas of this color. It is so likewise with the light illuminating the distant portions of a landscape. Experiments have shown that 25 milligrammes of ozone for every square centimeter of a layer of 80 kilogr. thick can produce this phenomenon.

We learn that Prof. H. S. Pritchett, Director of the Glasgow Observatory, has been appointed Professor of Mathematics in Washington University, St. Louis, Missouri.

THE VAN RYSSELBERGHE SYSTEM OF TELEPHONY.

For some time past electricians have been on the alert for descriptive details concerning the Van Ryselberghe system of telephony, their curiosity having been excited by the interesting and valuable results attained in experiments with this system, and repeated by the scientific journals at various times during the last two years. All publicity seems to have been avoided by the inventor and his friends, however. It has been known for some months in a vague way that this system accomplishes a desirable feat in eliminating all disturbances of an inductive character, and in admitting of simultaneous telephonic and telegraphic transmission over the same conductors; but the peculiarities of the apparatus used or of its *modus operandi* have remained a mystery. The curiosity which lingers in the minds of telephonists and electricians regarding the nature of a system which promises to do as much as this, becomes all the more legitimate in view of the fact that the system has lately been officially adopted by the Belgian government, which is now making active preparations to apply it to its 30,000 kilometers of telegraph lines, thereby inaugurating the use of long distance telephony which is destined to facilitate and cheapen inter-communication between cities and countries.

The illustrated description of the Van Ryselberghe system, of which we give the first part in the present issue, will therefore be acceptable to our readers especially inasmuch as it is the first descriptive article published about this system in the English language. It has also the great merit of being authoritative, since it comes directly from the pen of M. J. Banneux, chief engineer of telegraphs of the Belgian government, under whose direction all the experiments with this system have been made, imbued with the evident importance of the Van Ryselberghe system, we had taken prompt measures to gratify, at the earliest moment, the curiosity of our readers concerning it, by opening correspondence with both the inventor and M. Banneux. The latter has kindly sent us duplicate manuscript and diagrams of an article intended for the current number of the *Journal Télégraphique de Berne* (Switzerland), and in this way we are enabled to publish the article simultaneously with our contemporary.

The telephonic system of M. F. Van Ryselberghe is possessed of great interest, not only because it attains new results, but because it attains these results by methods and devices essentially new. The conductors, whose valuable properties have heretofore been ignored or neglected by telephonic inventors, especially on this side of the Atlantic, is assigned a rôle as important as it is unexpected, in this system. Its use insures comparative protection from the evils of induction, by furnishing the ounce of prevention rather than the pound of cure. This is indeed the fundamental object of the Van Ryselberghe system—to remove the cause of induction instead of combating its effects; to modify the character of impulses likely to produce induction, rather than to counteract the induction itself, in each of the contiguous wires acted upon. The simultaneousness of telephonic and telegraphic transmission over the same conductor, which is realized, though in itself a wonderful and a desirable result, was only attained incidentally. Its possibility suggested itself to the inventor as a logical corollary of the arrangements adopted to attain the first object—the elimination of the induction. The system is very creditable to M. F. Van Ryselberghe, who, we should state, is a scientist and electrician of note, and is Professor of Applied Electricity at the University of Ghent. He is also a meteorologist of distinction, and occupies the post of Director of the Meteorological Department of the Brussels Observatory. He is already famous as the inventor of the telemeteorograph—a wonderful instrument of precision for automatically recording atmospheric changes at a distance. It was precisely the telemeteorograph, by the way, which led M. Van Ryselberghe to experiment with a view to improving upon the ordinary system of telephonic transmission. His object was to arrive at some way of utilizing, for the purposes of telephonic communication, the special wire which connects the Observatory of Brussels with the meteorological station of Ostend, and which serves for the telemeteorograph. This line, which is nearly one hundred and twenty-five kilometres long, was laid on the poles of the government telegraph lines, which accompanied it throughout its course between the two cities in numbers varying from seven to forty. As these wires were for Morse and Hughes apparatus, it is plain that the telemeteorograph wire was subjected to serious inductive disturbances that must interfere greatly with telephonic transmission.

M. Van Ryselberghe at first sought to increase the loudness of articulation of the telephone, in order that, if possible, the voice transmitted might be heard above the din and crackle of the voices due to induction. On January 10, 1882, he made the first experiment with his improved transmitters and receivers on a line of 44 kilometres connecting Brussels (north) with Antwerp (east.) The results obtained were encouraging, but an incident occurred here a few days later which changed the direction of his experiments entirely.

M. Van Ryselberghe was in the Brussels station (north) trying experiments on the line just mentioned, and he noticed with surprise and joy that the Hughes telegraph wires going towards Ostend was creating more disturbance, by induction on the telephone wire, than a certain other wire which on the previous day was the most troublesome. The two wires seemed to have changed sides. On investigation it was found that the Hughes instruments on the two lines had changed places. The trouble was therefore due to the same instrument. On a comparative examination of the two sets of instruments, the transmitter of the less troublesome set was found defective in such a way that the currents of the battery were not sent into the line with wonted abruptness, because the contact was only gradually established. This observation was the "apple of Newton" which led M. Van Ryselberghe to think in the right direction, and furnished him the key to the solution of the problem. The disturbance was evidently due to the sudden character of the impulses of current passing over the wires. If he could in any manner make them begin and end more gradually in each wire by suitable modification of the telegraph instruments, then the telephone wire would be free from disturbance. Having thus succeeded in tracing the difficulty to its origin, the remedy was soon forthcoming in the condenser and in the graduating electro-magnets.

The history of the invention is, as we see, quite as interesting as the invention itself, and it is not devoid of elegance. Others who have explored this field of invention doubtless have stumbled repeatedly upon this little "point," but evidently without perceiving its relation to the problem. M. Van Ryselberghe stopped to study it, and thus found out its bearing. It is not the first time that a trivial circumstance, entirely accidental and apparently of no importance, has brought the experimenter or the inventor in sight of the very path he sought to reach by a more circuitous route. This goes to show once more that in scientific study every little detail is worthy of study: for it is often in the least promising quarter that the missing link to an important principle or a useful device is to be found.

TELEPHONE HERALD

VOL. III.—No 6. NEW YORK, FEBRUARY 9, 1884. [5 CENTS A COPY.

The Van Ryselberghe Telephonic System.

BY J. BANNEUX.

The experiments carried on with this system for more than a year past on the telegraphic lines of the Belgian government have caused considerable excitement in Europe. They were first heard of, with a very encouraging result, in May, 1882, when correspondence was carried on between Brussels and Paris, a distance of 320 kilometres (199 miles), simultaneously by means of

FIG. 1.

the telephone and of the Morse apparatus with interrupted currents, on a single iron wire of the aerial telegraphic line extending between the two capitals. Since then the invention has been completed and improved to such an extent that it is actually applied in Holland, on a telegraphic line of 18 kilometres, from Amsterdam to Haarlem, and, after a satisfactory trial on the telegraphic line between Antwerp and Brussels, a distance of 37 kilometres, it is to be immediately put in general use on the Belgian telegraphs, to provide telephonic service between the different cities of that country.

M. Van Ryselberghe has aimed at two objects: first, to make telephonic communication possible by means of a single wire, with ground connections, and forming part of an ordinary telegraphic line, by suppressing the disturbing effects of induction and leakage due to the action of neighboring and parallel wires; second, to utilize the wires of these lines for telegraphic and telephonic transmission at the same time. He obtains the double result by the graduation of the telegraphic currents, and by the separation of the telegraphic and telephonic currents in the stations connected.

Heretofore attempts have been made to overcome induction in the telephonic induced or secondary circuit itself, and the most satisfactory method of doing this has been to use a looped or metallic circuit, the two wires of which are arranged in a helical manner, either in the cables or on the poles. M. Van Ryselberghe, on the contrary, by acting on the inducing or primary telegraphic circuit, strikes the evil at the root—that is to say, induction at its source.

GRADUATION OF TELEGRAPHIC CURRENTS.

It is well known that the most marked, and consequently the most troublesome, induced currents caused by

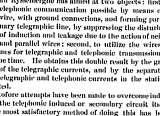

FIG. 2.

telegraphic action are those which correspond to the closing and the opening of the inducing circuit, and their intensity is directly proportional to that of the currents which have given rise to them at those two periods of the formation of a telegraphic signal; therefore to *graduate* the emission and the extinction of the primary current in such a manner that it may increase regularly from zero to its maximum and diminish regularly from its maximum to zero, is to reduce the strength of the induced currents and to *graduate* them, that is to say, in line, to make the vibrations of the telephonic receiver correspond to telegraphic signals of the same duration.

After having tried to obtain the requisite graduation by the use of keys, which automatically varied the resistance of the primary circuit, the inventor obtained infinitely better results by employing electro-magnets and condensers which accomplish the purpose in a purely electrical manner without necessitating any modification in the ordinary telegraph keys.

In Fig. 1 are shown two lines l_1, l_2, running close and parallel to each other. The key is shown at M and the relay at R. At S is shown a straight electro-magnet having a resistance of about 1050 ohms, interposed between the battery P and the key M. The currents sent over the line l_1 by the key M have no effect on telephone T_1, or are very much weakened, and their direct effect on telephone T_2 is considerably weaker than it would be without the use of the electro-magnet E. The result is better still when in addition, a condenser of about 0.5 microfarad is interposed between the line and battery connections of the key (Fig. 2). Finally, the telephones T_1 T_2 both remain absolutely silent, whatever may be the strength of the battery, when the condenser C (Fig. 3) is made to form a derivation to the ground between the two electro-magnets E_1 E_2, which then have a resistance each of 500 ohms. In order that the experiment may succeed, it is necessary that the line L_1 should have a certain length; the resistance of the relay R should not be lower than 300 ohms, and it has been found that a condenser having a capacity of two microfarads answers for the greater number of telegraphic installations. It is clear that the graduating electro-magnet S is not necessary if the telephonic currents pass through the coils of the relay R, *of the vesting station*.

In the case of the Hughes telegraph apparatus a marked retardation of the rise of induction is obtained by merely doing away with the shunt around the armature, without any other provision for graduation. It is preferable to include an electro-magnet of 1,000 ohms in this shunt; but

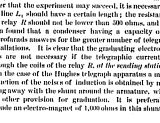

FIG. 3.

the combination which harmonizes best with all the variable conditions of the lines and apparatus is that shown in Fig. 3, namely, in each terminal station a graduating electro-magnet for the battery (E_1), another for the line (E_2), and a condenser (C) branching from the line to the ground.

A very interesting application of the anti-induction system has been made in Belgium, after experiments of M. Van Ryselberghe and M. Buels, chief of station, on a wire of 40 kilometres running the Hughes duplex, between Brussels and Antwerp. The working of this wire produced in the contiguous wires an intense telephonic disturbance, which it was necessary to overcome without interfering with the adjustment of the telegraphic balance of the line. The arrangement shown in Fig. 4 solves the problem completely. The two sides of the Wheatstone bridge are represented by two electro-magnets E_1 E_2, with movable iron cores; the balance is effected in the usual manner by means of the rheostat R; then in transmitting interrupted currents, the length of the cores presenting the coils is varied to such an extent that the equilibrium may remain constant under the influence of the static and dynamic effects produced in the electro-magnets. The graduating condenser becomes unnecessary.

It results from these details: First, that on a given telegraphic line, including a certain number of wires, a telephonic service may be established by means of a single wire with ground connections, when all the other conductors, common and parallel to it, which transmit telegraph currents, are provided with the anti-induction arrangement; and, second, that if all the wires without distinction are thus provided, any one of these whatever is capable of duplex telegraphic-telephonic working, safe from the perturbations caused by induction, and free from due to leakage of currents from one wire to another, as experience shows. In the first case, one of the wires is lost for telegraphic purposes; in the second, the absolute identity of the telegraphic and telephonic circuits would give rise in practice to such inconvenience that the combination would scarcely be acceptable. A simple observation has furnished the inventor with the directions for making the two services as independent as they can be. In Fig. 5 is shown a simple telephonic circuit T L T_1, having a shunt K M to the ground. A condenser of at least 0.5 microfarad capacity is included at C, and a resistance of 500 ohms or

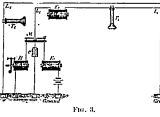

FIG. 4.

more at R; the resistance of the telephones T T_1 may vary from 0.1 to 300 ohms.

Whether the shunt K F M be connected or removed, the person listening at the telephone notices no difference in the intensity of the telephonic currents. We have tried the experiment on aerial lines of 40 to 110 kilometres, composed of iron wires 4 millimetres in diameter, and on that between Brussels and Paris, of 5 millimetres, with a length of 320 kilometres, as well as on the submarine cable between Ostend and Dover (138 kilometres). As to the proportions of resistance to be established between the line, the telephonic receiver, the secondary wire of the microphone transmitter induction coils, the battery, the microphone and the primary wire of the induction coil, experiments have shown that, *contrary to the laws* recognized in telephony, *it is better having only a few* turns of large wire *work perfectly on aerial lines of over* 200 kilometres, and that the results are the same when the factory wires into the inducing resistance at the transmitting station is diminished to the greatest extent possible. It is for this reason that M. Van Ryselberghe employs, as generators of electricity, batteries of very feeble internal resistance, such as accumulators, and that he multiplies the microphonic contacts by coupling them in multiple circuit.

(To be continued.)

Telegraph Wires Underground.

As our readers are aware, many of the telegraph, telephone and electric light companies in this country have devoted much time and money to experiments with underground wires. Among these is the Postal Telegraph Company, whose wires enter Chicago and run to its offices

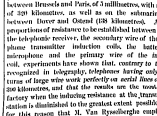

FIG. 5.

there in the heart of the city underground. They are laid in lead pipe in an iron box, and have recently, it is said, without failure since last August. For river crossings the Postal Company uses the Bishop gutta percha cables, with 300 pounds to the mile copper conductors and very heavy insulation, and also the Day kerite. Philadelphia will be erected underground with the Phillips patent lead covered cables.

In Washington the Postal Company is using a different appliance—what is called Hartlove's system. A trench is dug below the frost line; in this is placed a wooden trough, the bottom of which is first covered with asphaltum. On this asphalt bed are laid a set of wires strung

AN HOUR WITH EDISON.

Professor Edison's laboratory, in size and external appearance, resembles a country church. The interior, however, is not so church-like. The first apartment is a reception room, on the right of which is the private office, containing a large library of scientific works. Beyond these there is a large room containing materials and a number of glass cases filled with expensive physical and chemical apparatus. The machine shop at the rear is furnished with the best of machinery and tools, and is kept constantly in operation in carrying out the plans of Mr. Edison. On the second floor there is a single spacious room, which is the laboratory proper. Here, upon the walls, are shelves which are thickly studded with bottles, jars, and boxes, containing all known substances, both common and rare. It is a chronic habit of Mr. Edison to purchase every rarely discovered substance, so that it will be at hand should it be required. The Professor states that no substance can be named that is not included in his collection.

In the middle of the floor there is a stand containing a great number of batteries, from which wires run in all directions. Beyond is a table upon which, among other pieces of apparatus, there is a large induction coil, capable of yielding a spark 12 or 14 inches in length. Here also is the carbon relay, the progenitor of all existing carbon telephones, "motorphones," and other instruments dependent on the changeable conductivity of carbon under a varying pressure.

No one can pass by the phonograph, and the Professor himself does not tire in experimenting with this wonderful machine.

One phonographically cultivated can no longer be satisfied with "Mary had a little lamb" and selections from Mother Goose, now the phonograph can sing, and not only a simple melody, but a duet, and even fora-ch you with an accompaniment and applause at the same time.

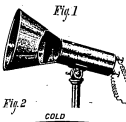
The phonograph which Mr. Edison uses in his laboratory has a double mouth-piece, and the machine will faithfully reproduce a duet sung in it; but the most interesting performance is to hear the Professor sing a duet alone. Singing first the air of "John Brown's Body," he then, and afterward the bass over the same matrix while listening to the air reproduced by the instrument, he produces a matrix which will sing both treble and bass. Not satisfied with this, he whistles Yankee Doodle, and finally, over the same matrix, talks in a loud voice, so that when the whole is reproduced we have a first-class street concert band, which is like this: Two fellows singing John Brown, another whistling Yankee Doodle, and a portwhich citizen crying from an upper window, "Get out! Go away! If you can't sing better than that the police will arrest you! Pollice! police!"

In the extreme rear end of the laboratory, among a load of tuning, jars, accumulate and pneumatic apparatus, there are telephone wires, with which are connected a carbon transmitting telephone and a receiving instrument. Standing some 8 or 10 feet from the transmitter, Mr. Edison said, in an ordinary tone of voice, "Do you take the SCIENTIFIC AMERICAN?" Answer from the other end of the line. "I do." Q. "What do you pay for it?" A. "Three dollars and twenty cents a year." Q. "What is your opinion of it?" A. "It is the best of its kind." Q. (while cramphing a paper) "What am I doing now?" A. "Crumpling a paper." Then followed music from a music-box of the smallest size, and other tests, showing the wonderful perfection and power of the instrument.

The thermo-telephone, explained by the Professor, although at present without special practical value, is certainly a novelty. It consists of a thermopile having placed in its collecting funnel a hard rubber disk, as shown in the first engraving. A sound made in front of this disk is heard in a receiving telephone connected with the thermopile.

The rationale of this is at once apparent when a strip of hard rubber is placed against the lips and heat, as shown in the second engraving, so that the strip will be alternately contracted and expanded. The difference in temperature is very perceptible, the convex surface being cold and the concave surface warm, and, however small the vibrations which render the surfaces alternately convex and concave, the result is the same.

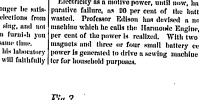
We witnessed an experiment illustrative of the principle of Mr. Edison's electro-motograph, a telegraphic instrument in which the sounder is operated without magnets. In this experiment, which is illustrated in Fig. 8, a strip of chemically prepared paper is laid upon a metallic surface, which is connected with one of the battery wires, and a platinum faced spring, which is attached to the other battery wire, is taken in the hand and pressed firmly on the paper strip; at the same time force is applied to the thumbtap of the lungth of the strip. A telegraph key is placed in the electric circuit, and when the current passes through the paper the salt contained by it is instantly decomposed, so that it acts as a lubricant, permitting the spring to slide easily on the, paper while the current passes, but immediately the current is broken the friction is sufficient to stop the spring.



THERMO-TELEPHONE.

The best solution for saturating the paper is made by dissolving 1 lb. of sulph. soda in 1 gallon of water. Any of the sodium salts will answer.

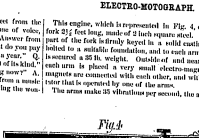
Electricity as a motive power, until now, has been a comparative failure, as 90 per cent of the battery force was wasted. Professor Edison has devised a novel electrical machine which he calls the Harmonic Engine, in which 90 per cent of the power is realized. With two small electromagnets and three or four small battery cells, sufficient power is generated to drive a sewing machine or pump water for household purposes.



ELECTRO-MOTOGRAPH.

This engine, which is represented in Fig. 4, consists of a fork 21/2 feet long, made of 2 inch square steel. The curved part of the fork is firmly keyed in a solid casting which is bolted to a suitable foundation, and to each arm of the fork is secured a 35 lb. weight. Outside of and near the end of each arm is placed a very small electro-magnet. These magnets are connected with each other, and with a commutator that is operated by one of the arms.

The arms make 35 vibrations per second, the amplitude of



EDISON'S HARMONIC ENGINE.

which is 1/4 inch. Small arms extend from the fork arms into a box containing a substance pump having two pistons, one piston being attached to each arm. Each stroke of the pump raises a very small quantity of water, but this is compensated for by the rapidity of the strokes. Mr. Edison proposes to compress air with the harmonic engine, and use it as a motive agent for propelling sewing machines and other light machinery. The power must be taken from the fork arms so as not to affect the synchronism of their vibrations, otherwise the engine will not operate.

SCIENTIFIC AMERICAN SUPPLEMENT No. 138

M. GAIFFE'S MODIFICATION OF EDISON'S CARBON TELEPHONE.

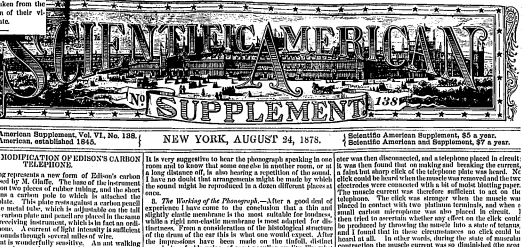
THE engraving represents a new form of *Edison's* carbon telephone, devised by M. Gaiffe. The inner face of the instrument is supported upon two pieces of rubber tubing, and the short pedestal contains the fixed pole to which is attached the square carbon plate. The lever receives against a carbon pencil contained in the metal tube, which is adjustable on the rod standard. The carbon plate and pencil are placed in the same circuit with a receiving instrument, which is preferably an ordinary Bell telephone. A current of light intensity is sufficient to transmit the sounds through several miles of wire.

The instrument is wonderfully sensitive. As not walking across the carbon plate produces a sound in the receiving instrument like the running of cabbits on a sanded floor. Scratching the surface of the carbon with a piece of paper makes a sound like the grating of iron, and rubbing the back of a feather on the carbon makes in the receiver a sound like hummers.

Blowing on the plate produces a sound like the rushing of waters.

Conversation in any part of a room in which the telephone is placed can be plainly heard in the receiving instrument.

It amplifies sounds in a marvelous manner, and is said to be the one that the microscope is to the eye. We take the engraving from *Illustration*.



LABORATORY NOTES.

By JOHN G. MCKENDRICK.

1. *Carl Zeiss' New Oil Immersion Lens.*—This is a 1/24th-objective, on the immersion system, in which the fluid used is oil of cedar-wood. For amount of light, clearness of definition, resolving power, and flatness of field, it is superior to any lens I have worked with. For use in biological investigation, it does not require any special arrangement of light. In examining such objects as blood-corpuscles or salivary cells with very high powers it is of great advantage to be able to use cover-glasses of ordinary thickness, and to have a still viscously-working distance. This is secured by Zeiss' lens. I have found that, with ordinary No. 6 and 7 Hartnack objectives, more light is obtained by using them as immersion lenses with a drop of equal parts of oil of cedar-wood and olive oil. The method of using fluids of high refractive index, on the immersion principle, seems to me likely to lead to valuable results. With oblique light, cutting off light from the mirror, the performance of *Zeiss'* lens is remarkably good.

2. *The Phonograph as a Transmitter.*—By placing Hughes' microphone on the disk of the phonograph the latter will transmit the sounds recorded on the tinfoil to a telephone at a distance. Thus we have a combination of microphone, phonograph and telephone, which promises to be of use. It is very suggestive to hear the phonograph speaking in one room and to know that some one else in another room, or at a long distance off, is also hearing a repetition of the sound. I have no doubt that arrangements might be made by which the sound might be reproduced in a dozen different places at once.

3. *The Working of the Phonograph.*—After a good deal of experience I have come to the conclusion that a thin and slightly elastic membrane is the most suitable for hearing, while a rigid non-elastic membrane is most adapted for dictiontones. From a consideration of the histological structure of the drum of the ear this is what one would expect. After the impressions have been made on the tinfoil, distinct speech, in a feeble voice, of most peculiar quality, like that one would imagine to be the toast of the fairies of old, can be heard from one of Marey's tambours, by bringing the point of the lever on the surface of the phonographic cylinder. With this method there is almost no friction, and consequently the sounds on the tinfoil are not quickly rubbed out. By connecting a tube with the tambour and carrying it from the mouth to the ear, sounds may be heard, even as speech, after the marks have been so erased from the tinfoil as to be scarcely perceptible to the eye. Thus the tambour, when so used, may be said to be a microphone.

4. *The Microphone.*—I have tried many experiments with the ingenious arrangement of Mr. Hughes, and have been much impressed with its extreme sensitiveness. It may be used in the same manner as the telephone for delivery of the inductive machine. When fixed to the box of a monochord the slightest touch of the wire with a lucifer-match will resonate loudly in the distant receiving telephone. Such a combination would, I think, have a most distinctly a compliment piece of gauze thirty yards away; when attached to the throat by an india-rubber band, the faintest whisper is magnified, and it transmits the smoothest sound from a powerful biceps.

5. *A Lecture Experiment.*—Place the heart of a frog on the electrodes of the microphone in connection with a receiving telephone, and the pulsations of the induction-shocks will then be conveyed by the sounding rod and fire of the coat of light on a transparent screen. This has often been observed by physiologists, but, considered as a lecture experiment, it is very instructive.

6. *The Sensibility of the Telephone to Feeble Currents.*—As an example of this, I may instance the following experiment: The platinum electrodes of a Bell-telephone are put in two polarizable electrodes of Du Bois-Reymond, so that the transverse section touches the one electrode, and the longitudinal surface the other; the current thus obtained, when the telephone is sensitive, gives a distinct sound. I have derive the spot of light from and to and of the scale, about three feet in front of the galvanometer; the galvanometer was then disconnected, and a telephone placed in circuit. It was then found that on making and breaking the current, a faint but sharp click of the telephone plate was heard. No click could be heard when the muscle was removed and the two electrodes were connected with a bit of moist blotting-paper. The muscle current was therefore sufficient to act on the telephone. The click was stronger when the muscle was placed in contact with two platinum terminals, and when a small carbon microphone was also placed in circuit. I then tried to ascertain whether any effect on the click could be produced by throwing the muscle into a state of tetanus, and I found that in these circumstances no click could be heard at all. In other words, during the state of muscular contraction the muscle current was so diminished the negative variation so sufficed as to be unable to affect the telephone so as to produce audible sounds. The telephone thus was used instead of the galvanometer in a physiological experiment.—*Nature.*

JABLOCHKOFF'S DYNAMO-ELECTRIC MACHINES.

AMONG recent improvements of the dynamo-electric machine, the device by M. Jablochkoff is worthy of notice. In this form, which is illustrated in the engravings, ashort bobbin of coiled insulated wire is placed between two soft iron cheeks or disks, which are fixed on a soft iron shaft that passes through the bobbin, but is insulated from it. These cheeks are curved backward, the coil either extending beyond them or coinciding with them as required. In order that the principle on which this machine acts may be understood, suppose an electric current is passed through the coil; each of the cheeks will then become magnetic, one pole, north or south, being presented at the circumference of the one and at the center of the other disk, and the opposite pole being presented at the center of the former and at the circumference of the latter. The two disks thus magnetized being united at their centers by the soft iron shaft, the shaft would form a magnet having a north or south pole at the circumference of the one disk, and the opposite pole at the circumference of the other. Conversely, when the two cheeks are magnetized so as to have polarity of the kind just mentioned, and when this polarity is alternated, then the central coil has currents of alternate direction induced in it. For thus magnetizing the cheeks the following arrangement is employed: Notches are cut in their periphery, so that they present a series of projections like those of a toothed wheel, and they are placed so that the coil exists as it were between the teeth of the wheel. They are caused to revolve in joining teeth of the wheel. They are caused to revolve in front of the two stationary magnets or electro-magnets, so arranged that as the cheeks revolve their projecting parts successively present two opposite poles of these magnets, and thus the alternating polarity required is induced upon them, and corresponding currents are induced in the central

TELEPHONIC COMMUNICA

ALTHOUGH six years have elap the invention of the telepho practically useful form, it has not, i this country is concerned, at least, position which it ought to occupy are several reasons for this appare of a really useful invention, the m portant of which is probably the p the Post Office, though the diff determining the rights of the holde patents has had something to do; delay. No doubt, too, there is some dissatisfaction the part of would-be us judging by their experience of a ventions, are, perhaps, justified in t improvements which will appea instruments at present employe telephone as devised by Bell, that holding the first place as the recei strument, is rarely employed for tran purposes—the instruments in whic conjucts are used being preferred reasonthat they allow of stronger cu currents being sent than are possib a magnet alone is available. Of thes ments there are several seeking its favour, some having many carbon l as the Jobr, the Crossley, and W while others have only one, as the phone. The fact that among ad known forms as the Edison, Bl Hummings so great a difference in the of contact pointeis found, leads Col the president of the Society of T Engineers and Electricians, whoever on the subject last week before the of Arts, to the conclusion that we a long way from comprehending t meaning of the work performed pressure of the carbon. So many an however in the last two or three ye devoted to the study of the telepho we may safely assume a marked ch any importance will be made in t struction, and those who can find a it may instal it with the certainty the answer its purposes even if somethin is found next year. The history telephone affords an instance of the d of intending even a meritorious in for although it is years have passed since it was patented, it cannot yet be said widely used as it deserves to be. It that in this country the application telephone has been delayed owing existence of rival companies, par mainly in consequence of the ac the Post Office, which, according to courts, is entitled to the monopoly claimed. The merits of the now us transmitting messages are, however fully appreciated, and there is not, subscribers whenever it is proposed t fish an "Exchange." In Germa France, in Belgium, in Italy, and countries on the Continent the s system of telephoning is in full we Berlin, for instance, it has reache degree of perfection which is indee the fact that any person can ha minutes' conversation with any of t scribers to the exchange by the expe of 50 pfennige (about 5½d.), by the p of a list of subscribers, and in this exchanges are already in existence cost the members about one pe

is certain, that the telephone exchange is a growing innovation which will ultimately absorb a great deal of business that is now done by telegraph, especially local messages, for there are several reasons why those who desire to send them would prefer to speak direct to their correspondents instead of writing the words on a form, and would also prefer to receive the answer in a voice that can be recognised instead of on one of the familiar forms. It will be difficult to make a general arrangements of the nature of the existing telephone exchanges, but it is satisfactory to learn that the Post-office is prepared to extend existing facilities wherever the public demands warrant the requisite expenditure.

CART AND WHEEL-MAKING.—XV

(Continued from page 669, Vol. XXXIV.)

By J. CHARLES KNOX.

IN the course of cart-making, much of the painting may be done as soon as the body is finished. In the trade, the body is often finished painting while the carriage or cart is yet in hand, and as the body has as much contact with the rainbows and the heads, in the riders getting in and out, it is the last course to have the body finished first. It will be useful to describe in turn the process of carriage-painting as followed in the best English shops. I, therefore, proceed to give full working details of painting on the body of a carriage, with a few hints of what to do if you would desire. You may have perfect confidence that the careful accomplishment of the job in a short time if the directions are followed; the time includes hardening stoutness, and flexible dexterity of wrist and fingers.

Before commencing to paint, be sure you have a shop secure from currents of the dust, and be careful to get your body and carriings free from dust, especially in the corners, and the wood free from glue, grease marks, smoke, from any part of the wood having been scoured in the last framework. Should any be on, scrape and wash off with turpentine.

The colours, as the best pigments are termed, are the priming colour for first, second, and third coats of paint. The priming colour is first, second, and third coats. The finny colour, by some different colour, to be finished by varnish on the last coat of colour, and Japan on the iron-work, and black paint where wanted. "Filling-up" is intermediate coat of paint between the priming coat of paint, and the first proper coat of paint; the last termed colour, and is a special mixture. How to mix these colours in proper proportions of ingredients will be fully explained, but it will be seen it is the simplest part of the process of painting. To lay on the first coat, and "flat-down" between the drying of each coat, requires the care of forethought and sensitive dexterity of touch.

To give confidence to anyone disposed to try his hand at painting, I may mention that I had to appraise a painter to do the work on a large estate near London. In closing a sale I also met out of several who wanted the job, I selected a man who had done painting before, and selected a farm-labourer who had never done such work: within a week's time he added finished a first-rate oak-graining job, with a fine flowing coat of varnish. His success was due to cleanliness, forethought, method, and a critical sense of touch in handling a brush.

As briefly as possible I proceed to tell how to use the various paints, "up-on" and flat-oil for varnishing. Priming colour is made of white-lead (as sold ground in oil) 2lb.; linseed oil, 1 pint, thoroughly well mixed, then add turpentine, 1 pint. The next is cream-colour, to darken to lead colour of any shade, add lamp-black, and add up till of the consistency of milk; to insure quick drying, add to the mixture 2oz. of "Japan"—this is sold ready for use.

I am obliged to remark now that as much of your cart as can be taken easily apart, must be so done so, before beginning to paint.

The body should be upside down on trestels,

THEILER'S TELEPHONE RECEIVER.

THE telephone receiver recently patented by L. Mouse, Theiler, of Canonbury-road, S differs from its predecessors in dispensing with an armature, the lateral vibration of the electro-magnet itself being utilised. In previous systems in which an electro-magnet is used, the sonorous vibrations are due either to the motion of an iron diaphragm or armature placed close to the poles of the electro-magnet, or to the expansion and contraction of the magnet itself. In Theiler's telephone the electro-magnet may be of the usual U shape, and may consist either of soft iron or of hardened steel, permanently magnet-ized, wound with a suitable number of turns of insulated wire. This electro-magnet is fixed in such a manner that the vibration of either one or of both its limbs is communicated to a diaphragm or diaphragms. The parentees also employ two separate electro-magnets in the same circuit, and utilise the vibration of both magnets in the manner described. By attaching a light disc or discs to the vibrating limbs the diaphragm may be dispensed with. Fig. 1

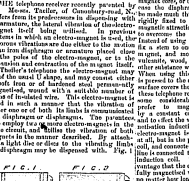

FIG. 1. FIG. 2.

represents one of the telephone receivers provided with two diaphragms or sounding boards, as usual, and in the two limbs or cores of the electro-magnet are fixed by silent tongues. These tongues are in contact with the two diaphragms and with the magnet, as shown. The poles of the electro-magnet are brought very close together by being shaped as shown, and the middle part of the magnet is firmly screwed to the case of the instrument. The ends of the bells surrounding the magnet-cores may be attached as usual to two terminals, or soldered to a flexible conductor communicating with the other parts of the telephone apparatus. When a voluntary current is sent through the bobs of the electro-magnet, the extremities are rapidly attracted and repelled and thevibratory motion of the magnet cores being communicated to the diaphragms or sounding boards, the latter are set in vibration of varying amplitude produced by a current of varying strength, as in all other telephones. Instead of using the electro-magnet in the continuous circuit, it may be employed to work the vibrations that it sets up, and it is even practicable to make it of the form shown in Fig. 2, where the electro-magnet represented consists of two limbs or cores, a sole piece, and pole caloudons, the whole being screwed together and peculiarly constituting one conspicuous piece of iron carrying the two coils. In Fig. 2 only one of the limbs or cores of the electro-magnet is attached to the diaphragm, the other limb being held fixed by a screw.

Sometimes the patentee hings one or the magnet cores, or both, in a cradle-piece in which are the diaphragms or sounding boards are to be made much thicker than when the cores are rigidly fixed to the sole-piece, because the magnetic attraction of the poles has then only to overcome the resistance of the diaphragm. Instead of using a diaphragm, they sometimes fix a stem to one of the cores of the electro-magnet, and mount thereon a light disc of cuticumite, wood, ivory, gutta-percha, or any other substance which is capable of vibrating. When using this telephone receiver, the disc is pressed to the ear in such a manner that its surface covers the aperture of the ear. When three telephone receivers are used on a line of some considerable length, the patentees prefer to magnetise the electro-magnet by a constant current from a local battery, and to employ the receiver in the constant battery arrangement inductively, and not directly. The electro-magnet is, then, not in-cted in the line at all, but is the primary circuit of an induction coil, and connected with a local battery. The line is connected to the secondary circuit of the induction coil. This device possesses the advantage that the electro-magnet can be powerfully magnetised with very little battery power, no matter how long the line may be, and that steel magnets are entirely dispensed with. It is not necessary to have a separate battery for this purpose, as the microphone battery may also be used for the telephone receiver. The shape of the vibrating electro-magnets is immaterial, as they may be made of a variety of forms.

MEASUREMENTS AND AMPLIFICATION OF TELEPHONIC VIBRATIONS.

"EVERYBODY is aware," says M. Salet, in a recent paper to the Paris Academy, "that it is impossible to hear through a thin sheet of pine, such as is known in an apartment that is otherwise quite closed. This case the sonorous vibrations transmitted by the air agitate synchronously the wooden partition, and this in turn transmits its movements to the outer air as a piston would. This familiar experiment must have struck physicists, as giving a result of the exquisite sensibility of the ear. The vibrations of the board are indeed very small, hardly greater than those of the membrane of a telephone receiver in action; but these latter are so weak that their existence has sometimes been called in question. They exist, however, and I proceed to give an idea of their amplitude."

The method adopted by M. Salet was as follows: He fixed on the iron diaphragm of a Bell receiver a small glass disc weighing 0·15 gramme, and in front of this was suspended a second, furnished with a Newton's rings. The arrangement resembles that devised by M. Forbes for study of vibrations. When one examines at a distance of about sixty centimetres from the telephone, or sends into the receiver a sound, the phonic current from a good transmitter (that of Ader, *e.g.*), the rings are observed to lose their distinctness, and disappear if the voice be a little forced. They vibrate, indeed, synchronously with the diaphragm, and nothing is simpler than to calculate, from the amplitude of their oscillations, that of the vibrations of the membrane.

It is certain, however, that the surfaces of the diaphragm with the discs must lessen the movements slightly; thus the results obtained are probably by defect rather than by excess.

To estimate the displacement of the plate, M. Salet arranges before the receiver telephone, which is connected to emit a continuous sound, a turning disc pierced with slits, like that of a physiological apparatus. He is then, with a certain velocity of rotation, the rings reappear with distinctness. On blowing a little more slowly on the disc, so as to make it act as a syren, it is found that the sound produced is so unisonous with that it is emitted by the telephone, if it be slightly lowered or raised, immediately the rings oscillate, at first slowly, then with such rapidity that they become invisible again. While they oscillate one may easily estimate their displacement; in one experiment, the is of the diaphason being emitted with the transmitter with the vowel *a* [æ], and with moderate intensity, the displacement was exactly half that the distance of two consecutive rings, and the amplitude of vibrations of the receiving plate would then be 2 to 3 one-thousandths of a millimetre.

If there be sent into the telephone currents of different intensities, but very weak, and each of which, *e.g.*, does not cause the motion of the rings beyond half the distance separating them, one may, by considering a point on the plate, infer from its brightness the intensity of the current. This singular galvanometric process, says M. Salet, might undoubtedly be utilised in the microscopic receiver.

In connection with the foregoing, we will here proceed to notice an interesting device for augmenting the dynamic effect of the vibrations of diaphragms, recently described by Mr. W. B. Cooper, before the Franklin Institute.

When a cord is passed over a resisting pulley it is well known that the tension on a pull on one side proportioned to the clearance of the surfaces in contact and the pressure on the axis. This pull is due to the friction of the surfaces on each other, and increases in nearly, if not exactly, the same ratio as the pressure. Now, if the pulley is loose on the shaft, and we pull a cord over it, we have the same forces exerted at the pulley and minus the friction of the shaft; if, however, the pulley is attached to the shaft and rotating towards the end pulled, then the result at the other end is the force applied *plus* the amount derived from friction on the surfaces of the pulley. This is the principle of the device, which, in the simple form, Mr. Cooper calls a phonic tachygraph. To one end of a wire or band by which a diaphragm or other pulsating body, then he gives a sudden or several turns round a drum or pulley which is loaded in one direction. To the other end he attaches a style, bearing a point ad-apted to indent a fixed sheet-metal passed under it at uniform speed by suitable mechanism. Mr. Cooper has thus reduced lines of the thickness of writing paper by the impact of the voice on a diaphragm of the size used in the phonograph.

The principle, he points out, is applicable to the telephone, both for the purpose of increasing the intensity of the electric impulses transmitted, and augmenting their effects at the receiving station. At the transmitting station, *e.g.*, the mouth, or by means of leverage a greater, amplitude of vibration may be given to a steater diaphragm; or an armature, compelled by a spring, playing before the poles of a magnet. The form of transmitter is, however, to my advantageous in which increased power is obtained by the use of a fit the telephone may be rendered available for greater dis-tance. For increase of power in the receiver, Mr. Cooper has devised a plan in which to applies the principle somewhat differently. A number of these electro-magnets are set rapidly in a frame, and their draft upon an armature on the face of the drum is increased by th- agency of friction of a wire or band passing round the drum, and connected with the armature and with a diaphragm. For details of the working we must refer to the original paper.

DYNAMO-ELECTRIC MACHINERY.

TELEPHONIC PERTURBATIONS.

CHRONOLOGY OF TELEPHONIC DISCOVERIES.

IN view of the partiality with which the history of telephony is presented in different semesters, the editor of *Scientific Enterprise* (M. Du Moncel) offers the following a brief chronological resume, which is as follows:—

1854.—First idea of electric transmission of sound by means of undulations.—Charles Bourseul.

1856.—Diaphragm.—M. Th. Du Moncel of the transmission of telegraphic currents by over interrupters with metallic contacts to be alternately closed, with the pressure exerted on them. Experiments proving the truth of this principle with the substances of medium conductivity.

1861, 1872, 1874, 1876, &c.

1857.—Representation of vibrations produced by the voice by means of a stretched membrane before which are spoken, by M. Leon Scott.

1859.—Application of M. Scott's system to the electric transmission of sounds, by M. Reiss.

1863.—Application of the principles of variations of intensity of currents with pressure to making tubes with variable resistance, by M. Clerac and Rimmery.

1865.—Discovery by Mr. Wright of the reproduction of sounds by a condenser.

1867.—Application of the electric transmission of sound of undulatory currents by Mr. Bell.

1874 (14th Feb.).—Discovery by Mr. Bell of the magneto-electric telephone.

1874 (19th April).—Application to the Reiss transmitter, or to Bell's liquid transmitter, of a contact with permanent action for electric transmission of sounds, by Mr. Dunnegh.

1877 (26th July).—Application of soft carbon contacts to the Reiss transmitter, to furnish more developed undulatory currents in telephonic transmission, by Mr. Edison.

1877 (30th Oct.).—Application of hard carbons with one or two contacts to the same transmitter, for the same purpose, and at the same time to form a receiver capable of repeating speech, by Mr. Hughes.

1878 (Jan.).—Discovery by Mr. Hughes of a telephonic action from conditions of the same movement in such as to magnify sound; an apparatus called by him the microphone, the cause of which was unknown.

1878.—Discovery by the same savant of the transmission of sounds by the mere contact by the voice on crushed fragments of carbon, or conductive powders, supplied to metallic electrodes connected with a battery and a telephonic circuit.

1878.—First application of the microphones to the hearing at a distance of sermons and divine service, by Mr. Crossley.

1878.—First application of the same instrument to hearing an opera, by M. Pataski.

1879.—Reproduction of speech by an iron wire used as receiver, by M. Ader.

1879.—Construction of the *telephone* of Mr. Edison.

1880.—Reproduction of speech by means of the condenser with sheets of paper, by M. Hiers.

1880.—Invention of the musical reproduction of speech, by Professor Graham Bell.

1880.—Researches of Messrs. Bell and Sumner-Tainter, of the *telephone*.

1880.—Transmission of speech without a battery by the effect of permanence between fragments of iron wires, by M. Ader.

1881.—Speaking condenser with air-layer, of Mr. Dibbern.

1882.—Simultaneous transmission a long distance, of speech and a telegraphic message, by M. Van Rysselberghe. Same problem solved in another way, and in laboratory experiments by M. Mulder, in 1880.

[It may be remarked as strange that no mention is made in the statement of the harmonic telegraphs of Mr. Varley (1870), and of Mr. Elisha Gray (1874).]

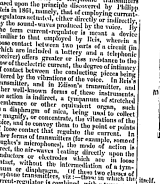
CONSIDERABLE attention has been made the subject of investigation by M. Gaulle, the well-known French electrician, and, curiously enough, his fads them to be due to the vibrations and oscillation of the two telegraph-wires in the wind. These extraneous sounds have hitherto been regarded as due to induction from neighbouring wires, but the telegraph-lines over which currents of electricity were passing; though this cause is doubtless operating, it is not the only one. M. Gaulle arranged a telephone line along the floor of his laboratory, and connected it by flexible conductors to the telephones at either end. An interruption was then purposely made in the circuit, which might be broken without disturbing the rest of the apparatus; and he soon found that the mere rubbing of the line-wire against itself generated a current which could be distinctly heard in the telephone when the circuit was broken by the key. Rubbing another metal on the line-wire produced the same effect, and the mere touching of a binding-screw upon the latter produced an audible sound, while scratching the line-wire along a file gave a comparatively loud result. It follows that the rubbing of a telephone-line against a screw or loose binding-wire will occasion currents capable of perturbing a telephonic message, and that consequently all the binding-screws should be made necessary for good telephony. A more serious drawback exists, however, in currents generated by the vibrations of the wire itself, as M. Gaulle has proved by inserting a rod of iron about 40ft. long in the circuit of the telephone, and striking it transversely with a hammer. Every stroke produced a distinct sound in the telephone, although the feeble resistance of the latter prevented a mechanical communication of the vibrations. This effect is evidently a molecular one, and reminds us of the late experiments of Prof. Hughes on electrical tension, where the mechanical vibration of iron wire was found to affect the galvanic resistance, and where the passage of a current through the wire was determined to produce a molecular twist in the latter. The vibrations produced by the wind in telephone-lines are, therefore, inimical to long-distance telephony, and the question arises, How to obviate the latter? Mr. Gaulle's action, like to obviate the latter? Mr. Gaulle's action, like that of current from zinc and carbon any such ground-lines are, of course, of no use as they are similar in construction to submarine cables, their great inductive capacity would prove a more serious hindrance than speed, and a hundred miles or less would probably render the telephones absolutely silent. Aerial wires of brass, or better still of manganese bronze, would, perhaps, solve the difficulty.—*Engineering.*

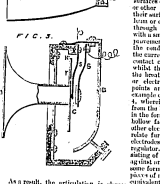
92

PROF. S. P. THOMPSON'S NEW TELEPHONES.

THE telephonic apparatus recently patented by Prof. S. P. Thompson, of University College, Bristol, is so simple and in many respects so suggestive, that it may be useful, as it certainly will be interesting, if we illustrate some of the forms devised by him. The improvements relate to telephonic transmitters and receivers, principles discovered by Philipp Reis in 1861, namely, that of employing current-regulators actuated by sound-waves, and that by the sound-waves produced by the voice. By the term current-regulator is meant a device similar to that employed by Reis, wherein a loose contact between two pieces of platinum, which are included in a battery and a telephonic receiver) offers greater or less resistance to the flow of the electric current, the degree of intimacy of contact between the conducting pieces being altered by the vibrations of the voice. In Reis's transmitter, and in Edison's transmitter, and other well-known forms of these instruments, the action is indirect, a tympanum of stretched membrane or other equivalent organ, such as a diaphragm of mica, being used to collect the sound-waves, or concentrate, the vibrations of the air, and to convey them to the point or points of loose contact that regulate the current. In other forms of transmitters (for example, somed Hughes's microphone), the mode of action is direct, the air-waves beating directly upon the conductors or electrodes which are in loose contact, without the intervention of a tympanum or diaphragm. (For these and other telephonic transmitters, see "Electricity.") The current-regulator is combined with a tympanum or diaphragm, and those in which the current-regulator is acted upon directly by the air-waves, or indirectly by the vibrations of a tympanum, such as Prof. Thompson discusses with the sound-waves, the tympanum used in Reis's transmitter; and does not employ the tympanic diaphragm of mica used by Edison's transmitter; he does not even employ any diaphragm in the sense of a partition between the current-regulator and the air-waves of the voice, as in Theiler's transmitter. In the latter instrument, the action of the air-waves act directly upon the current-regulator

itself. As a result, the articulation is clearer for musical sounds, which are only imperfectly or difficultly transmitted by telephones in which the current-regulator is affected indirectly through a tympanum, diaphragm, or partition. Transmitters of the class in which the improvements relate are ordinarily liable to two defects. Firstly, they do not articulate vocality as transmitters in which there is a tympanum appears to collect or concentrate the vibrations. Secondly, when, to obviate this difficulty, the speaker speaks with his mouth very close to the current-regulator, the moisture of his breath condenses upon the conductors or adjacent parts of the regulator, interfering with its action and spoiling the articulation. The improvements relate chiefly to means for remedying or obviating these defects. Prof. Thompson proposes to employ mirrors, sound-reflectors or reverberators (one form of which is shown in Fig. 1, by transverse section, consisting of glass, metal, wood, or other material, by which the sound-waves are turned aside from their straight or direct path, and are made to converge to the current-regulator, precisely as rays of light may be turned aside or converged by a reflector. If actual mirrors of polished metal or silvered glass are employed for this purpose, they have the additional advantage of resulting to the avoidance the presence of moisture. But in any case the mirror, reflector, or reverberator serves to collect the sound-waves as they come from the speaker's mouth, and direct them on to the current-regulator while intercepting moisture from the speaker's breath. M is the mouth-piece or tube; C is the current-regulator. It is the reverberator. An adjusting screw and an out-let cock for the water which collects in the mouth-tube are also provided when necessary. The mouth-pieces hitherto used on ordinary transmitters are not intended to serve either as reverberators or as protectors from moisture, and Prof Thompson finds that mouth-pieces for this purpose must, as shown in Fig. 2, be deep and of conical or parabolical form. Another part of the invention consists in employing, for the current-regulator, such materials as are at once sensitive to pressure, so liable, by their properties with respect to heat, to confess films of moisture, whilst at the same time they are good conductors of electricity.





Prof. Thompson prefers to use, as materials for the current-regulator, either spongy platinum, carbide of platinum, boron, coke, carbon, or elastic carbon specially prepared, having first deprived each material of its hygroscopic properties by treatment with paraffin-wax or other suitable hydrocarbon, solid or liquid. In some cases, and especially where the contact surfaces of the current-regulator are of platinum or other metal, he finds it convenient to keep their surfaces constantly moistened with petroleum or other hydrocarbon by supplying them through a cotton filament in communication with a small hydrotator or oil-vessel. The improvements also partly consist in so arranging the conductors or electrodes, or other parts of the current-regulator, that the points of loose contact can be actuated by the sound-waves, whilst they are protected from the moisture of the breath by some portion of the conductors or electrodes projecting between the contact points and the mouth of the speaker. An example of such an arrangement is given in Fig. 3, wherein the contact points C are protected from the breath by making one of the electrodes in the form of a cup, against the convex or hollow face of which the contact point on the other electrode is directed. The improvements relate further to the form of the conductors or electrodes combined to serve as the current-regulator. The current-regulator of Reis consisting of one piece of platinum resting lightly against another, is imperfect, except when, as in some forms of Reis's instrument, one or both the pieces of metal are acted upon springs or some equivalent elastic support; otherwise the contact is liable to very abrupt interruptions. In Fig. 3 is shown a current-regulator, wherein the two contact pieces are both open or loose (N, S); one of those springs is fixed to an adjusting frame B, and the other is fixed to an insulating block E, or it is found that when there are many points of contact instead of but a single pair of such points, there is less liability to such abruptness. Carbon is found to answer well for these purposes. One of the improved forms of current-regulator consists of a pencil or cylinder or rod of pressed carbon or metal tongues so connected to the current-conducting wires as to cause the next except through a piece or pieces of good conducting carbon or metal such as platinoid, or resting in loose contact against the tongues. In the instrument represented in Fig. 4, the tongues to

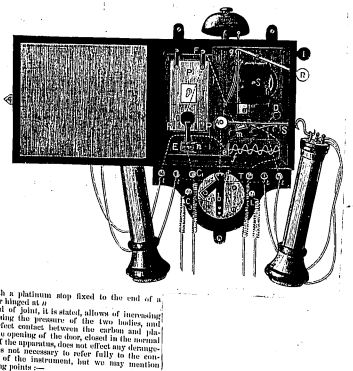
Scientific American Sept. 1, 1888.

M. DE LOCHT-LABYE'S "PANTELEPHONE."

THIS apparatus, which we, in our issue of August 25th, promised to describe, is not by any means new, as it formed one of the principal telephonic attractions at the Paris Exhibition of 1881, and it there achieved great success. It is said that persons speaking to this instrument might retire from it to a distance of 30 metres and yet the speech would be repeated at the receiving end. The instrument is sensitive to all kinds of sounds, loud or feeble, coming from long or short distances, and it is applicable to all kinds of telephonic receivers.

There is combined in the apparatus, shown fully in the drawing, the following parts: the pantelephone, the call button, *a*, *b*, of the bell, *s*, the visual signal, *g*, *h*, *i*, the interrupting switch, *k*, actuated by the weight of the receiver, and the induction coil, *c*, *f*.

The pantelephone is arranged on the left side of the figure, and P, P, P is a cork plate suspended by two small flexible springs, P; the plate bears at its lower extremity a small flat disc of carbon, *o*, which is in



contact with a platinum stop fixed to the end of a metallic bar hinged at *a*

This kind of joint, it is stated, allows of increasing and decreasing the pressure of the two bodies, and insures perfect contact between the carbon and platinum. The opening of the door, closed in the normal condition of the apparatus, does not effect any derangement. It is not necessary to refer fully to the connecting up of the instrument, but we may mention the following points:—

The pressure of the finger upon the call-button in the first station breaks the connection of the spring, *b*, with the contact, *d*, and establishes it with the stop, *c*.

The current traverses in the first station, *c*, *a*, *k*, *l*, passes by the line wire to the second station in the apparatus of which it enters by the terminal, *l*, arrives at the commutator, *A*, and the commutator lever being in contact with the stop, *8*, the current passes into the bobbins of the bell-magnet, *S*, whence by the armature, its spring, and the return wire, it returns to the negative pole of the battery in the first station.

The circuit being closed, the call-bell in the second post is put in action. This disengages the lever, *g*, *B*, which unsevers the disc, *i*. If the correspondent is absent at the time of the call, this permanent signal informs him on his return that some one desires to correspond with him.

This description will enable our readers to understand the mechanism of the apparatus.

All the regulation consists in manipulating the joint at the thumbscrew, so as to produce close contact between the carbon plate and the platinum stop and modifying, by inclination of the plate, the pressure of the plate upon the stop. This regulation is not difficult, since there is a space of more than a centimetre between the extreme positions of the stop.

This is the transmitter which M. De Locht-Labye mses with his "Hammer" telephone.

THE TELEPHONE.

*On the Retardation of Phase of Vibrations transmitted by the Telephone.**

By BENJAMIN P. TRUEMAN, B.A., D. Sc., Professor of Experimental Physics in University College, Bristol.

It was predicted from theoretical considerations by Helmholtz that a difference of phase, amounting to a quarter of a complete vibration, would be found to exist between the displacements of associated bell telephones, the receiving telephone being a quarter of a vibration behind the transmitter. A more complete theory, worked out independently by Helmholtz and Weber, gave a result of what contrariety would, and required only a small difference of phase. Recently Kreiz, in a series of delicate experiments, effected an optical comparison by the method of Lissajous' figures between the vibrations of a pair of telephones, receiving the vibrating impulses of tuning-forks armed with mirrors. The experiment is a difficult one to be performed under conditions not free from objection. The author has proposed the following method of observing. A pair of bell telephones are suspended by wires of about a metre in length, so as to oscillate as pendulums, to frames as disposed of the vibrating bodies the point of rest of each telephone, and at some little distance from it in the plane of swinging, is placed a steel magnet, so that the lengths of the wires have been so adjusted that the telephones shall swing in identical periods, one telephone is not swinging. As it alternately approaches and recedes from the magnet, the induced currents traversing the second telephone set it swinging. In every case the difference of phase observed was a quarter of a vibration.

In the case of Edison's telephones which transmit vibrations by varying the resistance of a circuit traversed by varying electromotive force, there is no such retardation of phase produced in the ordinary electro-magnetic receiver. If, however, the current so transmitted is first passed through an induction coil, a retardation of phase of one quarter is produced, and in the case of several successive inductions the retardation amounts to an additional quarter for each induction. This remark applies only to vibrations of harmonic and quasi-harmonic type. Vowel sounds, which consist of combinations of such vibrations, are unchanged in the perception of the simple ear, which is unable to distinguish differences of phase, or between compound sounds which differ from one another only in the difference of phase of their components. The vibrations of consonantal sounds, on the contrary, depart more and more widely from their original type at each successive induction.

In the case of Edison's undographic or electro-chemical receiver, the velocities, not the displacement of the disc, are proportional to the strength of the currents received. Hence vibrations already retarded one quarter in transmission will be in the with those at the carbon transmitter in conjunction with its induction coil, always send with this instrument vibrations retarded one quarter in phase. The vibrations of this receiver therefore agree in phase with the vibrations of the induction current (which correspond to the first function of flows of the original vibration), but with those corresponding to the function of which the vibrations of the induction current are the derivate; that is to say, they agree in type with the vibrations of the second function of flows. Hence the receiving telephone of Edison electrochemical sounds which depart widely from the purely harmonic type are better rendered than in a telephone, which, like that of Bell, both retards the vibrations in phase, and alters them in type.

* Royal Institution, February 6, 1879.
† Paper read before Section A of the British Association at Sheffield.

SOUTH AFRICAN TELEGRAPHIC.—A line of telegraph from Port Elizabeth to Pretoria is likely to be completed in about two months.

PROGRESS OF THE TELEPHONE.

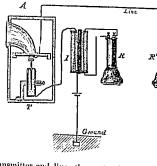
Recalling the recent telephone case, it will be remembered that Mr. Justice Pry held the Edison patent to be invalid because of the phonograph being included in it without connexion with the title of the patent and sufficient notice of it in the provisional specification. The United Telephone Company appealed against this decision, but their request for a hearing in the Court of Appeal could not be granted until after the long vacation. In the mean time the United Telephone Company have applied for a disclaimer and memorandum of alteration. The application will come before the Attorney-General in due course, and any objections to the application must be made within twenty-one days from June 2, the date of the announcement in the Commissioners of Patents' Journal. Almost simultaneously with the announcement of Mr. Fawcett that the Post Office have no intention of taking over the business of the telephone companies in this country, we learn that M. Cochery, the French Minister of Posts and Telegraphs, has asked the Chamber for a grant of 250,000 francs to enable him to establish a State telephone service between certain of the French towns. Absolute secrecy in telephone messages is considered as important in America that a new company with a capital of ten million dollars has been floated there to work the Rogers' secret system for large cities. Secrecy is obtained on this plan by employing two wires wide apart, and the message is sent piecemeal over both by means of a rotating transmitter, so that if either wire be tapped in a clandestine manner, the message will be unintelligible. A telephone circuit of this kind is now in use between the House of Representatives and the Executive Mansion at Washington.

This principle of electro-magnetic induction is one without which the telephone would still be well-nigh, if not entirely, useless—in fact, little more than it was in the days of the now famous Reis—a mere toy for the scientist, an interesting but commercially worthless instrument of the laboratory.

I, therefore, cite below a novelty in the way of telephone connections, touching closely upon this question of induction, in the hope that this account may possibly suggest some ideas to the experimenters of our times; if, indeed, many of them have not already noticed the same thing. I do not claim to have discovered the true remedy for the ailment, but wish to record my plan to reduce extraneous and interfering inductive currents.

I took two Hopkins' transmitters—instruments which, it is claimed, work by intermittent as contradistinguished from the undulatory currents of the Blake and other transmitters, they being the most easily at my disposal, and, withal, I think the best for the trial for various reasons. My line is one-half mile in length, and the instruments were connected as shown in the sketch, in which A and B are the two stations, T and T' the transmitters, I and I' the induction coils, R and R' the receivers. At each end of the line was placed one cell of the ordinary prism batteries.

At station A one element of the battery at that end was connected with the ground, and from the other element for the same battery an attachment was made to the primary of the induction coil, passing through



the latter to the transmitter and line, thence to the transmitter, primary of the coil, battery, and to the ground at station B.

The receivers and secondary windings of the coils, instead of being placed directly in the main line, as in the ordinary method, were connected so as to form with themselves a short or local circuit at each station.

With these connections I have been able to secure very remarkable results, which I shall not detail, except to say that I have succeeded in producing speech and understood by persons standing several feet away from the receivers, the latter hanging down toward the floor by the electric cord through which they were joined to the secondaries of the coils.

The advantages I claim are: first, the substitution for the line of direct currents, instead of the usual induced currents, which latter, as is well known, are of very much higher potential, and consequently more naturally disposed to fly off or leave the line wire at every possible chance; every insulator, therefore, favouring the leakage of current in a much greater ratio than they do the direct or lower potential currents; hence the direct currents started on the line by the transmitter at A are much more likely to reach it with a smaller loss of effective force than is the case with those induced.

In fact a great many telephone experts agree that it is necessary to the accomplishment of a higher utility for the telephone that some other current than the induced be used to traverse the line. Secondly, I claim that the outside induction and disturbance from other lines, telegraph, telephone, and electric light, is greatly reduced in the receivers by this method of connecting them, for the very simple reason that the receivers are not placed in the main line, and therefore an induced current coming from a foreign line must of necessity induce another current before they (the receivers) can be affected thereby, and by the time the receivers are reached by this second induction it has been greatly diminished, in the case of strong, first induction, while in the case of weaker original effects its power is entirely lost.

In the bell plan the receivers are always placed in the main circuit, and consequently respond directly to all induced currents passing on the line, whether from transmitters or from other wires, much to the annoyance of the operator, and frequently, as before stated, entirely nullifying or destroying their usefulness, until the disturbance or the cause of it has ceased.

THE ST. GEORGE TELEPHONE.

MR. A. F. ST. GEORGE has recently patented a telephonic system, which, in some points of detail, differs from those hitherto brought out. The inventor claims for his system that it enables messages to be readily transmitted for long distances, and that the apparatus is very effective and easily worked, whilst the interference of inductive action upon the transmitting wire or wires is reduced or prevented.

The first part of the invention relates to a form of transmitter. The inventor takes a disc of wood or other suitable organic material and carbonizes it between metal plates, so as to obtain a perfectly flat disc of a uniform character, and having great capacity of resonance by vibration and capable of conducting electricity. This carbonized disc is mounted by its edges in a case with an aperture to admit of sound waves impinging upon it. A ball of very hard carbon, hangs by a thin metallic wire or by a flexible non-metallic thread, and this ball is arranged so as to touch lightly against the surface of the carbonized disc. Sounds made to impinge upon the apparatus agitate the disc and the ball touching it so that the ball follows all movements of the disc and always is in contact with it, but whilst the disc vibrates the ball makes small excursions about the surface of the disc, that is to say, any movement of the disc causes the ball to roll more or less, and this rolling action of the ball brings into circuit, from time to time, fresh points of contact in the path of the current of electricity.

The carbon disc and the ball are placed in circuit with a battery and the primary wire of an induction coil in the usual manner.

Fig. 1 shows the arrangement of the transmitter. *a* is the carbonized disc or plate carried in the support, *c*, *c*, between washers, *e*, *e*, and held by the ring, *f*. The ball, *b*, is hung by the wire, *d*, in light contact with the plate, *a*. The electrical current passing through the wire, *d*, the ball, *b*, the plate, *a*, and the conducting

The second part of the invention relates to a form of receiver for receiving and rendering audible electrical vibrations. It consists of two or more discs of mica arranged parallel with, and in close proximity to, each other and suitably mounted by their edges so as to be free to vibrate. One side of each disc of mica is coated by electro-deposition with metal, preferably silver, and the discs are preferably perforated at their centre. The mica discs are arranged so that the metal side of one disc faces the mica side of the next disc, and so on throughout the series. The discs are connected alternately with each other, one set of the series to one conducting wire of the circuit, and the other set of discs to the other wire of the circuit. With these condenser plates so arranged advantage is taken of molecular strains of the mica forming the dielectric of the condenser arrangement of discs, and such molecular agitations produced by polarization of the mica discs in addition to the attractions to each other of the plates serve, it is said, to increase considerably the audible effects of the receiver.

In order that sounds transmitted or produced by the human voice or otherwise, through telephonic wires by means of the transmitting apparatus first described, or other means, may be recorded in such form that they may be at any time subsequently reproduced at any distance, the inventor uses a novel form of apparatus

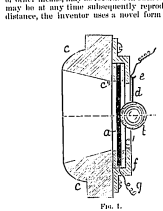


FIG. 1.

consisting of a flat transparent disc of glass or other material, which can readily be lifted up or removed from an axis by which it can be made to revolve in suitable bearings, preferably by means of clockwork or otherwise, by which sufficient uniformity of speed of revolution is obtained. One surface of this glass disc is coated with a film sufficiently sensitive to the action of light of the kind ordinarily known and used in photographic processes, and the disc so prepared is then adjusted upon its axis in a dark chamber. A very small aperture or lens is arranged, through which a beam of light from any convenient source can be directed, so that it falls upon the sensitive surface, and this aperture is made moveable in guides, so that the beam of light can be made to fall upon any point of the sensitive disc between its circumference and its centre, and the moveable aperture is connected to the axis of the disc in such manner that, as the latter revolves the former also travels simultaneously, and the beam of light thus traces a spiral line upon the sensitive surface. The width of the aperture through which the beam of light passes is made variable by means of an elastic or flexible or moveable shutter or diaphragm which is connected to the disc or diaphragm of an ordinary telephonic instrument in such manner that every vibration of the telephonic diaphragm varies to a corresponding degree the width of the aperture, or the electrical current passing through the wire, *d*, the ball, *b*, the plate, *a*, and the conducting wire, *g*, at the edge of the latter.

whilst the apparatus is in motion, a spiral line upon the sensitive surface will be affected by the beam of light falling upon it, and the width of the spiral line so affected will vary in exact proportion with the character and strength of each vibration. The message to be recorded for reproduction having been thus impressed photographically upon the sensitized disc the latter is removed and the impression is developed and fixed in the usual well known way. This disc may then be kept until it is desired to transmit or reproduce the message recorded upon it, and it is then replaced upon its bearings and made to revolve in the way already described, whilst a strong beam of light is made to fall upon and follow the variable spiral line upon its surface, and thence (after traversing the glass) upon a receiver of selenium or other substance having the property of varying in its conductivity of electricity in proportion to the degree of light to which it is exposed. This selenium receiver is arranged to form part of an electrical wire circuit, through which a constant current of electricity can be made to pass, and in any desired part of which one or more telephone receivers are situated; and in this way, as the beam of light falling upon the selenium receiver, varies in proportion to the opacity, thickness and width of the photographically deposited spiral line through which it passes, so will

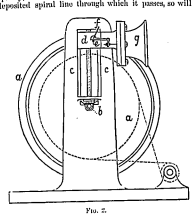

FIG. 2.

corresponding undulations be produced in the electrical current, which undulations will be reproduced in the telephone receivers as audible sounds.

Fig. 2 illustrates this arrangement. *a*, is a transparent glass disc, mounted in bearings at, *b*, and made to revolve at a uniform speed when desired. *c* is a guide in which moves the slide, *d*, having a small aperture at *e*, through which the beam of light is projected upon the plate, *a*. A screw, *f*, regulates the effective size of the aperture, *e*, and is itself regulated by the diaphragm of a telephone instrument at *g*, fixed by the diaphragm of which the sounds to be recorded are produced by the voice or by a transmitting instrument at any distance.

When the telephonic signals or messages have to be transmitted by means of submarine or other cables or wires in the immediate neighbourhood of other wires through which electrical telegraph or other currents are also passing, it is necessary to prevent, as far as possible, the effects of induction from such currents upon the telephone wire in order that the messages transmitted by the latter may be audible and intelligible; this action the inventor proposes to obviate by arranging in a convenient situation near the end of such submarine cable (assuming that a submarine cable is being used), an anti-inductive apparatus, consisting of a sufficient number of fine parallel insulated wires in the neighbourhood of the telegraphic or other wires in the neighbourhood of which upon the telephone wires, the inductive action of which upon the telephone

Patents for Telephones.

"Leetle, leetle boy, you may well ask which is which as set forth."

—there never was two such likenesses;" such was the facetious reply made by an itinerant showman of two life-size equestrian portraits, purporting to represent the Duke of Wellington and Napoleon Bonaparte. This incident of the showman has been forcibly recalled to my mind on viewing the drawings in several patent specifications at the Patent Office.

One of these drawings can be found in the specifications of patent No. 822, dated February 25th, 1882. Thus far this description describes Edison's transmitter, granted to Arthur French St. George. This drawing, which Mr. Justice Fry decided to be the combination placed side by side with that in Morgan Brown's patent of a diaphragm or tympan with a tension regulator. In her lady's telephone, suggests the inquiry "which is which?" In addition, however, to the button of carbon, "thin strips which, for there never was two such likenesses."

The description of this *invention*, so called, naturally begins with the words "Be it known that I," and proceeds to attribute to the writer thereof an attempt to use the diplomat's prerogative, namely, that of using language to conceal his intentions. All men are not, however, successful diplomats, and the attempt here is so lame and impotent that, despite of the circumlocutory verbiage, the intention fails in its object. The disguise is too thin to conceal the Bell receiver under its film. The inventor—I use the word inventor, not to designate a person who has made a discovery, but as a person who *hatched* something, the word being derived from the Latin word *inveneve*, to find. The inventor writes: My invention consists in the employment of iron or steel wire in such apparatus, and combining it with the circuit in such manner as to influence the latter by inductive action. . . . I arrange the iron or steel wire in connection with a resonant surface (a vibrating diaphragm of wood), so that any sound, such for instance as the human voice, when made to impinge upon the resonant surface, causes the latter to vibrate in such manner in relation to or in combination with the iron or steel inducing wire as to cause corresponding electric currents or variations in the circuit." This description of the "*invention* (?) and the manner in which it is to be performed" are certainly defective, especially about the "variations in the circuit." Failing to withdraw from this description what is the invention claimed, I turn to the drawings, and what do I find there? simply a resonant plate, made capable of inductive action, held down all round its edges in front of, close to, and not touching the pole of a magnet, upon the end of which is a bobbin wound with covered wire, the said wire forming part of the line circuit. The specification, or rather one of the claims, is for such an instrument to be used as a transmitter or receiver.

I submit that a correct and true description of this instrument is a correct and true description of Bell's receiver, as concisely set forth in the sixth claim of Morgan-Brown's patent, which is in these words:—"In combination with an electro-magnet of a plate of iron or steel, or other material capable of inductive action, which can be thrown into vibration by the receiving air, or by the attraction of a magnet."

I will now ask "was there ever two such likenesses?" Another patent, No. 6,039, dated 16th December, 1882, granted to George Lee Anders and John Benjamin Hensel, when placed side by side with Edison's patent, No. 2,909, dated July 30th, 1877, suggests the inquiry "which is which, for there never was two such likenesses?"

Edison's solitary claim remaining out of his 30 original claims, and claims is in these words:—"In an instrument for transmitting electric impulses by sound, the combination with a diaphragm or tympan of electric tension regulates substantially, as herein-before described, for varying the resistance in a closed circuit, substantially as set forth."

The writers of the specification of this *new* (?) invention describes a modification of their invention (?) in these words:—"This instrument consists of a metallic diaphragm, fixed in a horizontal position, and carrying at its centre a button of hard carbon or other suitable conducting material. Upon this button rests another similar one, mounted as in the Reis transmitter, so as to follow the vibrations of the diaphragm." Does not Hunning's patent claim "the use of finely-divided carbon

olums. The blackleaf gave a more constant resistance, ranging between 400 and 100 ohms.

Mr. Varley concluded from this that the effect of highly heating charcoal and blackleaf appears to be to make the particles more dense and to bring them closer together, so that they conduct.

It seems highly probable that had Mr. Varley been engaged as a scientific witness in the late trials, some very interesting information concerning the behaviour of carbon in different forms under various conditions might have been elicited, as it is hardly probable that his experiments did not lead him to think of it in connection with matters other than that of his lightning bridge.

A great deal has been said about Clerac's tube of carbon for obtaining variable resistance, and we believe that it was in use before Mr. Varley's invention; still, we think that in justice to the researches of the latter, we should not allow the matter to be unheralded because at the time it formed the subject of no particular praise or called for much remark in scientific journals.

THE TELEPHONE INDUSTRY.

MR. FAWCETT, speaking in the House of Commons last Saturday, said :—"It was desirable also that he should remove all doubt as to the relations of the Government to the telephone companies, as there had been a great deal of speculation on the chance that the Government would purchase them. It was said the truth should be known, for he believed that it was altogether improbable that the Government would do so. Their policy was to encourage free competition. If the thing could be done best by private companies he could only say he should be delighted to see the whole telephonic business of the country conducted by private enterprise. If, on the other hand, it was proved that the business was better done by the Government, the Government would have beaten the companies in the open field of competition, and could sweep the ground without being subject to claims for compensation."

We are pleased at the attitude taken by the Postmaster-General in this most important matter, and if the private companies can only have fair play, we may shortly hope to see an immense development of such a necessary adjunct to our business relations as the telephone. There are, however, several obstacles to be overcome, the chief one being the monopoly at present possessed by the United Telephone Company—at least in their own ideas. Even here the stumbling-block appears to be not so much in the receiving instrument as in the transmitter. A great difference of opinion still exists as to the amount of ground covered by Mr. Edison's single claim, and yet another battle must be fought over this subject. As far as we understand this Edison patent for a transmitter or tension regulator, it is limited in its character; but we believe that the United Telephone Company think it covers any semi-conductor placed in between any two points of a circuit, no matter how connected, or how constructed, as long as the impulses of the voice are directly employed to change the positions of the atoms composing the semi-conductor, and thus to vary the resistance of the circuit. This unsatisfactory state of affairs will, however, it is to be hoped, shortly be placed on a proper footing; for until such is the case, it is almost hopeless to suppose that the telephonic industry can make any great advance, even on the strength of the licences recently granted by the Postal authorities.

The telephone is no longer a novelty, yet we think our readers will be somewhat surprised at the table we now place before them.

We extract from the New York *Review of the Telegraph and Telephone* of July 15th, the following statistics of the progress made in seven countries of Europe. Number of telephonic subscribers in actual operation in Europe :—

IN FRANCE.

As the above statistics stand it would appear that private companies, and not the government, should have the telephonic business; but as yet so little has been done in Europe that the data we have at command is scarcely sufficient to allow of the deduction of any decided opinions.

We will now leave our readers to compare the respective telephonic industries of these countries, and we shall look forward to the time when we are able to state that England holds the leading position in this branch of electrical work, which she does at the present moment in regard to the telegraph.

* Price of each subscription license in every town, viz.: 200 marks (50 dollars), up to 2 kilometres and 50 marks (10 dollars) for each additional kilometre from the Central Bureau. To have a second additional instrument in the same house and on the second line, the price is an extra 50 marks (10 dols.).

An income of 403,853,471 dols. during the year ending with June, 1882, was more than the government has received during any previous year since 1857, and the cost of the government, including pensions, was but 182,630,603 dols., leaving a surplus of 141,001,307 dols. after the payment of 78,268,159 dols. interest on the national debt. Unfortunately, the pension payment will be very heavy this year; but the interest on the debt will be 13,896,220 dols. less than it was last year. The customs receipts, the greatest last year in all the history of the nation, 219,091,223 dols., would be sufficient to maintain the government and nearly reduce the national debt, were the internal revenue and income from miscellaneous sources wholly to cease.

103

Engineering, Oct. 26, 1883.

THE LARVE TELEPHONE

In the course of our articles on the Paris Electrical Exhibition of 1881, we referred to an ingenious and very efficient telephone transmitter, shown under the name of the Pantelephone, by the inventor, M. de Locht Labye, Ingenieur des Mines, of Liège. The remarkable feature of this transmitter was its extreme sensitiveness, by which receiver and transmitter could, at the distances usually employed, be used without speaking with the lips to the instrument, as thirty yards from it, and it was thoroughly efficient, at a distance of four yards, in transmitting whispered sentences. The instrument consisted of a single rectangular plate of cork, long freely from two thin brass or steel strips. To the bottom of the sheet of cork was fixed a button of hard carbon, held in light contact by a slight inclination of the plate, with a piece of platinum. This constituted the whole of the transmitter, which has now been supplemented by the an ingenious and efficient receiver which we illustrate on the opposite page. Considerable interest attaches to this latter instrument. Its articulation is at least as clear as that of the Bell telephone, whilst its action differs considerably, and the diaphragm common to other telephones is replaced by a thick, and mechanically rigid aluminium plate. According to M. de Locht Labye the action of this telephone cannot be explained by Bell's theory of undulatory currents. Mr. Bell claims as a point of vital importance, that in order that speech may be transmitted and reproduced, a flexible plate should be employed, and this must be put into undulatory movement corresponding to that of the air waves, in order that such undulations may reproduce the air waves, and that to effect this, it is necessary that the receiving line between the transmitter and receiver should undulate exactly in accordance with the movements of the transmitter, by which produces the vibrations of the diaphragm. On the other hand M. Labye maintains that in his telephone, articulate sounds are reproduced by a series of rapidly succeeding, but absolutely intermittent blows struck on the aluminium plate, the amplitude and rapidity of these blows depending of course on the impulse transmitted through the line, and being rendered audible by an exact reproduction of continuous sounds, the ear not being sufficiently sensitive to mark the intermissions,

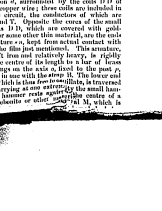

Fig. 2

supposing them to exist. Without dwelling on this theory, we may describe the telephone, which is illustrated by a front view and section, Figs. 1 and 2, and by a perspective view, Fig. 3. To a wooden plate A is secured by brass brackets B, B, a powerful horseshoe magnet N C S. To each pole is attached a small core of soft iron *c*, surrounded by the coils D D of silk insulated copper wire; these coils are included in the telephonic circuit, the conductors of which are shown at L and Y. Opposite the cores of the small electro-magnets D D, which are covered with goldbeater's skin, or some other thin material, are the ends of a brass screw *e e*, kept from actual contact with the cores by the thin pad mentioned. This armature, which is also of soft iron and relatively heavy, is rigidly attached to the centre of its length to a strip of brass *f*, which springs on the top of the pillar P, and is secured by the screw *g*. The lower end of this brass, which is less free to oscillate, is traversed by a screw, carrying at one extremity the small hammer H. This hammer rests against the centre of a thick disc of ebonite or other [illegible]ial M, which is screwed rigidly to a contractor *r*, the whole being secured to the baseplate A, by means of the metal posts B B. By means of the screw V at the end of the hammer, the space between the poles of the magnet and the armature, necessary to give the clearest articulation, can be very accurately adjusted.

Like the Bell telephone the instrument we have described can be used either as a transmitter or a receiver. The form, thickness, and practically the material of the aluminium plate M, are indifferent, although in the circular shape illustrated, is probably the most convenient. The hammer H, striking on the armature gives shortly articulate vibrations, and paper or leather lubbet to as great a thickness as the range of armature lever will allow, may be interposed between the aluminium plate and the hammer, without checking the clearness of the transmitted speech. The two parts—the abutment and the armature—may be made in one piece, and the more rigidly this organ is fixed, the more efficient the telephonic duty appears to be. If, on the other hand, a thin flexible sheet is substituted for the abutment plate—such as the ordinary Bell diaphragm, discs of mica, aluminium, &c., the sounds are very considerably reduced, and if the armature lever be connected to the abutment plate, all audible transmission ceases.

The following table describes the action of the instrument when used as a receiver: "The telephonic currents circulating in the helices cause the armatures to be alternately attracted and repelled. By reason of the reaction of the rigid electrolyte against which the armature lever rests, the repulsion alone is effective in the case of the latter, whilst the attraction of the former is meeting away from the [illegible] momentary rigidity of the electrolyte. The end of the lever from the hammer rises, and the latter falls. This repulsion is succeeded by the attraction of the armature crossed by the following current, and the armature is then pulled back to its original position, and tends to pass beyond this position by reason of the attraction and its own vis viva or momentum, but is stopped in this direction by the rigid piece or obstacle against which the hammer strikes. The intensity of the blow or shock consequently results from the combined effect of these two actions, and is in direct ratio to the electro-magnetic forces which produce the repulsion and attraction of the armature. The number of shocks is equal to the number of electrical charges produced in the telephonic circuit.

MUNRO'S TELEPHONIC EXPERIMENTS.

MR. J. MUNRO, whose name is well known not only as a very clear writer upon electrical subjects, but as an original investigator, has recently, with the assistance of Mr. Benjamin Warwick, been conducting a most interesting experimental investigation of the action of the microphone as a telephonic transmitter with the result of proving that much may advantageously be employed in the place of carbon in a transmitting instrument, a practical development of one of the very earliest of Professor Hughes's microphones, and which we described and figured when we announced for the first time his most important discovery.* The fact that metallic electrodes can practically be employed in microphonic transmitters has been denied of late with no such assurance and in such high quarters, that Mr. Munro's successful application of that portion of Professor Hughes's discovery, possess an especial interest, and must to a considerable extent affect the aspect of litigation in future contests in which the discovery of the microphone and the invention of the carbon transmitter are vital points at issue.

In investigating the properties of metallic contactors employed in the construction of microphones, Mr. Munro's first experiments were made with wires. These, in some cases, were caused by the action of a diaphragm, to rub the one on the other in such a manner as to make the point of contact vary louder the influence of the vibrations of the diaphragm; on one side or other of a position of normal potential, so that by the movement of a wire attached to a vibrating tympan along a fixed wire conveying a current from a battery, and thereby shunting the current at various positions along the length of the fixed wire, the strength of the current in the derived circuit, in which was included a suitable receiver, was varied accordingly. In other experiments mercury was employed, either as a sliding-drop, enclosing the fixed wire, or as an oscillating column; but these experiments, though instructive and interesting, did not for various reasons give encouraging results with a view to the practical application of the principle.

They, however, led Mr. Munro to proceed with compound wire structures, such as gratings resting upon or resting against one another, and a more practical form. In this instrument the very smooth, and led Mr. Munro to the consideration of different diameters, the larger disc D which characteristics and efficient of his practical apparatus, than the smaller disc D.

This instrument consists essentially of two pieces of iron wire gauze, the one fixed in a vertical plane, plumbline, but in reality they rest the one against and the other resting more or less lightly against it, the other; the smaller and movable disc D is held up against D with greater or less pressure by the spiral spring S, the tension of which can be adjusted by a screw or other suitable device at N. This form of the apparatus is more suitable for wall-some in a wall box with or without a mouthpiece, but it does not require the employment of any kind of diaphragm or tympan. Mr. Munro can employ with all his instruments an induction coil for installations where the resistance of the line wire makes it desirable to do so; the microphone and battery being included in the primary circuit and the telephone in the secondary.

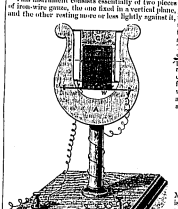

FIG. 1.

Fig. 3 is an ingenious arrangement devised by Mr. Munro, in which the adjusting spring or weight is substituted by a magnet which may be either a permanent or an electro-magnet. The figure shows an arrangement in which the fixed gauze g^1 is perforated as in the apparatus illustrated in FIG. 2, and the movable electrode e is bent or dished so as to press upon g^1 around its edge. E is a soft iron which by the electro-motive influence of a magnet

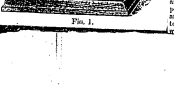

FIG. 3.

the pressure between them being regulated by an adjustable spring or weight. These gauze plates are so connected in a telephonic circuit as to constitute the electrodes of a microphone, for touching one another lightly in several points, they allow the current to be transmitted between them in inverse proportion to the resistance offered to it by its

* See ENGINEERING, vol. xxv., page 369.

passage from one to the other. Under the influence of sonorous vibrations the one plate dances more or less on the other, thus varying the resistance; and very perfect articulation is produced in a telephonic receiver included in the circuit. The gauze transmitter so constructed may be fixed within a wall-box with or without a mouthpiece, but as the sound waves acting directly upon the gauze plates, set them into agitation through their sympathetic vibration or by direct impact, no sort of diaphragm or equivalent device is necessary, and none is employed.

A convenient form of this apparatus is shown in Fig. 4, and to which the name of "The Lyra of Telephone" has been given from its resemblance to that impossible musical instrument. In this apparatus G^1 is a plate of iron wire gauze stretched vertically between two horizontal wires attached to a five-sided framework of mahogany; against the plate rests the smaller plate G^2, the normal pressure between them being regulated by an adjustable spring acting in opposition to a weighted lever W. The two plates are connected respectively with the attachment across X and Y, by which the instrument is placed in circuit with a battery and telephonic circuit.

A modification of this apparatus is shown in the diagram sketch, Fig. 2, which will probably be

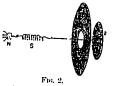

FIG. 2.

up against g^1 with a pressure dependent upon its magnetic intensity and upon its distance from the gauze. By making E an electro-magnet, and including its coil in the telephonic circuit, an instrument may be constructed in which the normal pressure between the electrodes can be automatically adjusted to the strength of the current, and in cases where an induction coil is employed the magnet E may be the core of such a coil.

Fig. 4 illustrates an apparatus devised by Mr. Munro, and to which the name thermo-microphone might be given; as it is a microphone in which thermo-electric currents are employed in the place of voltaic currents, its special feature of interest lying in the fact that the heated junction of the thermo-electric couple is identical with the microphonic contacts of the two electrodes. In this very elegant experiment a piece of iron wire gauze G is supported in a horizontal position by a light metallic support R. To another support A is loosely hinged a fauze, which at its further extremity carries a little coil of German silver wire C, which by its weight rests upon the centre of the gauze plate G^1; and in contact therewith, and to increase the pressure of contact, a little bar weight is laid with the convolutions of the coil. The two electrodes, the gauze and the coil, are connected, as shown, to a receiving telephone T. Upon the application of heat, as from the flame of a spirit

FIG. 4.

lamp placed below, a thermo-electric current is set up throughout the circuit; in this condition the apparatus becomes a very perfect microphone, and when the pressure between the electrodes is properly adjusted it is a very efficient telephonic transmitter, transmitting articulate speech and musical sounds with remarkable clearness and fidelity.

Mr. Munro is, with the aid of Mr. Warwick's manipulative skill, extending this portion of his investigation further by experimenting with gauzes and coils of various metals forming other couples in the thermo-electric series, as well as with iron and other gauze-electrodes tipped with bismuth and other metals, and we hope in due time to lay the results of these experiments before our readers.

Mr. Munro has, moreover, observed that if two pieces of gauze of identical material and in microphonic contact be heated, a peculiar sighing sound is heard in a telephone connected with them and with a battery, and he attributes this phenomenon to the electrical discharge between the gauze plates being facilitated and increased by the action of heat, but we are rather inclined to trace the effect to the mechanical action of the one gauze moving over the other under the influence of expansion and contraction of the metals by the variable temperature of the flame and convection currents of heated air, such movement producing the sounds just as would be produced if one of the electrodes of an ordinary microphone were as delicately moved by the hand or other agent.

Figs. 5 and 6 illustrate another and distinct form

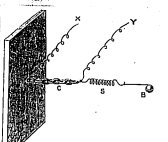

FIG. 5.

of metallic microphone transmitter designed by Mr. Munro and Mr. Warwick, in which a small chain, preferably of iron, forms the microphonic portion of the apparatus. In Fig. 5, A is a plate of sonorous wood forming a diaphragm or collector of the sonorous waves; to the back of this is attached a short length of chain C, the opposite ends of which are by the wires X and Y included in the telephonic circuit. The points of junction of the links with one another constitute the variable microphonic contacts, and the normal pressure between them is adjusted by the spiral spring S, the tension of which may be varied by the cord and winding pin P. Fig. 6 is the section of a transmitter con-

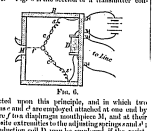

FIG. 6.

structed upon this principle, and in which two chains or of arc employed attached at one end by a wire f to a diaphragm mouthpiece M, and at their opposite extremities to the adjusting springs and s^1; an induction coil D may be employed if the resistance of the line render it advantageous.

Fig. 7 is a form of pencil microphone experi-

FIG. 7.

mented with by Mr. Munro, which differs from some of the Hughes's transmitters adopted by Cromby, Gower, Ader, and many others, only in the material of which it is composed. Mr. Munro's being of coal iron, while the others to which we have referred are of carbon rods such as are used in electric lighting. In Fig. 7 a light coal-iron bar m of the form shown, is supported in holes drilled in two blocks of coal iron r r, and the pressure between the bar and the blocks can be adjusted by a regulating spring s. In connection with the apparatus Mr. Munro has observed that rest has an appreciable effect upon the efficiency of the instrument unless it be to such an extent as to cause the two to adhere, or to be "mutual up" together.

Fig. 8.

Fig. 9.

We now come to another class of metallic transmitters with which Mr. Munro and his associate have been making experiments and to which he has given the name "Grain transmitter," since it consists of a box having metallic sides *e e* to which terminal screws *f f* are attached and filled in between with iron or brass filings, granules of spongy iron, or indeed small metallic particles in any form; one of the most efficient transmitters being a box such as is shown in Fig. 8, filled with a quantity of $\frac{1}{4}$ in. screws. Our readers will probably in connection with this apparatus be reminded of some of the very earliest experiments of Professor Hughes with very similar apparatus,* but in some instances Mr. Munro has immersed the apparatus in liquids such as oil and alcohol with the result of destroying the irregular buzzing sounds without injuring the articulation.

The results of Mr. Munro's experiments have led him to the opinion that the action of the microphone must be attributed to the action of sonorous vibrations upon the air or gaseous medium separating the so-called contact-points of the electrodes, and that across these spaces, or films of gaseous matter, silent electrical discharges take place, the strengths of which being determined by the thickness of the gaseous strata through which they pass, vary with the motion of the electrodes; and so, according to this hypothesis, the distances of

* See ENGINEERING, vol. xxi., 1876.

the electrodes from one another is determined by the sound-waves, the sound in that way controls the current.

We cannot agree with Mr. Munro in this view of the cause of the phenomena, although it would be difficult to disprove. The surface-contact theory which we hold has so firm a foundation of Professor Hughes's discovery is not, in our opinion, shaken by Mr. Munro's very interesting experiments, and, in fact, we think they are more easily explained upon that hypothesis than on his own. There can be little doubt, however, that the action of the microphone is not to be attributed to any one phenomenon to the exclusion of others, but is rather a compound action in which a number of phenomena are going on together, opposing and superposed each upon the others, and perhaps all or nearly all the theories explain some of the causes which enter into and take their share in producing that result which we call by the collective name of the "action" of the microphone. Whether or no Mr. Munro may in further experiments be enabled to prove his theory to be more consistent with observed facts than are other hypotheses, he deserves great credit for his interesting experiments, derived from the microscopic movements of the disc, and for having produced in his gauze transmitter an instrument which is simple to make, readily adjustable, and independent of previous inventions.

TELEPHONES.

The second of the series of six lectures on the application of electricity was delivered at the Institution of Civil Engineers on Thursday evening, the 4th of March, by Sir Frederick Bramwell, F.R.S., V.P. Inst. C.E., the subject being "Telephones." The following is an abstract of the lecture:—

Prior to the invention of the telephone, by making and breaking circuit at the transmitting station sounds had been produced at the receiving station—such as the ticking of a watch, or the vibration of a Morse sounder—but these were independent of sound at the transmitting station, and they could only be made to be intelligible sound at the receiving station, and only by the application of powers of audible telegraphy. Articulate speech was the object of the telephone, it was possible to reproduce at the receiving station, say by a tuning-fork, the vibrations of which break and make contact, the same note produced by a similar tuning-fork at the transmitting station; and if the note-there was a reproduction at the receiving station of the sound at the transmitting station. But the only thing that would be given forth by the note—the note-there was no reproduction of articulate speech. For example, the note might have been produced by a tuning-fork, or by a clarionet at the transmitting station; at the receiving station, however, nothing would be given forth but the note of the tuning-fork, or other vibrating implement, which was the same in every case. All the vibrations transmitted in a given time, whether the modes were due to the variations of the current caused by the human voice in the circuit, and were therefore articulate, or the sound obtained with such an agency was in the medium of breathe, in 1867, reproduced notes, and it would cause words were heard. That machine received no development, the invention of Professor Graham Bell, educated in this country in Germany, and now a citizen of the United States. Professor Bell, F.R.S., Past-President Inst. C.E., turned his attention to the recording of the vibrations of articulate speech. He effected this by means of an instrument called a logograph. This was communicated to the Royal Society, and exhibited in operation there. By its agency what was depicted on a travelling band of paper the mode of vibration of a membrane of any sonorous body under the influence of speech; and he found the results been known, they would probably have enabled the inventor seeking to produce a telephone, as it appeared the vibrations were not always the same for the same syllable, even when spoken with the speaker and from the circumstance. Professor Graham Bell graphically represented the variations in the vibrations of currents, either direct or reversed, caused by loud and weak tones, and showed that these were too abrupt for his purpose of producing by their agency articulate speech. He proposed to attain the object sought by having the circuit always closed, and by causing undulations, or waves, on the one might be, of electricity, which should be made gradually, instead of abruptly, to vary. The telephone made in which he obtained this end is one of the original forms of the Bell transmitter or receiver, and which we have examples of fulfilling the requisite by placing on iron or a steel plate in the neighbourhood of a permanent magnet, surrounded by a coil of insulated wire, so that on the plate being set into vibration by the voice it should induce, in the coil, undulations of electricity which exactly corresponded in character to the vibrations and the plate which had put the first disc into motion, and, in that way, reproduced in the original sound. Professor Bell said a few words that was obtained. Other modes were employed by him, such as the use of a battery in the line wire, and local of all, the use of two local batteries to send the current in a contrary direction round a core, the line wire being connected with each coil, coils acting by induced electricity. As transmitters the whole of the electricity in the current that broke, since the whole of the electricity in the former the three cases mentioned, and what might be called the operative electricity in the other two cases, had to be received from the microscopic movements of the disc, and for having produced in his gauze transmitter under the influence of the sonorous vibrations produced by the voice.

Edison then devised a transmitter, wherein the disc need not be metallic, but might be made of parchment. These were caused to operate on a coil in a local circuit, which carbon was introduced in the circuit of a battery. It was then found that the most unappreciable variation in pressure due to the vibration of the disc was sufficient, for some not very well understood reason, to alter the conducting power of the carbon, and to cause varying currents to be transmitted along the line-wire to the bell receiver at the opposite end. At the present day the transmitter most generally employed in this country appears to be the modified transmitter of Edison, or some modification thereof.

Professor Hughes' microphone was next alluded to, and it was stated how, by its means, the most minute sounds were rendered audible, and how, from the delicacy of the instrument, it was applicable to many scientific purposes. The microphone was, in fact, a modification of the telephone. Prior to Edison's disc it had been known that the friction of certain surfaces varied with the electric current passing through them, notably under such circumstances, the friction of the human tissue. Among other appropriate substances prepared chalk was one, and it was shown how Edison availed himself of this. By attaching a stem to the centre of the disc, and pressing this stem by means of an adjustable pressure upon the periphery of a chalk cylinder, a rotary motion was given to the disc and also to the cylinder through the stem. Upon the cylinder being turned by hand the friction on the stem caused it to move the centre of the disc—its edge being fixed—in a definite position depending on the friction, and on the rigidity of the disc; but, on a variation in the current, the change produced thereby in the friction caused the stem either to advance or recede, and thus the rigidity of the disc was altered, and in effect it to be bent more or less. It is this same vibrations were set up in the disc, corresponding with the vibrations of the transmitter that had sent the varying electrical currents. As in the case of this receiver the power was derived, not from the electricity, but from the hand of the operator turning the chalk cylinder, very considerable loudness was obtained, so that the utterances of the receiver were audible to a large audience.

In 1878, Edison had well having been good enough to lend a microphone, that beautiful invention of Professor Graham Bell was explained. Mr. Blyth showed how, by speaking to a disc, the first being a mirror on which a powerful light was directed, that light could be reflected on to a selenium cell, and as the disc vibrated under the influence of the voice the light played on the selenium cell with varied. Selenium was a metal the resistance of which varied according to the amount of light upon it. It was therefore possible, in this manner to cause a Bell receiver to speak, and reproduce the speech which had been addressed to the mirror disc. It was pointed out that, in this manner, there was no need of a wire connection between the transmitter and the receiver, the passage of a beam of light being all that was required.

Reference was then made to the various purposes to which the telephone might be put, and to the subsidiary apparatus necessary for rendering the telephone of practical use, such as switches for connecting subscribers to the exchange. Amongst special uses, a very interesting one was shown—that of the application of telephony to the diver's helmet. Thanks to the kindness of the Astley Life Saving Co., Mr. Blyth was able to exhibit a helmet with the apparatus in question was Gorman, a helmet with the apparatus in question was Gorman, a helmet with the apparatus in question was Gorman,

INDUCTION IN TELEPHONE CIRCUITS.

THE following is the full text, with the accompanying drawings, of Mr. Edison's specification, filed on March 14th, 1879, and referred to in our article on "Induction on Telegraph Lines" on pages 230 of the present number:

Improvement in Acoustic or Telephonic Telegraphs.—Thomas A. Edison, Menlo Park, N.J., Assignor, to the Western Union Telegraph Company, New York. N.Y. Also, Filed February 27, 1879.

"*To all whom it may Concern.*—Be it known that I, Thomas A. Edison, of Menlo Park, in the county of Middlesex and State of New Jersey, have invented an improvement in acoustic or acoustic telegraphs (Case No. 105), of which the following is a specification:

"In telegraphic lines there are very often numerous wires running in the same direction upon the poles, and it has long been known that induction between one wire of one set and wires of another set, and also between the other wires. These ordinarily are harmless in the ordinary systems of telegraphy; but when a wire for a telephone, acoustic or speaking telegraph, runs parallel to or near other wires of the electric influence of another wire, there are faint and confusing sounds at the receiving instrument that greatly interfere with hearing the message sent upon such acoustic lines.

"The object of the present invention is to compensate, neutralize, and destroy the extraneous or induced currents from contiguous circuits, so that the messages will not be in any manner interfered with by false currents.

"The invention is primarily adapted to telephonic circuits, as the induction upon such circuit is the most injurious, but it may be used with advantage where it is desirable to neutralize such extraneous currents.

"The present invention consists in the combination, with the telephonic circuit or other circuit to be freed from external influence, of an induction coil connected with the contiguous circuits in such a manner that a reactionary induction is established in the telephonic line of a power corresponding and similar to the primary inductive action, but opposed to the same, so as to entirely oppose and neutralize the action of the same.

"In the drawing," Fig. 1 is a diagram representing one

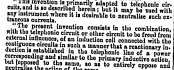

Fig. 1.

of the forms in which the aforesaid compensation is effected. The large coils C C are included in the telephone circuit at each end of the line. In the coils are iron cores surrounded by a primary coil, the coils of which may or may not be of the same number, according to the compensation desired.

Each iron core extends outside of the coils some distance. I have shown the cores passing for two circuits only. These circuits, which I call No. 1 and No. 2, running in close proximity to the telephonic line, may be many miles, as from a commercial center in it every time the circuits are

* For the sake of clearness of detail we have in Figs. 2, 3, and 4 represented on a larger scale from the modification showing the compensating apparatus at one station only of the line; the corresponding apparatus at the other station being identical in form, but reversed in arrangement, so that the same may be completed throughout perfectly symmetrical. It should mention, however, that the three coils both in Figs. 2 and 3 of Fig. 2 ought to have been drawn of equal size as they are in the original drawing.

opened or closed, the strength of which is proportionate to the proximity of the lines to each other, and the number of wires that they run side by side.

"The induced currents are in one direction in closing the circuit and the opposite direction on opening the circuit. To neutralize the induced current from, say, No. 1 circuit, place electro-magnets *a a* at each terminal in the circuit of circuit No. 1.

"These magnets are then adjusted to approach the iron cores *b b'* until the induced current thrown into coils *c c* and telephone line by the action of the magnets *a a* on coil *d*, is of equal opposite, the induced current from the circuit No. 1. Then the telephonic wire by running parallel to it. This is the first compensation is attained.

"If the two lines run parallel for any distance I connect the two coils of the primary coil *a a* in series together, and then retard the magnetism and consequent action of the same by a permanent magnetism the induced current thrown into *c c* and over the telephone line.

"Having the terminals for No. 1 the compensation for No. 2 is exactly similar. If the latter circuit does not affect the telephone circuit the coils *a a* in No. 1, the electro-magnets *f* and *f'* are placed a greater distance from

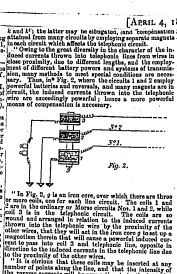

Fig. 2.

"In Figs. 2, *g* is an iron core, over which there are three or more coils, one for each line circuit. The coils 1 and 2 are in the ordinary or Morse circuits Nos. 1 and 2, while coil 3 is in the telephonic circuit. The coils are so wound as to be equal in relation to the induced currents thrown into the telephonic line from the proximity of the other wires, that they will act in the direction of fixed up a magnetism thereto that will cause a powerful current to pass from coil 3 and telephonic line in opposite direction to the induced currents in the telephonic line due to the proximity of the other wires.

"It is evident that these coils may be inserted at any number of points in the circuit, and that the intensity of the reverse currents will be in proportionate to the intensity of the currents exciting the inductive influence, and hence they will always be neutralized.

In cables containing a number of wires there is not only dynamic induction, but static induction. The latter appears sooner than the former, and is of exceedingly short duration. To neutralize this magnetic compensation above the static. Fig. 3 is shown a modification of Fig. 1 to meet this condition, which it is done to a considerable extent, but not entirely. Fig. 3.

"The induction coils 1 and 2 are included in derived circuits from the line circuits 1 and 2 that pass to the condensers C' and C' and to the earth. The object of the condensers is to prevent any leakage of current from the circuits 1 and 2, and at the same time to hasten the magnetizing and de-magnetizing of the cores *g*, so that no induced current of momentary duration is set up in coil 3 to meet and compensate for the static current from the circuits 1 and 2.

"I will here mention that to obtain perfect compensation, both the static and dynamic induced currents must be neutralized. In compensations, so they will circulate in the telephonic wire in opposite directions to those induced in the telephonic wire of the wires used to obtain these conditions, both magnets and condensers are necessary.—The former to set up dynamic induction currents, and the latter statical currents.

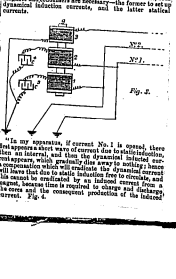

Fig. 3.

"In my apparatus, if current No. 1 is opened, there first appears a short wave of current due to static induction, then an interval, and then the dynamic induced current appears, which gradually dies away by metting; hence a compensation which will eradicate the former current will have that due to static induction four to circuits, and cannot because time is required to charge and discharge the cores, and the consequent production of the induced current. Fig. 4.

Fig. 4.

"Upon short circuits I use a coil with two or more wires wound side by side upon a soft iron bobbin, as shown in Fig. 4. One wire is placed in the telephonic circuit, while the others are placed in the circuits to be compensated for, and so connected therewith that the currents thrown into the telephonic coil are equal, but opposite, to those due to induction resulting from the wires running parallel.

"For long circuits, or long wires, and a large quantity of it, I am enabled to obtain nearly perfect compensation, as the coils act on both Gramme and Siemens cores, or iron cores being used to reduce the appearance of the currents.

"Instead of the coil of several wires wound side by side, several long strips of tinfoil may be placed side by side, but insulated from each other, and the currents passed through the strips in the same manner as if they were wires.

"Another method remains to prevent the telephonic receivers with differential coils, and running near the wire parallel with the telephonic wire and including in it the subsidiary coil.

"I claim as my invention,

"The method herein specified of compensating in one circuit for currents thrown from adjacent circuits, consisting in setting up a reactionary induction, and by an induction coil connected with the adjacent circuit or circuits substantially as set forth.

"Signed by me this 13th day of February, A.D. 1879.

"THOS. A. EDISON."

Chas. H. Smith.

THE TELEPHONE PATENTS.

ON Monday last commenced the hearing of the action of The United Telephone Company, Limited, *v.* Harrison, Cox-Walker, and Company, in the Chancery Division of the High Court, before Mr. Justice FRY. This action is brought against the defendants in respect of alleged infringements of the telephone patents vested in the plaintiff company for an injunction and damages. The patents alleged to be infringed are Edison, No. 2390, 1877, and Morgan-Brown, No. 4765, 1877. Edison's patent contained originally thirty claims, which have been reduced by declinatures to three only, relative to (1) the use in a telephone of a diaphragm of mica, (2) the use of a semi-conductor as " an electric tension regulator," by means of which the current passing through a mass of carbon is varied by the action of a diaphragm vibrating under the action of sound waves, and causing the resistance of the carbon to be varied by the pressure exerted upon it by the diaphragm, and (3) the phonograph. Morgan-Brown's patent relates to and includes the well-known telephonic receiver and transmitter of Professor Emilius Bell. Practically the transmitter in ordinary use is a carbon transmitter made according to Edison's patent and the receiver is in accordance with Bell's patent. The infringement charged relates both to the transmitter and receiver, and of the substantial similarity of the plaintiff's and defendant's apparatus there seems to be but little question. The main effort of the defence seems to be directed to showing that both patents have been anticipated by the prior publication of the chief elements of the inventions embodied in them. The counsel engaged in the case are, for the plaintiffs, Messrs. Aston, Q.C., Webster, Q.C., Cozens Hardy, Q.C., and J. F. Moulton, and for the defendants Messrs. J. Pearson, Q.C., Hemming, Q.C., Goodeve, and F. L. Mulford. Sir Frederick Bramwell, F.R.S., and Sir William Thomson, F.R.S., have been already examined as witnesses for the plaintiffs, but the case is still continuing, and is likely to last several days.

TELEPHONE PROGRESS IN GLASGOW.

IT was recently announced that the monopoly of the Post Office had been recognised by all the existing telephone companies in this country, and that the Post Office had agreed to grant licenses to the various companies, without in any way raising obstacles to hinder the development of the telephone, now that it has proved itself to be such a wonderful aid in our commercial and social relationships. So far as Glasgow is concerned, the settlement of that vexed question has brought about at least one important result, namely, the *rapprochement* of the various contending telephonic companies; and already the National Telephone Company has been registered whose object is to amalgamate all the existing telephone exchanges in Glasgow as well as in the neighbourhood. The exchanges hitherto existing in that city have been the A B C Telegraph Exchange (instituted by Mr. R. S. Symington, and one of the first things of the sort in the kingdom), the Bell Telephone Exchange, the various exchanges of Mr. D. and G. Graham (previously noticed in our columns), and the Edison Telephone Exchange. On the completion of the arrangements which are now in progress and being rapidly developed, every subscriber to any one of these exchanges will be able to hold communication not only with the subscribers on his own exchange but also with those of every other exchange in the city. There is satisfaction in being able to state that the National Telephone Company do not intend to put a "monopoly" charge on the subscribers; on the contrary, the original amount fixed by the Bell Telephone Company (£20, per annum) is to be reduced to, the subscribers having no other charge or expense whatever. Following the example set by Messrs. Graham it is proposed to keep all the exchanges open day and night and all the week through. The number of firms and individuals who will thus be actually put into speaking communication with each other is close upon 500, in addition to many of the public institutions, such as the Central Fire Station, the police stations, theatres, restaurants, newspaper offices, &c. As many of the leading medical men and dispensing chemists of the city and suburbs are also connected with the telephonic exchanges, the loan of telephonic communication can be as readily imagined as described. Glasgow has already been put into telephonic communication with Greenock by means of a private wire—the distance covered by it being about 22 miles—and formal application has been made to the Post Office authorities in London to couple up the exchanges of the National Telephone Company between Greenock and Glasgow, so that members of either exchange can, by payment of a certain fixed sum per annum extra, have the additional facility of talking to every member both on the Glasgow and the Greenock Exchanges.

MAY 26, 1882.]

ENGINEERING.

THE TELEPHONE PATENTS.

During the progress of the trial we referred shortly to the case of the United Telephone Company, Limited, *v.* Harrison Cox-Walker and Co., in which the validity of the telephone patents of Professor Bell and of Edison Bell has come into question. The case after having occupied the attention of the Court for fifteen days, came to an end on Friday last, when judgment was delivered by Mr. Justice Fry. The action was for damages for and an injunction against the alleged infringement by the defendants of the patents of Professor Graham Bell (Morgan-Brown, No. 4703 of 1876) and Mr. Edison (Edison, No. 2903 of 1877), of which patents the United Telephone Company are the owners. These patents have both been amended by disclaimers—Bell's patent once and Edison's twice—by means of which the greater number of claims have been in each case cut out. In fact, out of a large number only the substantial claims having references to the telephone as commercially used have been retained. In Bell's patent the only claims left refer to the "plates" numbered in the specification as the fourth and fifth. The "fourth plate" is the well-known Bell telephone with transmitter and receiver of the same form, in front of an electro-magnet, by acting inductively upon the magnets and the battery currents passing through the solid stump line wire, gives to a voltaic current which is otherwise constant an undulatory character which reproduces upon the diaphragm of the receiver the vibrations of the plate of the transmitter. In the "fifth plate" the core of the electro-magnet is replaced by a permanent magnet and the battery current is dispensed with, the only current passing along the line wire being the undulatory current produced by the motion of the inductive plate of the transmitter in front the permanent magnet.

In Edison's patent, as twice amended, only three claims are left, viz., 1st, "As an instrument for transmitting electric impulses by sound, a diaphragm or tympan of some, substantially as set forth;" 2nd, "As an instrument for transmitting electric impulses by sound the combination with a diaphragm or tympan of electric tension regulators substantially as hereinbefore described for varying the resistance in a closed circuit, substantially as set forth;" and 3rd, "The method herein specified, of recording the undulations of the diaphragm or pickling material, and thus the reproduction of sound by such material acting upon a diaphragm or communicate to the same vibrations similar to the original ones, substantially as set forth."

As is well known, in the telephone as now worked, the electric current is used to continuously vary the Bell receiver, and the infringements complained of by the plaintiffs referred to both these parts. These infringements were the Hunning's transmitter, used by the defendants, which was alleged to infringe Edison's transmitter; and the Cox-Walker and Hedding receivers, as to the identity of which with Bell's there was practically no dispute.

For the plaintiffs the counsel employed were Messrs. Aston, Q.C.; Webster, Q.C.; Cozens-Hardy, Q.C.; and J. F. Moulton, F.S.S.; and for the defendants Messrs. J. Parker, Q.C.; Graham, Q.C.; Chadwick, and A. Maxwell. The principal witnesses examined were, on behalf of the plaintiffs, Sir F. Bramwell, F.R.S.; Sir W. Thomson, F.R.S.; Dr. Hopkinson, F.R.S.; Mr. Varley, and Mr. E. H. Johnson; and for the defendants, the Rev. H. Hunnings, Professor Sylvanus P. Thompson, Dr. Muirhead, Mr. W. Ladd, Professor Dalbear, Dr. Stone, Professor Barrett, and Professor Ayrton, F.R.S.

The defences raised on behalf of the defendant company were very various, and covered a wide area; the defences as to the Bell patent and the Edison patent respectively being of course quite distinct.

As to Bell's patent, the main defence was that the patent was bad by reason of anticipation. Two anticipations were chiefly relied upon. The first was from the description and illustration of Reis's musical telephone published in the *Zeitschrift* of the German and Austrian Telegraph Union, and deposited in the libraries of the Patent Office and of the Institution of Civil Engineers. This periodical is in German, and a preliminary question arose as to whether the invention could be said to have been "published" in the sense necessary for anticipation.* Upon this point, which, in the form in which it was raised, is one of some novelty, Mr. Justice Fry came to the conclusion that, upon the evidence, the publication must be considered to have brought the Reis telephone within the knowledge of scientific persons in this country. But upon the invention thus published the learned judge came to the conclusion that there was nothing in Reis's receiver which could be considered to anticipate Bell's.

The second of the anticipations mainly relied on arose from the address of Sir W. Thomson at the Glasgow meeting of the British Association in 1876, and an instrument there exhibited by him. In that year Sir W. Thomson visited the Philadelphia Exhibition, and Professor Bell there, and hence articulate sounds through a telephone made and exhibited by that inventor. The receiver of this telephone consisted of a tubular electro-magnet about 3in. in diameter enclosing a bar electro-magnet, the top ends of the tubular magnet and the axial bar magnet being of opposite polarity. Over the tubular magnet was placed a disc of thin steel which touched the annular pole throughout its circumference, and was held there by magnetic attraction, when a current was passing, at a small distance from and within the inductive influence of the central magnetic core. The action of the instrument when used as a receiver was thus practically the same as that of the present Bell receiver, but it was contended by the plaintiffs that it differed from it in the fact that it could not be used as a transmitter as well as a receiver. Before Sir W. Thomson left America, Professor Bell presented to him one of his instruments as a present, which was not opened by Sir W. Thomson until he was on board ship on his way back to England. Upon opening it he found that the top disc was screwed by means of a screw at one point of its edge to the top of the annular magnet, and that instead of lying flat it touched the rim of the annular magnet only at this point, and was therefore free to vibrate as a tongue.† Upon this point Sir W. Thomson's evidence to the effect that he thereupon, on saving this instrument and supposing it to be similar to the one he had seen at Philadelphia, thought he must have been mistaken in his view of the *modus operandi* of the Philadelphia instrument, and in the description of the action which he had given in his report upon the Exhibition.

At the meeting of the British Association at Glasgow, Sir W. Thomson exhibited this instrument, which had been given to him by Bell, and in his address gave some account of what he supposed was the theory of its operation. According to the view of the evidence taken by the learned judge, both Sir W. Thomson and those who heard him were under the impression that the screw-down disc was meant to vibrate as a free tongue, and hence the kernel of Bell's invention, which consisted in the use of a stiff vibrating plate, was not made known. It was also shown that Sir W. Thomson had tried to make the Glasgow receiver speak and had failed, and that Dr. Muirhead had tried to construct a similar instrument and had failed to make it work. In addition to this the evidence went to show that the Bell receiver was a much better thing than the Glasgow receiver, and, therefore, upon the case as to what kind of anticipation is necessary, the onus of burden lying on the defendant to show that the anticipation of the Bell receiver by the Glasgow receiver was by an instrument practically as good as the patented one,‡ the learned judge gave his decision on this point in favour of the plaintiffs.

A further objection taken to Bell's patent was that his first claim was a general claim for any means whatever for transmitting electric impulses by sound. The claim was in these words:—"The combination substantially as set forth, and described respectively in the fourth and fifth plate above referred to, but subject always to the disclaiming none, of a permanent magnet (or other body capable of inductive action) with a closed circuit, as that

* The terms cited on this point were: Lang *v.* Gisborne, 31 Beav., 133; Plimpton *v.* Malcolmson, 3 Ch. D., 531; Plimpton *v.* Spiller, 6 Ch. D., 412; Household Co. *v.* Neilson, 1 W.P.C., 73.

† This instrument was illustrated in the number of ENGINEERING for December 22, 1876 (vol. xxvi., page 518).

‡ Hills *v.* Evans, 4 De G. F. and J., 288; Nelson *v.* the Overseers of Hull, one shall occasion electrical undulations in the other or in itself." This claim certainly reads, at first sight, like a claim to the discovery of undulatory currents pure and simple, produced by means of a vibrating magnet, which was known to Faraday. Bell, however, in his specification states that "It has long been known that when a permanent magnet is caused to approach the pole of an electro-magnet a current of electricity is induced in the coils of the latter, and that when it is made to recede a current of opposite polarity to the first appears upon the wire." In view of this statement Mr. Justice Fry, remarking that the patentee has himself shown that he knew what the previous state of knowledge upon the subject was, continues, "I have already expressed my opinion that Mr. Bell was the author of a very remarkable discovery. I think, furthermore, that he has understood honestly to describe that discovery in his specification, and where there two things are found. I think it is the duty of a judge to give, if needful, a benign interpretation to the words of the document." Other points, which were based on these noted above, were raised by the defendants, in opposition to the validity of Bell's patent, but they were all overruled by the judge, and an injunction was granted restraining the defendants from infringing Bell's patent.

Upon the Edison patent the defendants relied on four grounds, every objection to this patent being overruled except one, but that one being held sufficient to destroy the validity of the patent as it stands at present. The Edison transmitter, as is well known, is formed of the fact that a varying conductivity between varying surfaces placed in the circuit." In the Edison transmitter as generally used, a stiff diaphragm vibrating under the influence of the voice, acts upon a button of compressed lamp-black placed between two platinum electrodes, through the medium of a disc of cork placed between the disc and one platinum electrode. The pressure between cork and electrode is regulated by means of an adjusting screw. In Hunning's transmitter no screw adjustment is required. A layer of powdered coke is placed between two platinum foil electrodes which do not act as stiff diaphragms and do not vibrate as a whole like the tympan or stiff diaphragm of the Edison transmitter. The action of the Hunnings transmitter is therefore in this respect different from that of the Edison transmitter, and it was certainly open to argument whether Hunnings's transmitter ceases within the words of Edison's second claim as set out above. Upon this point the decision of the learned judge was in effect that the Edison "tension regulator," substantially as described," was a "tension regulator" made of a substance possessing the qualities of semi-conductivity, resiliency, and compressibility, and that the Hunnings transmitter was like Edison's, a "combination of a diaphragm (that being the platinum foil), vibrating with the voice, and a tension regulator consisting of a semi-conductive, resilient, and compressible substance, and it is therefore within the scope of Edison's specification."

Another point upon which a considerable fight was made by the defendants, was upon the first claim of Edison's patent, as set out above. It was said that this was a claim for making an old thing, viz., a vibrating diaphragm in a telephone, of a particular material, viz., coke, and that upon legal principle,* was a bad claim. Upon this point Mr. Justice Fry says: "Does that claim mean that he claims the mere diaphragm or tympanum in all instruments for transmitting electric impulses by sound? If it did, it appears to me that the claim would be bad, because that would be the claim of the application of an old substance to a particular purpose without the use of any ingenuity or invention in that application; but if it means that the mica diaphragm is claimed in an instrument for transmitting electric impulses by sound, which is described in the specification, and I think that is not in any way bad, and upon the whole I have come to the conclusion that it may be read as relating only to the mica diaphragm in combination

* Hill *v.* Thompson, 1 W.P.C., 222; Cutler *v.* Cutler, 1 Mer. † This was one of the instruments." If this be the true reading of the claim we are at a loss to see what it is use.

The one point raised by the defendants upon which they have succeeded is an objection founded on a variance between the complete and the provisional specifications, and upon this objection the learned judge dismissed the action as regarded the Edison patent. We understand that notice of appeal on this point has been given by the plaintiffs, and as in the mean time the law is in a state of uncertainty, but the decision, should it be upheld, will be of great importance. Shortly, the objection is that the subject of Mr. Edison's third claim, viz., the phonograph, is nowhere to be found described in the provisional specification, and that this invalidates the patent.*

The title of Edison's patent is "Controlling by sound the transmission of electric current, and the reproduction of corresponding sounds at a distance," and the provisional specification next includes the phonograph as ordinarily applied. The only words in the provisional specification which can be taken to refer to the phonograph occur in the following sentence: "To carry out the peculiarities of my invention under the varying conditions of use, I have devised several modifications of the transmitting, receiving, and intensifying devices specified in my *second telegraph*; portions of the apparatus are interchangeably available in transmitting or recording; others are adapted to local use; some are only available for transmitting, and others are only for receiving; and some portions of my improvement can be availed of (*sic*) to make a record of the atmospheric sound waves, or of the electric waves, or other disturbances of electrical conditions affecting them." The learned judge took the view that the provisional specification was intended to refer solely to the "sound telegraph" and its adjuncts, and that the claim for the phonograph apart from any application to such one invalidated it. After referring at length to the case of Bailey *v.* Roberton, the learned judge speaking in reference to the words above quoted from Edison's provisional specification, proceeded, "Now, no doubt, some of those words do explain, or might be held to refer to an instrument like the phonograph; but when I ask myself

Engineering Sept 18th

whether they in any manner determine the nature of the invention, I am bound to say that they do not; these, as I have already observed, are merely methods for carrying out the peculiarities of the invention; which invention, I repeat, is confined to the transmission of sounds by electrical agency to a distance. Supposing an inventor had during the last six months which preceded the complete specification, both poles of the magnet near the vibrating plate onion invented the phonograph, not as applied to the to the electric telegraph, but operating by itself, and so on, does exercising them with flat bobbins and it be said that the invention would have been protected by the description contained in this provisional specification of that instrument, I agree that the provisional specification need not describe the manner in which an invention is to be carried into effect. I agree that it need not describe the nature of the invention otherwise than roughly; but it ought to do so fairly and honestly, and if Mr. Edison was, at the time at which those letters patent were granted, in possession of that very remarkable mechanical invention by which speech could be reproduced, not necessarily at a distance, but in the same room in which it was uttered, I do not think the provisional specification was an honest statement of the nature of that discovery."

AN IMPROVED TELEPHONE.

M. D'Arsonval has been studying the arrangements of the Bell telephone best calculated to give a maximum effect. The results of his experiments lead to the general conclusion that a telephone should be constructed on the same principles as the dynamo machines. He finds that bringing the vibrating plate between the poles of the magnet near the vibrating plate between the poles of the magnet than in any other position. Supposing an inventor had, very close together as in the Gower-Bell instrument, lies between the poles of the magnet; and this supposition is further proved by the fact that a wire conveying an interrupted current has far greater power over the vibrating plate when placed between the poles of the magnet than in any other position. M. D'Arsonval declares Professor Bell the original inventor of the speaking telegraph, and confirms the American Bell Telephone Company the exclusive right in the United States of talking over a wire by means of electricity. He says: "If the Bell patents were for a mere arrangement or combination of old devices to produce a somewhat better result in a known art, then, no doubt, a person who substituted a new element not known at the date of the patent might escape the charge of infringement. But Bell discovered a new art, that of transmitting speech by electricity, and has a right to hold the broadest claim for it which can be permitted in any case—not to obstruct right of sending sounds by telegraph without any regard to means, but to all means and processes which he has both named and claimed." At first sight this decision appears at variance with that of our own judges, the learned Baron Pollock and Mr. Fitz-James Stephen, in the recent trial between the Post Office and the Bell Telephone Company. They ruled that the telephone was a telegraph, and in that case we may well ask if telephoning can therefore be a new art as the American judge defines it. The English judges were impressed by the counsel for the Post Office with the scientific evolution of the telephone, and evidently regarded the case from an internal point of view; they had been taught to see how Reiss's musical telephone was related to the ordinary "sounder," and how Bell's telephone could be assimilated to Reiss's. The American judge has, however, evidently looked at the case from an external standpoint, and decided on the difference of results effected rather than on the scientific likeness of the means employed; and we question whether his decision is not the clearest and the best. The telephoning of speech is fairly entitled to be ranked as a new art; and though Professor Bell cannot lay claim to the abstract right of sending speech, he is at liberty to claim all the means and processes covered by his patents. The decision will affect the prospects of a great many patentees who have taken out numerous patents for improvements in telephonic apparatus based on Bell's invention; and if it is confirmed by the Supreme Court of the United States it will put a gigantic stop-cock into the hands of the American Bell Telephone Company.

Engineering, Feb. 15. 1884.

THE INVENTION OF THE TELEPHONE.

The American press has long ignored the legitimate claims of Professor Graham Bell to be accounted the first and true inventor of the speaking telephone. That gentleman had the misfortune to be born an Englishman, or, speaking more strictly, a Scotchman; and the lion's share of the invention has always been accredited in the United States to native Americans, such as Mr. Edison and Mr. Elisha Gray. The recent decision of Judge Lowell, of the United States Circuit Court of Boston, Mass., has, therefore, caused considerable surprise and disappointment in America. The judge virtually declares Professor Bell the original inventor of the speaking telegraph, and confirms to the American Bell Telephone Company the exclusive right in the United States of talking over a wire by means of electricity. He says: "If the Bell patents were for a mere arrangement or combination of old devices to produce a somewhat better result in a known art, then, no doubt, a person who substituted a new element not known at the date of the patent might escape the charge of infringement. But Bell discovered a new art, that of transmitting speech by electricity, and has a right to hold the broadest claim for it which can be permitted in any case—not to obstruct right of sending sounds by telegraph without any regard to means, but to all means and processes which he has both named and claimed." At first sight this decision appears at variance with that of our own judges, the learned Baron Pollock and Mr. Fitz-James Stephen, in the recent trial between the Post Office and the Bell Telephone Company. They ruled that the telephone was a telegraph, and in that case we may well ask if telephoning can therefore be a new art as the American judge defines it. The English judges were impressed by the counsel for the Post Office with the scientific evolution of the telephone, and evidently regarded the case from an internal point of view; they had been taught to see how Reiss's musical telephone was related to the ordinary "sounder," and how Bell's telephone could be assimilated to Reiss's. The American judge has, however, evidently looked at the case from an external standpoint, and decided on the difference of results effected rather than on the scientific likeness of the means employed; and we question whether his decision is not the clearest and the best. The telephoning of speech is fairly entitled to be ranked as a new art; and though Professor Bell cannot lay claim to the abstract right of sending speech, he is at liberty to claim all the means and processes covered by his patents. The decision will affect the prospects of a great many patentees who have taken out numerous patents for improvements in telephonic apparatus based on Bell's invention; and if it is confirmed by the Supreme Court of the United States it will put a gigantic stop-cock into the hands of the American Bell Telephone Company.

THE TELEPHONE CASE.

We hear that the appeal on this long-standing dispute will be carried to the Lords. The plaintiffs in the suit are, it will be remembered, the United Telephone Company, the defendants the London, Globe, and Maintenance Company, and the question at issue was the right of the latter company to use Hunnings carbon transmitter and the Bell receiver. By a fault in the Edison (1867) patent, which erroneously included the phonograph, Mr. Justice Fry pronounced that patent invalid and the phonograph had to be disclaimed. In the mean time, while the patent was being reported upon, a considerable number of Hunnings' instruments were made for the Globe Company, and these they now set at liberty to use, and are using in their London exchanges. The Hunnings transmitter is a very fine one; everything considered, it is perhaps the best yet invented, and requires no adjustment, whilst the articulation is remarkably good and loud. Moreover, it is said to have a power of over-riding induction currents possessed by no other transmitter, the grains of carbon in circuit when vibrated by the voice, serving to break up and rub out, as it were, the induction noises, so that the persons talking can distinctly understand each other though there are noises in the wires. The Hunnings instrument will therefore prove valuable should messages have to be underground lines, as will probably be the case in the near future. The receiver employed by the Globe Company consists of an electro-magnet in circuit with the line, and having in front of its pole a non-metallic diaphragm, with a soft iron armature attached. This device was (it is said) disclaimed by Bell from his patent, and was described in England prior to his patent. In the ordinary Bell telephone the diaphragm is of thin iron. The public has heard so much of this case, and its settlement has been so long protracted, that it will be interesting to see the end of it. The London Globe and Maintenance Company have now established themselves in the City, and one peculiar feature of their system is that the workingbatteries are all kept at the exchanges, and are plugged into circuit for speaking, by reversing the exchange switch to connect two subscribers.

THE TELEPHONE CASE.

The appeal of the defendants in the case of the United Telephone Company *v.* Harrison, Cox-Walker and Co., came on for hearing on Wednesday last, in the Court of Appeal, before the Master of the Rolls and Lords Justices Lindley and Bowen. Wonderful that the appeal of the plaintiffs in regard to that portion of Mr. Justice Fry's judgment which pronounced the Edison patent invalid, has been abandoned; the United Telephone Company having preferred to amend the specification by disclaimer, and thus render the patent for the future valid. A novel point has been raised on the appeal which was not fully taken in the court below, viz., that in Bell's receiver, as illustrated in his specification, the attachment of the steel diaphragm or tympan to the rest of the instrument is of such a character as to permit "reed" vibrations. The defendants' contention on this point seems to be not that the nature of the sound vibrations of the armature either in this instrument or in the Reis anticipation, is of a reed character, but that the sound vibrations are of a "tympanic" or molecular character, independently of any special mode of attachment. Possibly this contention as to the meaning of Fig. 10 of Bell's specification, may postpone for some time longer the decision of this appeal, as the Lords Justices have intimated that they may require to read back the case for evidence to be given by experts on to the true intent of this illustration. The appeal stands adjourned to to-day (Friday), when the defendants' arguments will be continued.

* Two cases cited on this point were; Bailey *v.* Bakerite, 7 App. Cas., 1075; Stoner *v.* Todd, L.R., 4 Ch., 58; Cannot *v.* Elliott, 4 C.B.N.S., 320; Penn *v.* Bibby, L.R., 2 Ch., 128.

Engineering, July. 1878

THE TELEPHONE CASE.

The important case of The United Telephone Company v. Harrison, Cox-Walker, and Co., to the course of which we recently referred, has now reached a further, though not necessarily final stage. It will be remembered that the action was brought originally for the infringement of the Bell and Edison patents respectively, both of which are vested in the United Telephone Company. The result of the trial before Mr. Justice Fry* was a judgment for the plaintiffs in reference to the Bell patent, and upon the Edison patent a judgment for the defendants, on the ground that the invention of the phonograph, which was included in Edison's final specification, had not been adverted to in the provisional specification. The defendants appealed from the judgment on the Bell patent and the plaintiffs from that on the Edison patent, but as upon the latter patent every point except that referred to above was given in favour of the plaintiffs, they subsequently resolved to disclaim the phonograph, thus making good their patent for the future and to drop their appeal. The appeal of the defendants has therefore come on to be heard alone, and has now been disposed of, by being dismissed with costs, after a hearing lasting nine days. Upon the appeal, Messrs. Aston, Q.C., Webster, Q.C., and Moulton were counsel for the plaintiffs,

* Reported in ENGINEERING of May 24, 1877 (vol. xxiii., page 524).

and Messrs. Benning, Q.C., and Goodeve for the defendants.

The principal points urged by the defendants in support of their appeal had reference to the questions of anticipation and defective specification. The chief anticipation alleged was the exhibition at the Glasgow meeting of the British Association in September, 1876, of the original Bell receiver and transmitter, brought over in that year from Philadelphia by Sir W. Thomson, to whom they were presented by the inventor himself. It seems probable that at these Bell regarded his invention rather as purely scientific than of great practical importance, and that his anxiety to obtain priority as a discoverer in a field where so many experimenters were engaged, led him to take that opportunity of publishing his invention to the world without regard to commercial considerations. At events the instrument was exhibited at Glasgow, and announced to the world by Sir W. Thomson as one of the most wonderful discoveries of the age, and its modus operandi was explained, though Sir W. Thomson tells us he himself tried to make it work practically and failed. A considerable amount of was shown at this local reed, mounted opposite to the transmitter was shown at Glasgow with the "lid" filled, but it seems pretty clear that this was to the case. In fact, this seems to have been the general impression that the instrument gave, and ordinary pure. In another experiment the vibrator was an "ilk" is clearly shown in our illustration of the instrument exhibited at Glasgow, and which was the receiver, and a tuning-fork mounted opposite to the meeting.* Although the attempts to make the instrument speak failed at the time, it has since been demonstrated by experiments made in the Court of Session that this was due to the transmitter, and that with a good transmitter the original receiver will work with the "lid" either up or down. Hence the receiver, as a receiver, seems a practical working instrument, though it was not in fact practically worked. At the trial this fact being that any vibrator will respond to all that the exhibition of the instrument at Glasgow added nothing to the stock of public knowledge, and was not in law a publication of the invention.

* Reported in ENGINEERING of May 25, 1877 (vol. xxiii., page 524).

The judgment of the Court of Appeal on this point, which, as the result the same, is in detail some of the vibrator, subsides immediately the differed, and has proceeded on other lines. It vexiting cause is removed. As we have indicated, having been shown that the receiver, as such, was this fanciful distinction in principle was not relied a working instrument which could be copied and on in the Court of Appeal, but the case was rested worked with a good transmitter, it has been held on specific differences of construction without that the publication thereof was in law complete, regard to principle involved.

and that no subsequent patent for the instrument A point was raised by the defendants upon the could be good, consequently the validity of the Bell's patent rests only upon the differences which exist between the instrument as patented and as shown at Glasgow, and these, small as they appear, have been held to be sufficient. The only substantial difference seems to be that in the patented receiver the "lid" or tympan is secured to a wooden frame round its edge, and is fixed in position relatively to the magnet, and this difference seems to rest only upon the fact that the "lid" of the Glasgow receiver was "tilted."

The original specification of the patent claimed generally the combination of magnet and tympan for telephonic purposes, and would clearly have included the Glasgow receiver. The specification as amended by disclaimer claimed only the combination as described, thus excluding the Glasgow receiver, but excluding at the same time everything but the form shown in the specification, thus running the risk, that any form not quite the same as the patented form would not be within the scope of the patent and would not be an infringement. In the course of the argument the Court indicated its opinion that nothing but an almost identical receiver would infringe, but it was held that the defendant's receivers are practically identical and are therefore infringements. It will be seen, however, that the field is open, more or less, for other inventors, since what the patent must now be taken to cover is not a principle, but a form of application of a principle, a vast difference, well illustrated by a consequence of this case with that of Otto v. Linford.†

† See ENGINEERING, vol. xxiii., p. 548, † Ibid., vol. xxiii., p. 525.

Of the antiquity of the Bell patent by the Reis telephone we need say but little, the Reis instrument never appears to have been used except as an intermittent, as distinguished from an undulatory current.

In the Court below, the plaintiff's case, as to the difference between the patented receiver and the Glasgow arrangements, was chiefly grounded upon

construction of the specification, which is of little interest in itself, but of considerable moment on one part of the principle involved. Confessedly, the specification was ambiguous and might be read in two ways. According to the more obvious reading, the patentee claimed generally the production of undulatory currents, a thing undoubtedly old. According to the less obvious, but equally possible construction, he claimed only the application of undulatory currents to the purposes of telephony as described. Upon this the Court ruled that where there are two constructions equally open, one of which would support and the other destroy the patent, in the case of a *bond fide* and meritorious invention, the construction most favourable to the patentee should be adopted, and the "benignant interpretation" was accordingly adopted. So one can grudge Bell the legitimate fruits of his invention, but it is open to question how far the adoption of the "benignant" principle, as applied to the construction of specifications, is fair to the public or in the end advantageous to inventors themselves.

On the one hand it has been, over and over again, decided, that the specification should in "particularly describing and ascertaining the nature of the invention," tell the public clearly what they may do and what they may not do without infringing the patent. It would seem that a specification which contains an ambiguity which may upon the face of it claim an old invention can hardly satisfy this requirement. On the other hand the wholesale application of the benignant principle tends to make the administration of the law uncertain, and encourages inventors and patent agents to make their specifications into conundrums which are to be solved in one way or another according to the course of events, and which oftener than not prove snares to the inventors and invaluable to their patents. It may be well doubted whether a strict construction which would condemn unequivocally an uncertainly sounding specification, would not be better for all parties. At all events the present slovenly way in which the majority of specifications are drafted seems to support this view. Unfortunately it is not only on questions of construction, but also of anticipation and infringement that this "benefit of the doubt" is exercised, and the administration of the law becomes uncertain in the highest degree. "Hard cases make bad law" is an old saw, but it would seem better for one deserving inventor to be occasionally sacrificed than for ninety-nine to be left in doubt and uncertainty.

The commercial importance of the present decision was strikingly illustrated by the fluctuations in the market value of the shares of the plaintiff company during the course of the appeal. As the hearing proceeded, and a judgment for the defendant seemed to be a foregone conclusion, the shares went down, but the result announced on Tuesday afternoon sent them up 2½. Barely has there been a case in which the uncertainty of the result from time to time during the hearing afforded a fairer field for speculation.

THE TELEPHONE.

The principal event in connexion with the recent progress of the telephone in this country was the trial at Edinburgh before Lord M'Laren in the High Court of Session of the suit between the United Telephone Company (Limited) and Mr. Alexander Bachem, of Edinburgh. The United Telephone Company wished to restrain Mr. Bachem from using the Sheater or other microphone transmitter and the Bell receiving telephone; and Lord M'Laren gave judgment in their interests. The merits of the microphone as a new invention cannot however rest upon such a decision; that has already been decided by the general sense of the scientific world in favour of Professor Hughes. A Department commissioned the Postal Telegraph officers of the country into their own hands, is also credited by the Postmaster-General; and the public must not regard the fact, for telephonic businesses, as from its private and confidential nature, depending for its success on the satisfaction they give their clients. The exactions of Government officialism are not likely to conduce to that easiness with which a private individual loses in convenience, or to that willing assistance which the attendants of an ordinary company are taught to render. Should the telephone be adapted to long lines connecting town to town the question will take a new phase and require a fresh consideration; but at present the telephone is merely a local convenience for saving people the trouble of going to meet in order to speak with one another. Microphones have been fitted up on the Handel organ at the Crystal Palace and connected by wire to the houses of Major Flood-Page and Colonel Gouraud in the vicinity so as to transmit the music of the organ. It was found that speaking could be carried on whilst the organ tones traversed the wire, and indeed as "new discovery" but it is a discovery which dates back almost to the birth of the telephone itself. With regard to the application of the telephone, we learn that the German Government are now purchasing a new instrument which is stated to be capable of transmitting vocal sounds from Hamburg to Berlin. At home, Messrs. Barraud and Lund, patentees of the time-signalling system now in use in the metropolis, are arranging with the Postal Department to extend the system to telephone subscribers, so that any of these may receive an hourly Greenwich time-current without disturbance of the speaking powers of his instrument.

DRAWBAUGH'S TELEPHONE.

An important suit affecting the "monopoly of the American Bell Telephone Company has just been decided by the Circuit Court of the United States in New York; and a new telephone (dating to be old) has just been unearthed. It strikes us as very remarkable that in a country like America, where journals are largely read, were the telephone was well known, and speakers are as a rule so anxious to publish their claims, that we have not hitherto heard a syllable about the new telephone which has been sprung upon the public; a telephone which not only anticipates Hall's receiver but Edison's and other carbon transmitters, in fact, the telephone which is now worked by the American and English companies. The suit by between the People's Telephone Company and the older American Bell Company, and was decided in favour of the former, Bell's patent being declared void according to the American law; and Hall not the true inventor in the eyes of that law. This result was brought about by the evidence of numerous witnesses who testified to the genuine character of Drawbaugh's telephone. We incline for the present to view the decision with some reserve, notwithstanding the published drawings of Drawbaugh's instruments; but are of course open to conviction; on the matter when it has been thoroughly sifted. Witnesses declared that they had heard Drawbaugh's telephone speak in 1867 and up till 1876, and Mr. F. L. Pope, a well-known electrician declared that his apparatus was a speaking telephone. Drawbaugh's early transmitter (date 1860) was "current regulated" consisting of a vibratory diaphragm or tympan having a stylus projecting from its centre and bearing on a mass of powdered metal (or plumbago) contained between the two metal plates in circuit with the line. Its receiver of this year consisted of an electro-magnet in circuit with the transmitter, and attracting a vibratory armature connected by a string to a membrane stretched across the open bottom of an empty sustenal tin. In 1867-68 Drawbaugh improved these instruments, using carbon powder in the transmitter and suppressing the string in the receiver by attaching the armature direct to the membrane. In 1870 he found that a permanent magnet could be used for the electro-magnet in the receiver. This instrument is the same as Bell's 1877 telephones, and transmits or receives speech without a battery. In 1875, 1874, 1875, and 1876, he added further perfected his apparatus, employing blocks of hard gas carbon, held together by springs in the transmitter, one form closely resembling the well-known Blake transmitter. The series of improvements produced as Drawbaugh's are remarkably complete, and so perfectly anticipate the apparatus now in use, that we cannot help a suspicion as to their genuineness. If proven, it is, if anything, too close, and Drawbaugh's work too obviously forestalls that of recognised inventors. If, however, it should turn out, on due investigation, that Bell's work was forestalled by Drawbaugh will deserve much honour for his great invention.

Engineering March 14 1884

TESTER'S TELEPHONE.

M. Tester, of the French telegraph administration, has invented a magnetic telephone which has given good results. It resembles a watch, with the glass replaced by an ebonite mouthpiece. The iron plate vibrates before a double magnetic ring, having projections like the indented edges of two concentric cogs. The magnetic polarity is different in the two rings, one ring presenting north, and the other south poles. Each ring is provided with a fine coil of wire, and the entire magnetic field is traversed by the current.

Engineering March 14 1884

THE DOLBEAR TELEPHONE.

At the last meeting of the Society of Telegraph Engineers and of Electricians on March 5th, Professor Dolbear, of Tufts College, Massachusetts, U.S., delivered a lecture on the telephonic receiver invented by him, and recently introduced into this country. Professor Dolbear began by tracing the history of the speaking telephone from the first experiments of Page on "galvanic tones" unaided by interrupting the current in a coil having a core of soft iron. Most of his audience were probably unaware of the forgotten researches of Farmr, a resident of the town of Keen, in New Hampshire. Farrar was, perhaps, the first to set himself to transmit actual speech by electricity. He succeeded in transmitting the music of a series of vibrating tuning-forks which were struck by keys; but he gave up his efforts to transmit speech because an eminent American physicist of the time, whose name Professor Dolbear did not give, advised him that the thing was impossible. Farrar employed a receiver which bore an essential resemblance to that of Professor Bell. It consisted of two electro-magnet coils enclosed in a box, and having in front of their poles a vibrating plate of soft iron. According to Professor Dolbear, Farrar also used a receiver consisting of an electro-magnet having a vibrating armature of soft iron before its pole, although the fact is not generally known. We propose shortly to describe and illustrate the Dolbear telephone in detail; for the present we may limit ourselves by saying that it consists of two small round metal plates enclosed in an ebonite case not much larger than a watch, and fitted with an ear-piece. One plate is free to vibrate, and is connected to one pole of the secondary wire of an induction coil; the other pole of the wire being to earth, or to the other plate of the telephone through the coils. The primary wire of the coil is in circuit with the line, and is traversed by the vocal currents from the microphone transmitter. The induced secondary currents electrify the free disc, and the attraction between the two plates, which are placed close together, causes the free disc to vibrate in accordance with the varying potentials of the secondary circuit. The person of the listener so he holds the telephone in his ear is a sufficient connexion between the fixed plate and the ground, so that a wire connection is not absolutely necessary, though the effect is louder with one than without. This fact has already been published, but Professor Dolbear astonished most of his audience by demonstrating that it was not even necessary to have a wire connexion to the earth plate of the telephone and a secondary pole of the coil. In fact, the telephone could be held quite free from any connexions in the hand, and still speech could be heard if the listener did not go too many feet (say over fifty) from the coil. The effect was increased by allowing a connecting wire from the telephone to hang free in the air. The effect here is evidently due to induction acting through the air between the poles of the secondary wire of the induction coil and the telephone plates; but it is surprising to find it so marked. Mr. Willoughby Smith, at the end of the lecture, invited members to see a piece of apparatus which he had been experimenting with, and which seemed to give similar results. This consists of a gossamer web of fine iron wire in contact with the poles of a horseshoe magnet wound with a coil, through which telephonic currents are passed. When those currents pass, a large number of persons in the vicinity holding disconnected telephones to their ears can hear the telephonic messages. It is not, however, clear in this case whether the effect is really due to induction as in the case of Mr. Dolbear's experiment; or simply to vibration in the air, and the enhancing effect of the resonance cavity of the telephone when held to the ear. Some experiments made by Professor Hughes, about two years ago, have a less elaborate bearing on the point. Those experiments were made before Mr. Spottiswoode, Professor Stokes, and others, and consisted in transmitting sounds without the air of a room to a telephone which was not in circuit with the battery and transmitter. The electricity from the battery and transmitter appeared to have thirty or forty feet of the air itself and not on the telephone. As Mr. W. H. Preece explained to the meeting, Professor Hughes did not publish those experiments because Mr. Spottiswoode believed them to be due to *induction*, and Professor Hughes, himself, thought they were due to *conduction*. It is generally, we think, unfortunate that the opinion of one authority should in any way check the labours of another; nor is it at all certain that the effect is simply due to induction. Perhaps if Professor Hughes had continued his researches he might have settled the question, and at any rate would doubtless have thrown fresh light on the nature of induction. Probably we have not yet heard the last of the subject.

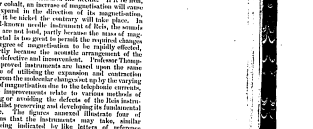
Engineering March 14 1884

THE STATIC TELEPHONE IN RESEARCH.

Thomsquatic-telephone of Graham Bell has proved of great value in research, and Professor S. P. Thompson has now applied the static telephone of Dolbear to the same purpose with considerable success. Professor Thompson has used it for investigating the action of "influence" machines, such as those of Holtz, Toepler, and Winnshurst (see ENGINEERING, vol. xxxiv., page 5). When the coil of the wire from the insulated plate of a Dolbear receiver is held near the revolving discs of those machines, a sound is heard in the telephone by induction. As might have been expected, Professor Thompson finds the discharge from the Holtz class apparently more continuous than that from the Winnshurst or carrier class. The Dolbear instrument has also been used by Professor Thompson to take the place of the galvanometer in a Wheatstone balance of conductivity, if one may use the term, when conductors are compared instead of resistances. The conductors which correspond to the divided coil of the Wheatstone balance have been ingeniously combined by Professor Thompson in the following manner. Two glass tubes are coated with tinfoil and a brass tube slides into both the glass tubes, and forms the common insulated armature of both condensers, while the tinfoils form the earth armatures of the two condensers thus combined. The arrangement allows of the ratio of the capacities of these two condensers being varied by sliding the inner brass tube between them. When the "balance" of condensers is made up in a similar way to Professor G. G. Foster's method of joining up the Wheatstone balance, the results are more delicate than with the ordinary method. This disposition was suggested to Professor Thompson by Mr. Starling, his assistant. Other applications of the Dolbear telephone will suggest themselves to experimenters, now that Professor Thompson has shown its value; and it has the advantage of being a very handy instrument. For example, as Professor Thompson showed, it can be employed to jump out capacities of surfaces round charged bodies; but in this, as in the other cases mentioned, the fluctuating current from an induction coil must be used instead of a continuous charge. Thus when the two terminal wires of the telephone are on the same equipotential surface no sound is heard in the telephone; but a sound is heard if they are not.

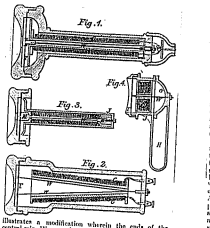
TELEPHONIC RECEIVERS.

Professors SILLIMAN and T. Thompson has lately devised a new form of telephonic receiver of the type originally invented by Phillip Reis. In the Reis instrument the telephonic currents are passed through a coil of wire surrounding a needle or rod of iron or steel mounted upon a suitable sounding box or resonator. The variations of the strength of the current produced by the tions in the degree of magnetisation of the needle which in consequence of the molecular changes thus set up, emits sounds. The final result of such molecular changes is, in general, to produce either an expansion or a contraction of the needle. If it be less, steel, or cobalt, an increase of magnetisation will cause it to expand in the direction of its magnetisation, while if it be nickel the contrary will take place. In the well-known needle instrument of Reis, the sounds emitted are not loud, partly because the mass of magnetic metal is too great to permit the required changes in its degree of magnetisation to be rapidly effected, and partly because the acoustic arrangement of the parts is defective and inconvenient. Professor Thompson's improved instruments are based upon the same principles of magnetising the armature and conducting coil, but the character chiefly sought for by the varying degree of magnetisation of the needle is the telephonic currents, and the improvements are due to various methods of obviating or avoiding the defects of the Reis instrument while preserving and developing its fundamental principle. The figures annexed will explain the form of the instrument. The instrument takes, similar parts being indicated by like letters, the form shown in each case. In the example shown in Fig. 1, a thin rod or piece of wire W, of iron, steel, or nickel, is fixed by one end to the centre of a tympanum T of wood, horn, ebonite, sheet metal, or other suitable substance. Its other end is fixed to an adjusting screw or pin S, by means of which the rod can be strained to any degree of tension. C is a coil of wire wound upon a tube of sufficient diameter not to interfere with the vibrations of the central rod. The combined tympanum, wire, and coil are enclosed in a case of convenient form, having an earpiece. The general action of the instrument is as follows: If the current received in the coils C, through the wires from the transmitter, increase in strength, it will change the molecular condition of the central rod, causing it to stretch slightly if of iron, steel, or cobalt, or to contract slightly if of nickel. A decrease in the strength of the currents will be followed by a partial diminution of the central rod, producing an inverse movement. Hence if one end of the rod is tightly screwed up to the case of the instrument, the varying or fluctuating currents will cause corresponding vibrations of the tympanum. This telephonic receiver, when compared with any existing instrument, reproduces sounds much more loudly than the original Reis-needle instrument, and its articulation, especially of the sibilants and of some other consonants, is much clearer and more distinct than that of the common magneto-telephonic receiver.



In the form of instrument shown in Fig. 2 there are two wires W and w attached to the tympanum at different points, but terminating in a common adjusting screw and surrounded by one coil. The wires may both be of iron or steel, but a better effect is obtained if one is of iron and the other of nickel, so that whilst one is expanding the other is contracting. Fig. 3

Digitized by Google



illustrates a modification wherein the ends of the connecting wire W are coiled to receive M of magnetic material in order more effectually to produce the magnetism. One end of the wire is connected to the tympanum and the other to the closed coil of an iron tube H, which serves as the case of the instrument. In Fig. 4 the iron case J is shown wide and short, and provided with a pair of handle which carries an iron cap G, to the centre of which the wire W is screwed, the spring of the band handle being serviceable to keep the wire in the proper condition of tension.

Sonn – Nov. 7, 1884

THE BELL EXHIBITION.

Amongst the Bell telephone exhibits at the Philadelphia Electrical Exhibition is a most interesting apparatus, Professor Bell's audiophone. Its function is to transmit speech by means of a ray of light, and without wire. It consists of a flat mirror, properly suspended, by means of which a ray of light is reflected through a cell containing a slum water, which absorbs the heat rays, to a vibrating diaphragm about 4 feet distant. The diaphragm is itself a mirror, and reflects the ray back through a suitable lens to a parabolic reflector, in the focus of which is a selenium cell, the terminals of which are connected with a magneto receiver. Now, connected with the back of the mirror diaphragm referred to is a flexible tube, fitted with a mouthpiece. On talking into this tube, the mirror diaphragm vibrates, the rays which it reflects through the lens into the parabolic reflector are thereby disturbed, and undergo modifications of intensity; these rays are forced upon the selenium cell, and their changes affect the current in the cell in the same way that a vibrating armature effects the induced current around the poles of a permanent magnet. This current from the selenium cell is carried through the back of the reflector to a hand receiver, and, holding this to the ear, the speech is heard. It is said that Professor Bell has conveyed speech 500 feet in this way by means of a strong ray of light.

SOUND MOTORS.

Mr. Edison's "motophone," in which the vibration of a telephone plate or "tympan" under the action of the voice, is made to work a ratchet wheel round, anticipated the apparatus of Dr. Drouhk, of the University of Agram in Croatia. Through the kindness of Mr. H. Preece, F.R.S., we have seen a set of Dr. Drouhk's apparatus in action. The source of sound is a tuning-fork kept in vibration by electro-magnetism and mounted on a resonance box. The open mouth of this box or chamber is the source of sound, and the sound-mills are placed in front of it. One of these consists of a cluster of light glass balls suspended from a cross-shaped frame which is pivotted on a needle point. Each ball has a little nipple blown on its side, the nipple being pierced with a hole. The holes are on the same line of each ball round the cluster, that is to say, they all point in one way and receive the sound impulses one after another as the group of balls revolves, just like the sails of a windmill. The wall of the balls opposite the nipples is, of course, entire, and the medium is due to the reaction on it. Another mill consists of four little stiff flags or plates of paper-like material pierced with holes, and suspended from four cranks carried by a pivot as before. The holes are no pierced as to make small open nipples as before on a needle point. The holes are .3 centimetres apart. When placed before the resounding cavity, with the smaller ends of the nipple-like holes towards it, the cord is repelled and attracted if the back of the cord presenting the wider openings of the nipple is placed before the resonator. A similar mill is made with plane flags without holes, and the motion is intensified by placing between it and the cavity of the resonator a brass ball, or Helmholtz resonator, with open nipples at opposite diameters. These nipples are placed in line with the resonating cavity and the mill, the larger nipple being next the cavity. When a lighted paper or the hand is held behind the Helmholtz resonator, a distinct puff or wind is felt to issue from the nipple farthest from the resonator; and it is this puff of wind which, impinging on the vanes of the mill, causes it to rotate. A screen pierced with 100 conical holes may also be placed between the ball resonator and the mill in order to distribute the breeze. Another of Dr. Drouhk's rotators, also very interesting, is a fist cylindrical paper box, of glazed paper, having four projections on its sides, each carrying a short open tube of paper. It is a resonator with four openings, and, when suspended by a silk thread from a standard in front of the sounding box, begins to twirl round.

A NEW TELEPHONE.

A PAPER "On the Conversion of Radiant Energy into Sonorous Vibrations," was read before the Royal Society recently by Mr. W. H. Preece, the electrician to the Post Office. The remarkable discovery by Messrs. Graham Bell and Sumner Tainter that the rapid intermittent incidence of vibrations has attracted very much attention and has excited much physical work to refer to the asserted problem. The advocates of the emission theory of light have striven for ten years to obtain such a proof of their theory as Mr. Bell has. Why have Bell and Tainter succeeded, or believed to have succeeded at all? May not their phenomena be due to some other cause than to the instantaneous light? It was suspected by many that it was a heat effect, and not a light one at all. Mr. Mercadier, in Paris (*Comptes rendus*, Dec. 8, 1880), and Professor Tyndall (*Proc. R. S.*, Jan. 3, 1881), have placed this beyond the region of doubt, and now Mr. Preece has completed the chain of evidence by a careful and elaborate inquiry into the cause of the phenomena. In the first part of the paper he has shown that chonite and indiarubber though opaque to the light rays, are remarkably shallow transparent transparent to the heat rays, and therefore that sulphur cells can act though screens of these materials. Indeed, ebonite is shown to be almost perfectly transparent to radiant heat, while it is absolutely impervious to light. He also shows by experiments, which no doubt will be repeated in this country, that the effect of the second can possibly be produced by the direct impact of light waves causing expansion of the mass of the disc, and therefore that the Bell-Tainter effect is not due to the absorption of heat changing the volume of hard substances experimented upon. He next inquires whether the effect observed is due to a molecular pressure similar to that which produces the radiometer or the radiometer, for this being a mere motor action, the element of time is eliminated. Many experiments are described which were made with discs of various kinds in different ways, but the results were so unsatisfactory and uncertain that the opinion was raised whether the disc vibrated at all. By the aid of microphones and specially-constructed chambers, he proved clearly that the sound-waves are those of the air immediately next the disc. In fact, the sounds were produced in the air over the discs. Moreover the effects were materially assisted by cutting the sides of the containing vessel with a calotonic coil of the boldest kind, such as the carbon deposited by barnish on camphor. It is next shown that the effects depend not on the number of heat rays that pass through the discs, and that on these that are incident on them, and that the greater the absorbed number of the air or vapour contained in the case, the more intense the sounds emitted. All these results are repeated and shown with ordinary flicks lamphlacked on their exterior and interior. Finally, it is shown that there is a close element interdicted, and that the loudness of the note emitted depends not only on the rapidity with which the luminous air absorbs the radiant energy, but also on the rapidity with which it gives up its heat to the sides of the case and the cells upon to it. It varies also with the form of the enclosed space and with the character of the contained vapour, and with the substance of the sides. The effect being thus due to radiant heat and its absorption by the surrounding air, Mr. Preece concludes that if a beam can be completely reduced to a lamplblacked case, sounds were emitted when currents of electricity were rapidly and intermittently transmitted through the wire, and, moreover, that when these currents were produced by a proper microphone transmitter articulate speech was produced. Hence these phenomena are simple effects of radiant heat, and they are due to the changes of volume in absorbent gases and vapours produced by the absorption of thermatomic heat in a confined space. All the varied and novel experiments which Dr. Graham Bell performed when he was recently in Europe with solids, liquids and gases, with tubes, flasks and discs are thus brought within our simple explanation, and are due to a remarkable influence of degraded heat rays on absorbent vapours. The final result of this inquiry has been, not only to unravel an exceedingly interesting scientific problem, but to produce another form of telephone based on new principles.

THE TELEPHONE IN GLASGOW.

The telephone exchange system has undergone very great extension in Glasgow within the past couple of years. In the month of March, 1881, the different intercests then existing were amalgamated in the National Telephone Company; and whereas there were at that time 200 exchange subscribers, there are now 650 exchange and 200 private lines. There are now no fewer than six exchanges—one each in Queen-street, St. Vincent-street, Douglas-street, Morrison-street (south side), Hillhead, and Bridgeton; and all of them are connected together by means of trunk wires. The final-named exchange is the principal one, there being in all about 400 subscribers connected with it. There are bright switch-boards in it, each of which affords communication with fifty subscribers, and all the boards are intercommunicated, so that a subscriber in one may be "connected up" with a subscriber in another. At each of the boards there are two operators, and nearly all of them are young ladies. There is no ringing of bells, or anything of that kind; but when a subscriber calls a small disc falls down which at once attracts the attention of the operator. All the exchanges are open night and day, in which respect they are in advance of the telephone exchanges in London; and communication can be had with Edinburgh and Leith, Greenock and Paisley, by means of trunk lines; and with the Ambulance Association, the infirmaries, most of the public buildings, and many warehouses, offices, and public works. It is especially worthy of remark that there are many private lines from Glasgow to places at distances of ten, twenty, or even thirty miles beyond the boundaries. Further, it is interesting to notice that each subscriber on the average calls up another five times a day, and allowing for five replies, each telephone is used ten times a day; but some subscribers make their telephones fifty or sixty times daily. Among 4000 connections are sometimes made in one day. The National Telephone Company have now obtained a concession from the Postmaster-General by which a reduced tariff can be charged for short communication between the large towns and cities and Glasgow.

Engineering July, 1881

APPLICATION OF THE PHOTOPHONE TO THE STUDY OF THE NOISES TAKING PLACE ON THE SURFACE OF THE SUN.

On visiting the Observatory of Meudon, at the invitation of M. Janssen, Mr. Graham Bell examined with much care the large photographs which are being made there for the study of the solar surface. M. Janssen having informed him that he detected movements of a prodigious rapidity in the photospheric matter, Mr. Bell had the idea of employing the photophone for the reproduction of the sounds which these movements must necessarily produce on the surface of the sun. M. Janssen approved of the idea, and requested Mr. Bell to attempt its realization at Meudon, placing all the instruments of the observatory at his disposal. The weather being very fine on Saturday last (October 30), Mr. Bell came to Meudon to attempt the experiment. A large solar image of 0.65 metre in diameter was examined with the selenium eyepiece. The phenomenon were not sufficiently decided to be regarded as successful, but Mr. Bell does not despair of succeeding on further examination. M. Janssen suggested that the chance of success would be much greater if in place of directly interrogating the solar image where the variations are produced, though responding to considerable changes on the sun's surface, are not sufficiently rapid even in the most powerful instruments to cause the production of sounds in the photophone, a series of solar photographs of one and the same spot, taken at sufficient intervals to obtain well-marked variations in the constitution of the spot, might be passed with a suitable rapidity before an object glass, which would give conjugated images upon the selenium apparatus. This would be a means of condensing into a time as brief as could be desired the variations which in solar images are much too slow to give rise to a sound. M. Janssen has placed himself at Mr. Bell's disposal to provide him with solar photographs suitable for carrying out this idea, and the latter has left M. Janssen the photophonic apparatus requisite. It has appeared to M. Janssen that the idea of reproducing on earth the sounds caused by great phenomena on the surface of the sun was so important that the author's priority should be at once secured.

LECTURE PHOTOPHONE.

A simple form of Photophone, which is sufficient to show the principle of the instrument, and may be used for lecture purposes, has been arranged by Mr. Shelford Bidwell, and exhibited before the Physical Society of London.

The reflector for receiving the light is discarded, and the beam focussed on the selenium by the lens.

The two lenses used cost only about six dollars, and the beam is rest fourteen feet.

The selenium cell was made by spreading melted selenium over sheets of mica, and then crystallized by heat. For mica Professor Bell recommended microscopic glass.

The resistance of the cell was 14000 ohms in the dark and 6500 in the light. Speech was distinctly transmitted by this apparatus.

A PHOSPHORUS MICROPHONE.

In his photophonic experiments, Professor James Blyth, of Edinburgh, was led to construct a useful form of selenium cell by dovetailing two brass screens, having alternate teeth knocked out, and filling up the spaces between the interlocking teeth with the selenium. A modification of this pattern is made by fastening a brass disc on wood and sawing it across until it consists of radial sectors which are afterwards connected by selenium. While trying substances he found the phosphorus evolved a phonic, and the idea occurred to him that a microphone could be made from it, which would not generate its own electricity, but therefore took a shallow wooden box having a brass bottom, and spread a lid covering the box upon it; a thin flexible brass Wires from a telephone were then connected to the metal top and bottom of the box, and on speaking the words were distinctly reproduced. The varying pressure of the sound waves on the phosphorus, established an undulating current which passing through the telephone, caused it to give out the original words. When a battery was included in the circuit the sounds were remarkably clear and loud and free from the grating which disturbs the carbon microphone. Professor Blyth also finds that the cell, which is really a form of loose contact, operates as a receiver as well as a transmitter, and will of itself emit articulate sounds under the influence of the vocal currents.

THE MICROPHONIC ACTION OF THE SELENIUM CELL.

At a recent meeting of the Physical Society, Dr. James Moser read a paper expressing his opinion that the well-known action of the selenium cell in Professor Graham Bell's photophone is not so much a mechanical, physical, or chemical one as it is a microphonic action. The cell is usually composed of metal plates connected together by annealed selenium, and having wire electrodes. Dr. Moser therefore argues that the junction between the metal and the selenium is what electricians term "a bad joint," or in other words a microphonic contact. The varying beam of light from the photophone transmitter falling upon the cell, expands and contracts the metal plates or the electrodes by virtue of the heat rays, and thereby tightens and slackens the microphonic joint. Another effort of modulating the current of electricity which flows through the cell, and causing the modulations of the voice to be audible in the telephone, Dr. Moser showed that with copper plates the selenium cell was really a pile of copper, selenide of copper, and selenium, built up in order, and he compared it to the thermopile of Professor Hughes and Mr. Edison, in which a number of little cubes of carbon are arranged end to end in a glass tube with brass fillings between. When a current is sent through this combination it becomes very sensitive to heat rays falling on it, owing to the expansion of the carbons by heating and the consequent closing of the microphonic joints between them. The idea of Dr. Moser is highly interesting, but it requires to be further supported by experiment.

Enemon.

Like some old Titan of majestic bright,
His march has been with grand and solemn tread,
The lands profoundly working, while the head,
Circled by mists, was often hid from sight;
Yet from its cloud, when great thoughts flushed to light,
That mighty brain by the elect was read.
The many saw not, turned away, instead;
His brightness, veiled, to them was only night.
But, as he walked, anon at either side
Fell pregnant seeds of thought, which, taking root
In minds long barren, showed the tender shoot
That later blossomed. Closely might praise hide,
Yet everywhere the great man planted fast
His mark remains, and shall through time abide.

ELIZABETH C. KINNEY.

What is "The Secret Telephone?"

For the last week or two the voracious scientist of the daily press has been serving up to his readers, well-seasoned accounts of a new telephone company recently formed, to carry on a general telephone business. The somewhat mysterious title of the new organization is stated to be "The Secret Telephone Company;" and the instrument by which the achievements of the new company are to be accomplished is denominated the "The Secret Telephone."

The secret of the electricity shrewdly mentioned, says: "It is called the secret telephone, because when two persons are talking, no one else, although he may be on the same line can hear what is said." After describing the secret telephone and its circuit arrangements the scientific chronicler goes on to enumerate its further advantages, as follows: "The secret telephone is about one-half the size of the Bell telephone. A carbon diaphragm is used in the transmitter instead of a metal one, as in the ordinary telephone, and in the receiver a common horse-shoe magnet is used instead of the vibrating armature. The inventor claims great advantage for his instrument, (of course he does—was there ever an inventor who didn't, from Tubal Cain to Rogers), instead of being suspended, the electricities float in mercury, which gives distinctness to the sound and enables the telephone to be operated at long distances. There are many other differences between the 'secret' and the common telephone, but the advantages enjoyed are secrecy and the superiority in transmission. In an experiment in Washington, conversation in a low tone at a distance of 25 feet from the transmitter was heard plainly two and a half miles away." It may be fairly presumed that about two-thirds of the daily and weekly newspapers of the United States, have printed within the last two weeks, some such statement as the above. We are persuaded that this estimate does not overstate the mark; and judging from the number of samples we have received, with the wards to the effect aforesaid, carefully marked in blue pencil on the second page, we should suppose that our estimate is considerably too small. By the way, why does the telephone man always mark such articles in blue pencil, when he wants to attract your attention? Is it indicative of the tum his feelings would take if he thought there was any adequate foundation for a new and opposition telephone company to be started upon, or is it merely a straw which denotes the growth of esthetics among telephonists?

After reading some two thousand extracts of the same general character pertaining to The Secret Telephone, there came a pause, and we had time to breathe, and then we received duly the REVIEW of the TELEGRAPH and TELEPHONE, etc., etc., and we read with lated breath the details of the organization of the "National Secret Telephone Company," with the momentous fact that a Harris Improvement, of New York, took 19,991 shares, leaving to the majority of his fellow stockholders but one share each, and trusting to the dear public to come boldly forward and take the remaining 10,000 shares. Since it appeared that more than ordinary public interest had been excited by the articles which we have generally described, we have thought that a few words explanatory of the real character of the secret telephone would be generally acceptable.

The secret telephone company, claims thus, to be based upon the patents of James H. Rogers, at present out-of-sight in number.

The first and most characteristic patent was issued December, 1881, and is for the secrecy feature, and the method and apparatus whereby it is attained.

The second purports to be for a battery transmitter, consisting of a mouthpiece, a diaphragm, which may carry a suitable electrode, or which may itself be of carbon; a mercury bath in which floats one or more particles or broken fragments of carbon, which are supported by the mercury and caused to touch the under surface of the diaphragm or of the electrode carried thereon.

One of the circuit wires is connected with the diaphragm, and the other with the mercury bath, and a battery is placed in circuit.

This, according to the specification, may be used with or without an induction coil, and the existence of the circuit is of course varied when the diaphragm is spoken to, causing electrical undulations which traverse the line and influence any electro-magnetic receiving instrument which may be there in circuit.

Patent No. 3, is for a receiving telephone, although the patentee states that it will also transmit.

To understand it without a picture — imagine a sheet of metal, iron or steel for example, about six inches long and three inches wide, folded close round a cylinder or core until it acquires the cylindrical arcuate-like form, with the edges very near to each other but not touching; after the form is acquired the core is withdrawn, one edge is then wound round length-ways with insulated wire and forms the core of the magnet, or if desired, the covered wire may be wound over the whole of the cylinder. The covered wire forms part of line circuit.

Patent No. 4, describes and claims different methods of carrying out the secrecy feature mentioned in No. 1, and shows several ways of putting it into practical operation.

Patent No. 5, is for another variety of battery transmitter, in which the electrical undulations, to quote the specifications, are produced by varying the resistance, quantity or bulk of a fluid conductor, and consequently its conductivity.

A word as to the relative value of patents may here be not out of place: Many persons are now fully acquainted with the general rules by which such relative values are governed. Many more, however, are not But the facts of the matter are something like the following:

Any person who first discovers or invents a new art, or process of manufacture, or machine, or any new article, may obtain a patent for it, in all its breadth, no matter how simple and easy his discovery or invention may have been. The very fact that until the date of his invention, it had remained undiscovered, presupposes a certain amount of inventive or discovering talent to have been necessary, and the protection for seventeen years from the date of issuance of the patent, is his reward for the use and benefit which the world will derive from the free and unrestricted employment of the invention after the seventeen years have expired.

Furthermore, any person who may have made a discover any new and useful *improvement* upon any art, process or machine, may obtain a patent for his improvement, and he is entitled to his improvement just as fully as the first inventor was to *his* invention.

The improver may not use the first invention without the permission of the inventor, and the inventor, while having full right to the first invention, may not avail himself of the improvement unless he first agrees with the improver. For example: Mr. Brown may be the first inventor of a button, Mr. Jones subsequently discovers that buttons having four holes through them possess certain advantages, and patents a button having four holes.

Mr. Brown has a full right to button, but he may not use a four-holed button unless such a button was fully shown in his specification. Mr. Jones again, while controlling his four holes, may not make buttons at all unless he gets permission from Mr. Brown. Carrying the matter still further, let us imagine Mr. Cox to have subsequently found that, by making Mr. Jones's four holes square, he obtains certain additional advantages; this is Mr. Cox's invention and he patents it. At this point, to carry on our argument, Mr. Brown still retains his right to button *per se*.

Mr. Jones monopolizes four-holed buttons if he can get permission from Mr. Brown to use buttons at all, and Mr. Cox may enjoy exclusively the right to make buttons with four square holes—with the trifling

ible age of, thirteen, in the year 1805, revealing three eight years; and during the chief part of the time bound books. Now if was in those books, the hours of the day which I found the beginning of my philosophy." There were ten that especially helped me,—the Encyclopedia Britannica, from which I gained my first notions of chemistry, and Mrs. Marcet's "Conversations on Chemistry," which I devoured with unspeakable delight. Does not suppose that I was a very deep thinker, or was marked a precocious person; I was a busy imaginative person, and could believe the Arabian Nights as easily as in the Encyclopedia. But facts were, impressed to me and saved me; I could trust a fact and always cross-examined each assertion. So when I questioned Mrs. Marcet's book about certain experiments as I could find means to perform, and found it true, I was delighted beyond measure; and I felt that I had got hold of an anchor in chemical knowledge. I clung fast to it. Thence my deep veneration for Mrs. Marcet—for any one who had conferred personal good pleasure on me;—and then as one able to convey the truth and principle of those boundless intellectual delights which concern natural things to the young, tastefully and lucidly. Then, you may imagine my delight when I came to know Mrs. Marcet personally, and found that I was my thoughts backward, delighting to connect the past and the present bow often, when sending her a paper as a thank-offering, I thought of my first instruments; and such thoughts will remain with me."

Henry wrote on the inside of the cover of Gregory's work the following words in his book, although by no means a profound work; but, under Providence, was a remarkable influence on my life. It accidentally fell into my hands when I was but seven years old, and was the first book I ever read with utter interest. It opened to me a new world of thought and enjoyment; invested things before almost unnoticed with the highest interest; fixed my mind on the study of nature, and caused me to resolve at the time I was reading it, that I would devote my life, or devote my life to the acquisition of knowledge.—J. H. Each of these philosophers worked with simple instruments, and was dependent on his own hands; and by methods so direct that he appeared to have almost intuitive perception into the workings of nature; and each gave great care to the composition of his writings, sending his discoveries to the world clothed in simple and elegant English, purified and illustrated by occasional humor. Such was Henry's relation ships with other men. There was sympathy between the men; and Henry loved to dwell on the hours that he and Bakewell, Davy, and Faraday—I shall never forget Henry's account of his visit to King's College, London, where Faraday, Wheatstone, Daniell and Sir Charles Bell were exhibiting the electric spark from the thermopile. Each in turn would try and fail. Then came Henry's turn. He succeeded, calling in the aid of a second battery, the effect of a long interpolar wire wrapped round a piece of soft iron. Faraday became as wild as a boy; and, jumping up, shouted, "That's the Yankee electricity." And Faraday and Wheatstone reciprocated the high estimation in which Henry held them. "During a visit to Wheatstone's, in 1837, Wheatstone's uncle, he told me that Faraday and he had, after Henry's classical investigation of the induced currents of different orders, written a joint letter to the Royal Society, claiming that the Copley medal, that laurel wreath of science, should be bestowed on Henry for his further consultation with them; that the award it was decided to give for the honor till it would come with greater *éclat*, when Henry had made his discovery of the electric telegraphy. Henry's reward to Wheatstone, from those former investigations, Wheatstone promised to give me this letter to convey to Henry. Wheatstone's experiments on light agreed with Faraday and he had for Henry's genius, but Wheatstone's untimely death prevented this." Both Faraday and Wheatstone thought in the philosophy of education, and in the mode in which he agreed. I may in this connection be excused for quoting another letter from Wheatstone, addressed to Professor Henry, after he had received the news I had given him of his name. After a playful discussion of the name Joseph, the letter proceeds: "I hope that both his body and mind will be developed by proper training and instruction; that he may become an intelligent, wise and good man; I say efficient and wise, because an efficient man and a wise man are not always united in the same person. Instruction, whether intellectual or moral, is the work of time. Instruction. Wisdom may be taught, but it cannot be done, but it requires the aid of industry to accomplish the desired object. I hope that in the education of your son due attention will be given to the proper development of both these faculties, but also they will be cultivated in the order of nature; that is, doing before knowing, and knowing before reasoning. By inverting this order much injury is frequently done to a child, especially in the case of the only son of a widowed mother; in which case the temptation becomes an inducement to err. The education in such a case, will generally be found that the boy has never been drilled into habits of industry, of order, of punctuality, of arithmetic, or of spelling; of attention, perseverance, or, in other words, of the habits of an active and efficient life."

Henry was a man of extensive reading, and often surprised his friends by the extent and accuracy of his information; and by the original manner in which he brought his knowledge before them. Not only was he well versed in those subjects in which one might naturally expect to become him proficient, but in departments of knowledge entirely distinct from that in which he gained his reputation as an original thinker. Of poetry, especially the descriptive, he had a keen feeling for the movement of a poem; and was fond of drawing from his retentive memory poetic quotations apt; it the occasion. He was a diligent student of mental philosophy, and also took a lively interest in the progress of biological science; especially in following out the generalizations of Darwin; while the astonishing development of modern research in tracking the history of prehistoric man had for him a peculiar attraction. Of all his learning, reputation and influence, I may say, as evident in his last hours. One day, on opening Henry's copy of Young's Lectures on Natural Philosophy—a book which he had studied more than any other work of science—I read on the fly-leaf, written in his own hand, these words:—

> "In Nature's infinite book of secrecy
> A little I can read."—*Shakespeare*.

And did he not read a little "in Nature's infinite book of secrecy ?" And did he not read that little well ? May we all read our little in that book as modestly and as reverently a did Joseph Henry.

THE PHOTOPHONE.

By Alexander Graham Bell.

In bringing before you some discoveries made by Mr. Sumner Tainter and myself, which have resulted in the construction of apparatus for the production and reproduction of sound by means of light; it is necessary to explain the state of knowledge which formed the starting point of our experiments. I shall first describe the remarkable substance selenium, and the manipulations developed by various experiments: but the final result of our researches has evidenced the class of substances sensitive to light-vibrations, until we can propound the fact of such sensitiveness being a property of all matter. We have found this property in gold, silver; platinum, iron, steel, brass, copper, zinc, lead, antimony, German silver, Arabin's metal, Babbitt's metal, ivory, celluloid, gutta percha, hard rubber, soft vulcanized rubber, paper, parchment, wood, mica and silvered glass; and the only substances from which we have not obtained results are carbon and thin microscopic glass. We find that when a vibratory beam of light falls upon these substances they emit sounds,—the pitch of which depends upon the frequency of the vibratory change in the light. We find further that, when we control the form or character of the light-vibration on selenium, and probably on the other substances, we control the quality of the sound and obtain all varieties of articulate speech. We can thus, without a conducting wire as in electric telephony, speak from station to station, wherever we can project a beam of light. We have not had opportunity of testing the limit to which this photophonic influence can be extended, but we have spoken to and from points separated apart; and there seems no reason to doubt that the results will be obtained at whatever distance a beam of light can be flashed from one observatory to another. The necessary privacy of our experiments hitherto has alone prevented any attempts at determining the extreme distance at which this new method of vocal communication will be available. I shall now speak of selenium.

In the year 1817 Berzelius and Gottlieb Gahn made an examination of the method of preparing sulphuric acid, in use at Gripsholm. During the course of this examination they observed in the deposit a sediment of a dusty reddish, purple color brown color, which, on the return of the blow-pipe gave out a peculiar odor, like that attributed to decayed horseradish. They suspected the existence of extreme rarity; but upon subsequent examination from this deposit; but he was unable, after many experiments, to obtain further indications of its presence. He found plentiful signs of sulphur mixed with mercury, copper, zinc, iron, arsenic and lead, but not a trace of tellurium. It was not in the nature of Berzelius to be discouraged by this result. In science every failure advances the knowledge of the investigator. Berzelius reasoned therefore felt that, if the characteristic odor that had been observed did not proceed from tellurium, it might possibly indicate the presence of some substance then unknown to the chemist. He opened on by this hope he resumed with renewed ardor to his work. He collected together a considerable quantity of the material, and submitted the mass to various chemical processes. He succeeded in separating successively the sulphur, the copper, the lead, the arsenic and all other known substances whose presence had been indicated by his tests;—and after all these had been eliminated, thereafter remained

a residue which proved upon examination to be what we were in search of—a new elementary substance. The chemical difference between the two specimens of selenium was very striking. Whereas the one was crystalline, the other, according to Berzelius, was the allotropic state of "Selenium," from the Greek word σελήνη, the moon—"reflecting," as it is well known being derived from ἄνθος, the earth.

Although tellurium and selenium are alike in many respects, they differ in their electrical properties; tellurium being a good conductor of electricity, and selenium, as Berzelius observed, a non-conductor. Selenium is also a non-conductor when in the crystalline or when fused; but fused, like tellurium, that is contracted, as ordinary temperatures, when in one of its allotropic forms. When selenium is rapidly cooled from a fused condition, it is a non-conductor. In this, its vitreous form, it is of a dark-brown color, almost black by reflected light, having a conchoidal fracture and surface. In this form it is transparent, and converted into a beautiful ruby-red color when viewed by transmitted light. Selenium is cooled from a fused condition with extreme slowness, it presents an entirely different appearance, being a dull lead color, and having throughout a granulated or crystalline structure, and looking like a metal. In this form it is perfectly opposite to light, upon it, very little flows. "Tenacity" selenium, or as Berzelius called it, "metallic" selenium, is what exhibited this singular property which I have termed "sensitiveness" to the electric force. It is the only one of the three allotropic states of selenium that is a conductor of electricity at ordinary temperatures. He also found that its resistance in the passage of an electrical current diminished continuously by heating up to the point of fusion, and that the resistance suddenly increased in passing from the solid to the liquid state. Hittorf has also observed the same phenomena, and has likewise the change of selenium from one allotropic form to another; and this observation is significant in the light of recent discoveries.

Although selenium has been known for the last sixty years it has not yet been utilized to any extent in the arts, and it is still employed simply as a chemical curiosity. It is usually supplied in the form of a black powder, which is amorphous selenium, and is not the metallic condition; but grow usually they are in the vitreous or non-conducting form. It occurred to Willoughby Smith that, on account of the high resistance of crystalline selenium, it might be usefully employed at the shore-end of a submarine cable, in his system of testing and signaling during the process of submerging. Upon experiment selenium was found to have all the requisite properties—none of the bars employed measuring as much as 1 ohm resistance—a resistance so that which would be affected by a telegraph wire long enough to reach from the earth to the sun! But the resistance was found to be extremely variable. Experiments were made to ascertain the cause of this variability. The bars of selenium were subjected to various tests, and at once more was but seen the selenium was exposed to light that when it was in the dark.

In order to be certain that temperature had nothing to do with the effect, selenium was placed in a vessel of water, so that the light had to pass through from one to two inches of water in order to reach the selenium. The lapcock of a lighted candle was placed at the same distance from the selenium bar as the water, and the galvanometer connected with the selenium, and the lighting of a piece of magnesium wire caused the selenium to measure less than half the resistance it did the moment before.)

These results were naturally at first received by scientific men with some incredulity, but they are verified by Adams, Day, Moser, and others. When selenium is exposed to the action of the solar spectrum, the greatest effect is produced in the red, and the least in the outside the end of the spectrum, it is exactly co-incident with the maximum of the heat rays; but, according to Adams, the maximum effect is produced in the greenish-yellow or some intermediate part of the spectrum. Lord Rosse exposed selenium to the action of the spectrum, and found that the bar was affected in the dark spaces of the spectrum as the maximum action of the solar rays,

I am extremely glad that I have the opportunity of making the first publication of these researches before a scientific society, for it is from scientific men that my work of the last six years has received the most valuable encouragement. Not only the encouragement which I received from the late Professor Henry at a time when the speaking telephone existed only in theory indeed, it is greatly due to the stimulus of his appreciation that the telephone became an accomplished fact. I cannot state too highly also the advantage I received in preliminary experiments on several occasions in this building from Professor Cross, and from Professor Houston, of the Franklin Institute. The interest of the public were introduced to the possibility of electrical speech the American Academy of Arts and Sciences, the Philosophical Society of Washington and the Essex Institute of Salem recognized the reality of the results and honored me by their congratulations. The public interest, I think, was first awakened by the judgment of the very eminent scientific men before whom the telephone was brought by Professor Thomson, F.R.S., and Professor William Thomson before the British Association for the Advancement of Science.

At a later period, when even practical telegraphers considered the telephone as a mere scientific toy, Professor John Pierce, President of the National Academy, Mr. Cromwell Varley, Mr. Cooke and Mr. Jones, of Freedom, N. H., devoted much time and the service of experiments for the purpose of assisting me in making the telephone a practical utility; and they communicated to me, from time to time, the result of their experiments with a kindness and generosity I can never forget. It is not only pleasant to remember these things and to speak of them, but it is a duty to repeat them, as they give encouragement to scientific men to persevere, and to the kindness of scientific men to unaccustomed novelties, and of their friends of unknown inventors who dare to enter the charmed circle of science. I trust that the scientific favor which was so readily accorded to the telephone may be extended by you to this new claimant—the photophone.

PLAN OF THE CEREBRO-SPINAL NERVOUS SYSTEM.

BY S. V. CLEVENGER, M. D.

[Abstract from the paper (B 41) read before the American Association for Advancement of Science, Boston, August 26th, 1880.]

The great French and German cerebral anatomists Luys and Meynert had endeavored to declare the architecture of the human brain from a multitude of microscopic sections, but no luminous nor relational law of fibres, nerve-cells, arteries, veins, connective tissue, etc., that it was at once seen to be necessary to study lower animal life anatomically and physiologically before the plan could be determined. Luys did nothing in this direction, while Meynert went as far as the brains of small mammals. Spitska has carried the scrutiny still further. The scheme of Meynert started with the upper part of the cerebrum as the seat of consciousness and, working downward, his "projection systems" ended in the periphery.

The nerve fibres composing the cerebrum and cerebellum were mainly considered. The presence of a multitude of nerve-cells and ganglia dispersed throughout this region was unaccounted for, and as these were of undoubted importance and all well known to anatomists, it was seen by pathologists that these schemes were insufficient.

No scheme can be correct which ignores any part of the nervous organization, or excludes any form of life as anomalous. The conclusion I have reached, is that the sympathetic system of vertebrata corresponds to the general nervous distribution of invertebrata above protozoa, presiding over the nutritive functions. The vaso-motor has been differentiated from the sympathetic distribution, whose office is to produce the vermicular motions of the intestines. Differentiation proceeds dorsally because that portion of the animal which is in most constant contact with the changing molecular motion of the environment would be precisely the portion to give origin to the higher series of nerve divisions. The enclosure, alter the gastrula, stage remains under control of the sympathetic system. The so-called cerebral ganglia of Vermes, are homologous with the spinal segments which afterwards become coalesced in the vertebræ. This is the second system to be developed and *Amphioxus* has not acquired the third or cerebral system proper. In *Trigla Adriatica*, the third system series may be seen developed dorsally upon the second or spinal cord. This third system is the intervertebral ganglia. *Fusion of several of the higher intervertebral ganglia produce the cerebellum*, and accounts for the co-ordinating function of that organ. The several cerebral lobes, the tubercula quadrigemina, mammillary eminence, Gasserian ganglion, olfactory lobe, olivary body, etc. are hypertrophied or atrophied (as the case may be) intervertebral ganglia. Projection systems and commissures, as the callosal, make their appearance in exact accordance with laws operative in the lower series.

The three systems develop gradually, and it may be said, commissurally one upon the other, and this scheme appears to account satisfactorily for physiological and pathological phenomena.

In addition to its publication in the proceedings of the Association, the paper will be produced in full, in the *American Journal of Nervous and Mental Disease* for October, 1880.

ANCIENT AGRICULTURAL IMPLEMENTS OF STONE.

BY HON. WILLIAM MCADAMS, OF OTTAWAVILLE, ILLS.

In the rich, alluvial and about the mouths of the Missouri and Illinois rivers are found many of these ancient stone implements used by the Mound-builders in their rude agriculture. Mr. McAdams exhibited a fine collection of these implements.

They are all chipped from flint, or a hard silicious limestone and some of them beautifully made. Some are nearly a foot in length and six inches wide at the broader end.

Some are made to be fastened to handles, like our modern spades. Others resemble our modern hoes, having a deep, lateral notch, to facilitate the fastening to a handle. Some of these stone hoes are made with such ingenuity as to have been effective implements.

Mr. McAdams also exhibited stone implements which evidently were made to fasten to some kind of stock to be pulled through the ground like a plow. As these ancient people had no domestic animals for this purpose, it is probable that manual force was used to perform the work. The broad cutting edge of these stone implements was highly polished from long use by the attrition of the soil.

Mr. McAdams had found these implements of agriculture in the ancient graves associated with pottery, some of which contained carbonized corn. Cobs in a carbonized state were found, and the speaker is of the opinion that these ancient people lived principally on corn and vegetables, which they cultivated to a considerable extent.

The paper elicited much interest in the association.

A very interesting report addressed to the committee of public health in France by M. Wurz, describes a process for retaining the green coloring of vegetables which is generally destroyed by boiling. It consists in the use of an excess of chlorphyl obtained from spinach (spinacia oleracea) which holds in its cells a large amount of coloring matter. A watery solution of this rendered alkaline by soda, is added to the boiling vegetable which is slightly acidulated with hydrochloric acid. The chemical result is common salt and a deposit of coloring matter on the organic tissue. There cannot now be any possible temptation for the unwarrantable dyeing of preserved vegetables by salts of copper, or the employment of adulterants for obtaining that vivid coloring so attractive to the epicure.

Engineering, July 5th, 1878.

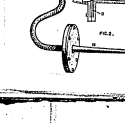
RADIAPHONIC RESEARCHES.

*Upon a Modification of Hunnings's Microphone, and its Application to Radiophonic Researches.**

By ALEXR. GRAHAM BELL.†

In August, 1880, I directed attention to the fact that thin discs or diaphragms of various materials became sources when exposed to the action of an intermittent beam of sunlight, and I stated my belief that the sounds were due to molecular disturbances produced in the substance composing the diaphragm.‡ Shortly afterwards, Professor Tyndall undertook a series of exhaustive investigations, which, however, did not seem to the contrivance that the audible effects were produced by the heating of the plates under unequal heating.§ This explanation has recently been called in question by Mr. Preece,‖ who has expressed the opinion that although vibrations may be produced in the discs by the action of the intermittent beam, such vibrations are not the cause of the sounds heard. According to him the aerial disturbances that are produced are second order spontaneously in the air itself by sudden expansion due to heat communicated from the diaphragm, every increase of heat giving rise to a fresh pulse of air. Mr. Preece was led to demand the theoretical explanation of Lord Rayleigh by the results of a series of experiments undertaken to test the theory.

He was thus forced, by the supposed insufficiency of the explanation, to seek in some other direction the cause of the phenomenon observed, and as a consequence he adopted the impulsive hypothesis alluded to above. But the experiments which he had personally undertaken in the hands of Mr. Preece were unable to succeed when repeated in America under better conditions, and the impulsive theory was necessarily for another hypothesis at once exploited. I have shown in a recent paper read before the National Academy of Science,¶ that audible sounds result from the expansion and contraction of the material exposed to the beam; and that a real loss of vibration of the diaphragms occurs capable of producing sonorous effects. It has occurred to me that the following experiment with a delicate microphone the sonorous vibrations that were so easily observed in our experiments might be carried out. The apparatus has in fact employed the ordinary form of Hughes microphone shown in Fig. 1, and that the vibrating area was confined to the central portion of the disc. Under such circumstances it might easily happen that both the centre (a-b) of the microphone might touch portions of the diaphragm which were practically at rest. It would of course be impossible to determine whether any such localization of the vibration as that would be really occurred, and I have great pleasure in showing to you to-night the apparatus by means of which the point has been investigated (see Fig. 2).



This instrument is a modification of the form of microphone devised in 1877 by the late Mr. Charles Wheatstone, and it consists essentially of a stiff wire A, mounted which is rigidly attached to the centre of a metallic diaphragm B. In Wheatstone's original arrangement the diaphragm was caused directly against the ear and the free extremity of the wire was rested against some sounding body like a watch. In the present arrangement the diaphragm is clamped at the circumference like a telephone diaphragm, and the sounds are conducted to the ear through a rubber hearing tube. The wire A passes through the perforated handle D, and is caused against the diaphragm. When the point A was rested against the centre of a diaphragm, upon which was focussed an intermittent beam of sunlight,

* A paper read before the Philosophical Society of Washington.

† American Association for Advancement of Science, August 27, 1880.

‡ *Nature*, vol. xxiii., page 274.

§ Royal Society, March 10, 1881. ‖ April 21, 1881.

a clear musical tone was perceived by applying the ear to the hearing tube D. The surface of the diaphragm was then rubbed with the point of the microphone and sounds were obtained in all parts of the diaphragm, and in the corresponding senses the other side of the diaphragm. Outside of this area on both sides of the diaphragm the sounds became weaker and weaker, until at a certain distance from the centre they could no longer be perceived.

At the points where the sounds naturally place the apparatus of a Hughes microphone (see Fig. 1) to sound vibrations, it was found possible to detect any audible effects when the point of the microphone was merely applied to the support in which the diaphragm was mounted. The sensitive results announced in Europe by Mr. Preece were, therefore, be reconciled with the positive results obtained in America by Mr. Sumner Tainter and myself. A still more curious demonstration of localization of vibration was obtained in the case of a horse-radish nave. An interrupted beam of sunlight was focussed upon a brass weight (it bluegrammed), and the sounds heard. It was then explored with the microphone shown in Fig. 2, which had distinct sound was heard upon touching the weight within the illuminated area, and for a short distance outside, but not in other parts.

In this experiment, as in the case of the thin discs, absolute contact between the point of the microphone and the vibrating surface is necessary in order to obtain audible effects. Now I do not mean to deny that sound waves may be originated in the manner suggested by Mr. Preece, but I think that our experiments have demonstrated that the kind of action described by Lord Rayleigh actually occurs, and that it is sufficient to account for the audible effects observed.

precise ingredients herein mentioned, as this part of the invention consists essentially in the protective intervention of a substance (alcohol or other) in an solid liquid for the purpose of repelling the fatty ink. Under the term "solid fatty ink" is included not only acids properly so called, but also combinations of those acids with substances which, as they do not neutralise the acids, permit the combinations to act in the same manner as if the acids were free. The paper is thus enabled to use soft acids, by reason of their acid nature repel fatty ink; they are also solid to the compositions which fulfil the double purpose of preserving the paper and of repelling fatty ink, certain substances of a hygroscopic nature, which will retard the evaporation of the composition and keep the material impregnated therewith at a suitable degree of moisture. These substances may be lately named as being either of organic origin, such as gelatine rendered soluble, either hot or in the cold, soluble gluten, starch, dextrine, mucilages, gums, sugars, and glucosides, &c., or of inorganic composition, such as deliquescent salts, &c.; and, in short, all soft-bascule capable of retarding the desiccation of materials impregnated with the composition.

These substances may either be mixed directly with the composition or they may be applied upon the surface of the paper previously to or after application with the composition.

For the production of autographic paper, any kind of paper of medium thickness, glazed or not, or other material may be used. The inks employed are composed of protein substances (albumens, caseine, fibrine, &c.), and of thickenators, peroxides, alums, &c., forming liquid compositions capable when dry of retaining fatty inks. The following is the method of preparation:—dissolve in a quantity of water 2 to 3 times greater than the quantity of albumen (or other protein substance) a mixture of 2 parts of bichromate, prussiate, or alum, &c., to 1 part of ferrocyanide of potassium, by which a liquid brown solution is obtained. Then set apart exactly a certain quantity of albumen and its equivalent of water, which quantity will be necessary in order to obtain sensitive results. Now I do not mean to deny that sound waves may be originated in the manner suggested by Mr. Preece, but I think that our experiments have demonstrated that the kind of action described by Lord Rayleigh actually occurs, and that it is sufficient to account for the audible effects observed.

solution of carbonate of ammonia or of soda. Diluted; 10 to dissolve in pure water 10 to drain upon a plaster slab or blotting paper; 11 to dry it by strong pressure between blotting paper.

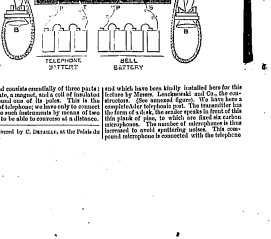
The process of reproducing printed matter is as follows :—The mixture of alcohols and acids is used, before referred to, is applied with a brush either upon the front or back of the printed matter to be reproduced. The paper becomes instantly saturated with the liquid, and the surface is then immediately washed by applying or plunging in pure water. The sheet has been spread very carefully upon a glass plate or has been previously wetted, and a lithographic ink roller is passed over the print, taking care that the roller is passed across from side to side in order to moisten the surface of the paper with the slightly acidified water in reverse of the way adhering to the roller. If the operation, which is very simple, has been performed by a skilled hand, it is only necessary to lightly wash the print to remove the excess of acid; which would otherwise bite the stenotone deeply, then to drain upon a slab of plaster, and when brought to the proper degree of humidity to lay it down upon the stone and pull it through. The transfer is then complete, and the ordinary lithographic operations with the stone will be used. When it is desired to reproduce both sides of a sheet, the sheet is first transferred, and then the other side is damped, inked and transferred. For the reproduction of typographic printed matter it would be made to adhere to the printed sheets, and then bitten in with acid in the ordinary way.

THE APPLICATIONS OF ELECTRICITY.*

(Continued from page 155.)

THE telephone is certainly one of the most important recent applications of electricity. It formed one of the greatest attractions of the Exposition. The telephone was invented by Professor Bell, and consists essentially of three parts: a vibrating plate, a magnet, and a coil of insulated wire wound round one of its poles. This is the transmitter. The receiver is composed of a magnet, the coils of two such instruments by means of two wires, in order to be able to converse at a distance.

* Lectures delivered by C. Decalle, at the Palais de Trocadéro, Paris.



The working of the telephone is easily understood. When we speak near the latter the vibrating plate, we cause it to vibrate in agreement with our voice. The plate vibrating so close to the front of the magnet, causes fluctuations in the strength of its magnetism, and these fluctuations suffice to induce small electrical currents in the coil surrounding the magnet's pole. These currents are transmitted along the line wires, and received in an exactly similar instrument, where they cause the receiving plate to vibrate in unison with the sending plate. In Bell's instrument only one pole of the magnet is utilised, but in Gower's and Ader's telephones both poles are made use of. Besides the telephone we have a microphone, another important class of apparatus, the microphone. Hughes' microphone is certainly one of the simplest electrical apparatus. It merely consists of a pencil of carbon pointed at both ends, and supported by two pieces of carbon, which have each a concave end in which the pencil's points rest. Let us make up a telephonic circuit, and insert in it a battery and a microphone. If we touch the microphone or speak before it, we soon or not to vibration the carbon, which, by pressing more or less on the pencil, causes the resistance more or less of the current to flow through the circuit. We can thus set up important variations in the current, and the two plates of the telephone in the circuit will vibrate in accordance with these variations. Carré, Hughes' microphone, when properly regulated, is an extremely sensitive instrument, and will enable us to hear a fly walk on the ceiling, or a mouse in a corner, when you will easily hear the ticking of my watch, which I have placed upon it; by listening attentively, you will distinguish the noise which the different parts of the watch make in moving. If it works the microphone but very lightly with a feather, you will hear the tickling of the feather. The microphone is also used to make the sensitive for practical purposes, for it converts articulate speech into a continuous current undulating, altogether unintelligible.

Let us now turn our attention to the practical and every-day applications of the telegraph. The most important of these is the clock. In fact I can do no better than to give the interesting account recently compiled for that purpose, on the hour of the *Société générale des Téléphones*,

Digitized by Google

ON THE ACTION OF THE MICROPHONE.*

By Professor JAMES HUGHES, M.A., F.R.S.E.

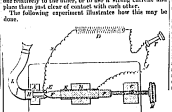
In the Hughes microphone, as usually employed in circuit with a battery and a Bell telephone, we have essentially two pieces of carbon resting lightly against each other through which the current passes. That the instrument may work efficiently two things are requisite; first, that the carbons be always in contact or at least sufficiently near for the current to pass between them, and, secondly, that they may be set exceedingly delicately to the point of any section of the one resting lightly on the other. This state of things is well described by the term "loose contact," first used, I believe, by Professor Stokes.

To understand the action of the microphone we have to find out what effects are taking place at the loose contact when the instrument is acted upon by sonorous waves. These are twofold; first, the effect produced by the sound waves (that is, the variations of density due to the condensations and rarefactions) on the air which surrounds and through it and other they act at the loose contact, and, secondly, the effect produced by tremors set up in the entire instrument, wooden supports and carbons together, by the sound waves which strike against it and are thereby stopped.

For distinction we may call the first of these the air effect and the second the tremor effect.

In my experiments I have endeavoured to arrange the parts so as to get rid of the tremor effect, as far as possible, and to examine carefully the air effect. To reduce the tremor effect as much as possible it is necessary either to fix the sections rigidly in their supports so as to avoid any motion of the one relatively to the other, or to use a strong current and place them just clear of contact with each other.

The following experiment illustrates how this may be done.



A, B, and C are three blocks of lime firmly fixed to a heavy wooden subplank. To the top of A is soldered a piece of brass tube H about 2 in. long and ⅜ in. bore. To the top of B is soldered a piece of similar tube, E, about 4 in. long. Through C passes a fine screw S worked by a milled head M. A piece of carbon rod K is fixed firmly into H and has a hole 1 in. in diameter drilled through its centre. A piece of carbon rod L is fixed firmly into the upper end of the tube E and can be moved backwards and forwards by the screw S. A piece of india-rubber tube J is passed over the left end of the tube H, and to this is attached a mouthpiece M. By means of the wires r and s soldered to the carbon rods, they are put in circuit with the battery (twenty Grove's cells) and the telephone T, which must either have high resistance or be altered in a way not necessary here than containing the battery so as to be kept open inductively.

When the carbon F is forced tightly into the hollow of E the circuit is completely closed and no sound uttered into H is heard at T. But when F is drawn gradually back until small electric arcs are seen to pass between F and G, every sound uttered into M is loudly and distinctly reproduced at the telephone T. Here we have the air effect produced by the small but noisy sparks the small electric arcs passing the carbons.

I have found it as yet, somewhat difficult to get the sounds to last for any length of time in consequence of the arcs distances soon getting too great for the current to pass and requiring re-adjustment. When the arc begins with a sharp click is heard in the telephone; but in the latter case the sound is continuous, and not intermittent.

As far as the tremor effect is concerned, it is obvious that the microphone action must depend, either (1) upon the variation of resistance due to variation of pressure, or (2) to variation in the extent of surface contact due to the elastic yielding of the carbons under pressure.

To test the first of these points, I made about two years ago some experiments on the effect of pressure upon the specific resistance of carbon. For this purpose I took a short length of carbon rod, the ordinary form in which it is sent distance from each end. By means of three wires the resistance of the carbon rod was balanced in the Wheatstone bridge. Pressure was then applied by means of a lever to the carbon in a longitudinal direction. No appreciable variation in the resistance was observed even under considerable pressure; and it only became manifest when the carbon was bent, or when it was crushed by the vulcan. I have recently repeated these experiments with the greatest care, and found the same results. I observed also that similar experiments, with the same result, have quite lately been made by Professor Silvanus Thompson. Hence we can hardly, I think, believe that variation of specific resistance due to pressure can have the slightest effect in producing the microphone action.

To test the second point, the elastic yielding, that is, the variation of resistance due to variation in the extent of surface contact due to elastic yielding under pressure, I experimented as follows: In the apparatus already described, I replaced the tubular carbon by a finely-pointed piece, so as to have two fine points exactly opposite each other. The resistance of the points was balanced in the bridge in the usual way. Pressure was then applied by a known weight to the one point, and the effect on the resistance read in the chord of resistance coils. The screw was then brought back to former position, and the pressure relieved so as to allow the elasticity of the carbon to act and restore the points to their first condition. It is obvious that if the change of resistance were due merely to elastic yielding it should now be the same as before. This I found not to be the case. From the gritty nature of the carbon the points of contact I found were perpetually changing, and the resistance, when the pressure was relieved, was not always the same here. From this irregularity it is impossible, I think, to conclude that this cause could explain the transmission of musical sounds far less articulate speech.

As far as my experiments go, the following appears to be something like the true explanation of the microphone action. When I have heard the sounds in the telephone effects take place at the loose contact. The tremor effect produces a pulse or two of the carbons sufficient to allow momentary minute electric arcs to take place between the points which are just clear of contact with each other. Simultaneously with this the air effect comes in, and, on account of the vanishing of density due to the condensations and rarefactions of the air, acts upon the minute electric arcs so as to vary their resistance. The tremor effect is comparatively powerless in producing sound. The sounds heard in the telephone, whereas it is into the air effect that we must look for the transmission of the quality of the sounds uttered into the microphone transmitter. The microphone is thus so far a delicate make and break analogous to the old Bain transmitter, with the important addition, however, of minute momentary gaps filled with a material which is sensitive to the minute harmonic variations of the atmospheric density which constitute sonorous vibration.

Dated 1882.

ELECTRICAL DISCOVERY.—It is stated that a new electrical contrivance has been perfected by Mr. A. St. George, the inventor of the telephone which bears his name. This invention is really supplemental to the telephone, and will enable every description of conversation carried on through the instrument to be not only recorded, but reproduced at any future time. The principle of Mr. St. George's invention may be thus described. A circular plate of glass is coated with collodion and made sensitive as a photographic plate. This is placed in a dark box in which is a slit to admit a ray of light. In front of the glass is a telephone diaphragm, which, by its vibrations, opens and closes a small shutter through which a beam of light is constantly passing and imprinting a dark line on the glass. Vibrations of the diaphragm cause the dark line to vary in thickness according to the tones of the voice. The glass plate is moved on by clockwork, and the conversation as it leaves the telephone is recorded on the sensitive plate, the imprinted words spoken being fixed as is done in photography. The plate can be brought forward afterwards, and when replaced in the machine and connected with a distant telephone will, when set in motion, give back the original conversation.

—Mr. Edison claims a telephonic invention by which two railroad engineers driving at full speed can communicate with each other when a mile apart. A man capable of such an invention ought to have the skill to get up a contrivance by which a man running at full speed can attract the attention of a car driver a quarter of a square away.

A SPEAKING CONDENSER.

It is well known that an electric condenser of tinfoil sheets when connected by its terminals to the ends of the secondary circuit of an induction coil will reproduce musical notes when the primary circuit is excited by a battery and a Reis transmitting telephone with intermittent contacts. The notes to be reproduced is sounded near the transmitter, whose vibrating diaphragm makes and breaks the primary circuit in accordance with the vibrations of the note, and the corresponding induced currents setting upon the plates of the condenser set them into sympathetic vibration, which is audible as a humming sound. This is the phenomenon of the "singing condenser" as first discovered, we believe, by Mr. C. F. Varley, and carefully investigated by Count du Monsel and other French savants. An important advance in its application to telephony has just been made by M. Dumand, who has succeeded in making it reproduce articulate speech after the manner of the Bell telephone receiver. M. Dumand found that when a carbon microphone was placed in the primary circuit of the coil instead of a Reis transmitter, the ticking of a clock and the striking of a bell could be imperfectly heard; but speech degenerated into a murmur. Following up this promising step, however, by including a battery in the secondary circuit along with the condenser, M. Dumand found that speech was then delivered with perfect distinctness. The battery is simply included between one end of the secondary circuit and one pole of the condenser. Then the forces of infoil which, under the simple influence of the induced currents of the microphone, only gave out simple sounds, were found to reproduce with fidelity the most delicate articulations when they were already charged with condensed electricity. The best results were obtained from a condenser of six centimetres in the side, and thirty-six leaves of tinfoil. With a seven-centimetre induction coil, one Leclanché cell in the primary circuit gives pure musical tones, and with a twelve-centimetre coil one Leclanché cell employed to give resistance effects. For articulation the battery in the secondary circuit should be at least composed of two or three cells; but in that case the voice is rendered feeble. With ten cells in the secondary, a twelve-centimetre coil and two cells in the primary, the voice is as loud as that of a good Bell telephone; and with fifteen Daniell elements in the secondary the sounds were heightened, and speech could be heard with the ear held a yard away from the condenser. This is a practical result of some importance. M. Dumand has yet further increased the loudness of the voice by inserting three or four bichromate of potash elements in the primary circuit; but the effect is not lasting, for the strong current heats up the contact points of the microphone and enfeebles the sounds. Perhaps, however, this defect will be overcome, and M. Dumand will be able to produce a condenser which will speak as loud as it sings. In commenting on M. Dumand's paper to the Academy, Count du Monsel remarked that he had himself made a similar experiment to that of the author, but with feebler though distinct results; and owing to a lack of battery power he had not pushed his researches further. M. Dumand has shown that the singing condenser, and in fact any electric condenser, can act as a good telephone receiver of atmospheric speech.

LONG-DISTANCE TELEPHONING.

When the telephone was first introduced the public was promised that the name of the instrument would be justified by the transmission of ordinary conversation over the same distances as are covered by the telegraph. The companies now operating, however, have taken no practical steps towards the connection of points more than 15 or 20 miles apart, and a clear field is open to the latest comer, the Long-Distance Telephone Co. The system to be introduced by them was invented by Webster Gillett, of Tuxiland, Md., and has been tested with thorough success between New York and Chicago. The main invention consists of a multiplication of "variable distances"; or, in other words, of points of contact on a single diaphragm, by means of which an unlimited amount of electric force can be applied to send the induced current over the wire, thus giving the power for long-distance talking. In ordinary telephones the force from only one, or at most three cells of a battery, can be used without burning the carbon, rendering the transmitter useless.

The system also includes an arrangement for duplexing or using the same wire at once for telephoning and telegraphing.

The company are said to have been experimenting for more than a year to bring the inventions to a state of perfection, and are now completely satisfied that they have reached a point where they can be put into immediate and successful operation.

Scientific American Aug 22, 1885

THE HAND AS A RECEIVING TELEPHONE.

In order to utilize the hand as a receiving telephone, a primary circuit should be arranged, comprising a microphone, three cells of a Leclanché battery, and the primary wire of an induction coil; a secondary circuit composed of the secondary wire of the same coil, a Leclanché battery of twelve cells, and two metal contact pieces secured for medical purposes. Let two persons each hold a contact piece in one hand, placing their disengaged and gloved hands over the ears of a third person, the latter will hear the words spoken into the microphone as if coming out of the inside. At a recent meeting of the French Physical Society, a piece of paper was successfully substituted for the gloved hand, the two persons holding the contact pieces, placing their heads together, the ears separated by the paper. The words spoken were distinctly heard by both.

AGENTS FOR "ENGINEERING."

BELGIUM: C. Bellavia, 76, Boulevard Anspach, Brussels.
BRAZIL: Messrs. A. Asher and Co., 6, Unter den Linden, Berlin, S.W.
CANADA: Hugh C. Low and Co.
EGYPT: Messrs. Johnston and Co., 19, Exchange-avenue.
FRANCE: Messrs. J. Baudry, Librairie Etrangère, 72, Rue de la Banque, Paris. 31, Cité Trévise, 31, Boulevard Bonne Nouvelle, Paris.
GERMANY: Hoffman Lange.
HOLLAND: Martinus Nijhoff, 9, Plein-straat, The Hague.
INDIA: W. A. Smeaton.
LUXEMBURG: Max Theiler, Leading Store.
SPAIN: Librairie Centrale, 23, Calle de Peligros, Madrid.
SWEDEN: Hasselberg and Co., Stockholm.
UNITED STATES: Lemoe Smith, 41, Pine-street, New York.
WALES: Lehmann and Wenzel, Haverfordwest.

Advertisements cannot be received for insertion in the current week later than Five o'clock on Thursday. The charge for advertisements is 40s. for a single insertion, or 3l. 10s. per month. Special prices for each additional line. The free carriage notice works. Payment must accompany all orders for single advertisements, and for the first insertion of a series. Cheques and Post Office Orders should be made payable to the publisher, and crossed "London Joint Stock Bank, Limited."

The charge for Special Terms for Contract Advertisements to subscribers in the United Kingdom, including postage to any part of the world, is 3l. per page, 1l. 15s. for half a page, and 1l. for a quarter of a page, for each insertion, this including two double numbers. If space be taken by the year, 3l. 3s. for 52 weeks, the subscription being payable in advance.

FOREIGN SUBSCRIPTIONS

The terms for subscriptions to "Engineering" for delivery from abroad are 1l. 15s. 6d. for all the following countries, viz.:—Adelaide, Austria, Hungary, Belgium, Brazil, Bulgaria, Canada (including postage), Cape Colony, Ceylon, Chili, Constantinople, Denmark, Egypt, Germany, Gibraltar, Greece, Italy, Java, Malta, Mauritius, Natal, Netherlands, Norway, Portugal, Roumania, Russia, Servia, Spain, Straits Settlements, Sweden, Switzerland, Tahiti, Turkey, United States of America, Australia, and New Zealand.

To all other countries, especially when receiving their subscriptions through Agents, the subscription is 2l. 2s. per annum, payable in advance.

All accounts are payable to the publisher, Mr. CHARLES GILBERT, 35 and 36, Bedford-street. Cheques should be crossed "London Joint Stock Bank, Limited." Post Office Orders to be made payable at the Strand, London, W.C.

Exchange Subscribers, especially when receiving their subscriptions through Agents, are requested to see that the number of the transmission of the first copy sent, and the amount of the sum which it is made payable. If this precaution is omitted, some difficulty is very likely to occur in obtaining the name of the sender.

Terms for Publication and Advertisements, Nos. 25 and 26, Bedford-street, Strand, W.C.

ENGINEERING is registered for transmission abroad.

BINDING CASES.—Binding cases for containing twenty-six Numbers of ENGINEERING may be had of the publisher or of any newsagent. Price 2s. each.

NOTICE TO AMERICAN SUBSCRIBERS.

We beg to announce that we have appointed Mr. Lemoe Smith, 41, Pine-street, New York, to act as our Agent for the sale of ENGINEERING in the United States, and all subscriptions for the United States will in future be payable to him. Mr. Lemoe Smith is also prepared to receive advertisements for ENGINEERING, and will forward the numbers containing them to subscribers and others on the usual subscription for Exchange Subscribers delivered from to the United States is 31 shillings, each copy payable in advance.

NOTICES OF MEETINGS.

THE INSTITUTION OF CIVIL ENGINEERS.—Ordinary meeting, Tuesday, March 15, at 8 p.m. Paper to be read, "On Iron Ore Deposits," by William Thomas Doyle. Also, "The Tide-Gauge, Automatic Recorder, Assistant, and Tide-Predictor;" and paper to be read, three persons retiring "On the Compensation Endurance" are not eligible for re-election when proposed to Unfinished Business," by David Phillips. M. Inst. C.E.

THE METEOROLOGICAL SOCIETY.—Wednesday, the 16th instant, at 7 p.m., at the Institution of Civil Engineers, there will be an Ordinary Meeting of the Society, when the following papers will be read:—"Results of Observations of Temperature at Kew, from 1871 to 1880," by Mr. Ellis. "Hail Storms in the British Islands on January 1, 1880. During the evening the President will give a Discussion on the Instruments and Methods of Registration, and will hold conversation such forms as are exhibited.

The Publisher desires to draw the attention of Manufacturers and Inventors to the fact that ENGINEERING is largely circulated among the Engineering Trades and Industries of the new editor of this Journal. In this views are kept for the benefit of Subscribers, files of the principal English and foreign technical journals, and the circulars and catalogues of the leading manufacturers in the Engineering Trades, either for reference or distribution. A complete set of the Specifications of Patents published during the current year, and a large collection of those published in previous years, will also be available for reference. Manufacturers or Inventors desirous of introducing their machinery and which will be indexed and placed under the care of an attendant.

ENGINEERING.

FRIDAY, MARCH 11, 1881.

THE PANAMA SHIP CANAL.

THE publicity with which the subscriptions for the construction of the Panama Ship Canal were taken up by the public, has been followed by an almost equally surprising celerity in the commencement of the works, ground having been broken on the first of February. A meeting of shareholders, recently presented to a general meeting of shareholders, combined this announcement, together with much interesting information as to the mode by which he proposes to carry out the work that it is to supersede the continents of North and South America. A similarly sanguine as to the triumphant termination of the great project, M. de Lesseps points out that the problem is not complicated with a number of the difficulties which beset the construction of the Suez Canal, that no ports will have to be formed, that the materials to be dealt with are of a nature far more tractable than the sands of Suez, that the difference in level of the two oceans will present no difficulty, and that extensive workshops and workmen's dwellings will not have to be set up in the midst of a waterless desert. The total length of the canal itself will be about 41 miles, the remainder of the navigable channel being formed by widening, deepening, and straightening the River Chagres. After the Panama Canal Congress of 1879, when an approximate route was decided upon, an International commission was despatched to Panama, and commenced a detailed examination at the beginning of last year. The result of the labours of this commission showed that a considerable reduction might be made in the amount of excavation necessary for the canal works, the originally estimated quantity of nearly 100,000,000 cubic yards being diminished by more than two-and-a-half millions yards, the total amount consisting of 59,381,000 yards of earth, and soft and broken rock, and of 37,353,000 yards of hard rock. The total estimated cost of the whole work is 214,000,000*l.*, of which 27,000,000*l.* will be absorbed in making the canal, the protecting banks for it, and for the Chagres and Rio Grande, and for the transport of material to the site of the works. Chagres river dam, a supplementary but decided upon in consequence of some exceptional floods which occurred upon the Chagres last year. Nearly two millions will be expended in the construction of this dam, its protection works, rising portions of the canal, and in making a pier in the bay of Colon. The improvement of the ports, the formation of docks, and the establishment of lighthouses will cost 4,000,000*l.*, and 7,000,000*l.* more will be occupied in the final location of the route, and the establishment of preliminary works, which will necessarily be of an extensive and very costly nature, but it is expected that by the end of the season 5,000 workmen' dwellings, repairing shops, and machinery will be completed, and a complete railway laid down, the system of transport organized, and a large proportion of the excavation plant on the ground, and it is confidently anticipated that excavations will be vigorously commenced.

That MM. Hersent and Couvreux have undertaken the completion of the canal is one undertaking is a sufficient guarantee that the highest amount of energy, intelligence, and skill will be employed in successfully carrying out so gigantic and somewhat similar works as those which have been successfully carried out in Russia, and which are experiencing peculiarly valuable in this new undertaking. The methods they have already employed to overcome vast quantities of earthwork will be substantially employed at Panama, including the excavation similar to those they used on the Suez Canal, in making the Gaud and Suzweaze canal, and the improvement of the Danube, and also the dredging plant also employed in the latter work. As far the steel plating, MM. Hersent and Couvreux have learnt how to deal with it at Brest and Cherbourg. M. de Lesseps anticipates that excavations in the canal will be opened for traffic in 1883, assuming that 40,000 cubic yards of materials of all kinds can be excavated and dealt with during each month. Within the succeeding years, and that a force of 10,000 men can be kept employed continuously. The remaining and last feature of the work is the utilization of water power from the Chagres, which will be employed for rock cutting. A tunnel 5 miles long is proposed to obtain this by forming the dam, already mentioned as a necessary part of the work, and returning by its fall the air compressors required for the rock drills.

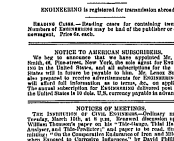
Such is a very general outline of the scheme for carrying out what will be, when completed one of the greatest engineering undertakings that the world will have seen. That it will be carried to a successful issue there is no room for doubt, since the physical obstacles are great only from the magnitude of the materials to be dealt with, so that the contractors have but to repeat what they have done many times before on a smaller scale. The problem of raising the necessary capital has been solved by the 100,000 subscribers, and all the political and financial difficulties appear to have been removed by the energy and diplomacy of M. de Lesseps. In every sense, conditions and opinions have changed since this indefatigable worker astonished the world with his proposal to divide two continents by the Suez Canal. In this country especially this proposal was met with ridicule, and received but little support. It was regarded as impracticable from an engineering point of view, and ridiculous as a financial undertaking. Objections like these have not been urged against the Panama Canal, for the successful completion of the Suez Canal, and, later, of such tremendous undertakings as the Mont Cenis and St. Gothard Tunnels, have silenced all disbelievers in the possibility of great engineering works; while the vast change wrought by the opening of the short canal to the East must convince every one that this new gate to the Pacific will develope (not possibly direct) trade to an incalculable extent, and the army of large and small capitalists who have so readily contributed their money to effect this development, will be benefactors of the world at large, even if they should not themselves reap a sufficient reward for their enterprise.

THE TELEPHOTOGRAPH.

THE apparatus recently exhibited by Mr. Shelford Bidwell to the Physical Society is probably the first detailed step towards the perfect solution of the great electrical problem, how to transmit the image of a natural object along a wire to a distant place.

Mr. Bidwell has for some time past been experimenting with the photophone of Professor Bell, and his letters form of this beautiful instrument is now well known. In this way the capabilities of selenium cells, especially those of high resistance, for transforming the energy of light into an electrical effect, became familiar to him, and this idea suggested itself that by combining a sensitive selenium cell with a modification of Bidwell's sequying telegraph, it would be possible to make an optical image focussed on the cell reproduce itself by delineation at the other end of a line in circuit with the cell.

The theoretical arrangement which he has adopted is shown in Fig. 1, where the positive pole of a battery B is connected, through a set of adjustable resistance coils as R, to a platinum stylus



or pen P, which rests its marking point on a plate of zinc M, covered by a sheet of paper moistened with the solution of iodide of potassium used in Bidwell's electrograph. The circuit of the battery is completed through a galvanometer G by a wire from the plate to the negative pole of the battery B. This is the receiving part of the apparatus; and the transmitting part consists of a second battery B' having its negative pole connected with the platinum stylus P through a sensitive selenium cell S, and the circuit is completed likewise through the zinc plate M and galvanometer. Now, if the selenium cell be exposed to light of equal intensity in other words if a sheet of paper be focussed on it, and the variable resistance R be so adjusted that the opposing currents in the two battery circuits exactly neutralize each other, no current will flow from the stylus P on the paper across the insulated joins, and hence no mark or line will be made with the pen P if the stylus be drawn across it. But if the light be shaded off the selenium, the resistance of the latter will increase and the current from the first battery will therefore, proportionate as so to cause a flow of electricity down the stylus. When the stylus is drawn across the paper it leaves its trace as a brown mark of liberated iodine; and this trace is strong or faint according as the current is strong or faint, that is to say in proportion as the light is bright or more intense. The galvanometer serves to indicate when the balance of currents is zero; and the connecting wires W W, which correspond to the telegraph line between the two stations, where the transmitter and receiver are placed, may of course be of any length.

The actual apparatus constructed by Mr. Bidwell

which are nearest to the surface. A great part of it will, however, be mechanically retained and remain entirely, and when the wax is reduced to fine powder, it will be set free, exactly as the enclosed gas becomes freed by the disintegration of the steel or pig iron.

That this is the case is of the greatest importance to the steelmaker; because he will be enabled to remove the gas from his metal and produce a sound casting free from honeycomb. Dr. Mueller sound casting free from honeycomb. Dr. Mueller has observed, that the castings as at Bochum, are always dense and sound, when the cession of the spiegel is very active in the converter. This rejection can only be explained when the wax is introduced into the metal in a certain quantity of oxygen; the carbon of the spiegel takes this oxygen; the carbon of the spiegel takes this oxygen, blue with this oxygen to form carbonic oxide, which causes a sudden ebullition by which the absorbed gases are driven out, exactly as chlorine and bromine are removed from their respective solutions whenever a current of nitrogenous air is blown through. Dr. Mueller's investigations are therefore of the greatest importance to the practical steel manufacturer, and he deserves the thanks of a large part of the metallurgical profession.

THE BATTEY BOILER EXPLOSION.

As we have already briefly recorded in this journal, there occurred on the 10th ult., at Messrs. Greenhow and Hirst's New Brighton Mills, Carlinghow, near Batley, a boiler explosion of an unusually disastrous kind, this explosion causing sixteen deaths, besides serious injuries. The inquest on those killed by this explosion was twice adjourned, and was only brought to a conclusion on Tuesday last, the 15th inst. During the inquiry, the coroner, Mr. Thomas Taylor, had, we are glad to say, the valuable assistance of Mr. T. W. Hall, of Leeds, as to the cause, and the investigation of the circumstances attending the explosion has been carried out in a thorough manner. We give, on page 200 of the present number, a report by Mr. John Waugh, the chief engineer of the Yorkshire Boiler Insurance and Steam Users Company, which contains a full description of the boiler which exploded, while the illustrations on page 201 will give a fair idea of the havoc which the explosion caused. Under these circumstances it will be unnecessary that we should in the present article enter further into these details, but we may make one conclusion clear to the extent facts brought out in the course of the inquiry.

The history of the boiler which explosion proved by the evidence given at the inquest, is briefly as follows:—The boiler was made in 1858, by Thomas Hill, of Heywood, in 1855, for the Halifax Flour Society, to whom it was delivered in September of that year.

The boiler was at that time one of Mr. Hill's patent screw-fluted boilers, but in 1859 it was altered to a two-fluted Lancashire boiler by Messrs. Crossley and Worthington, of Halifax, at a cost of 80*l*. The Halifax Flour Society worked the boiler until October, 1870, when they sold it for 50*l*. to Messrs. Savage and Norton, by whom it was again sold, in February, 1871, to Mr. Job Terry, trading as *Terry, Sanford, and Co.*, Lastly, Mr. Terry, in his turn, disposed of it, in 1877, to Messrs. Greenhow and Hirst, by taking in exchange 70*l.* and an old boiler, which he subsequently sold for 10*l.* The boiler appears to have been originally made for a working pressure of 50 lbs., and it was being worked at 40 lbs. when the Halifax Flour Society disposed of it, it being stated that they only drove the engine, owing to leakings in the furnace, which was cracked. After the boiler had left Halifax Flour Society no repairs were done to it before it came into the hands of Messrs. Greenhow and Hirst.

As to what was done to the boiler after it came into Messrs. Greenhow and Hirst's hands, information was given at the inquest by Mr. Israel Umpleby, of Cleckheaton. He deposed that he was first asked to look at the boiler in March, 1879, when there was a slight leakage, and he was instructed to put some rivets in the furnace. In October, 1879, some slight repairs were done to the flue, and in December of the same year a piece of angle iron was put in on the left-hand side of the left-hand flue. He also taken out being fractured for a length of about 18 in. In May, 1879, some further repairs were done to the flue and some new rivets put in, while other new rivets were put in the furnace in June of the same year. Again in October, 1879, the engineman, after emptying the boiler for cleaning, attempted to fill it with cold water, and found that a seam in the outside shell was ripped for about 4 ft. This rip was repaired, and in January, 1875, a patch was put in one of the flues, while in March of the same year, some slight repairs were made by putting in rivets. On August 18, 1879, the flues were overheated and partially collapsed, yet notwithstanding they were left in the boiler for 4 days, the boiler not being used until the 17th of September following. The three first plates over the fire in each flue were then renewed. In January or February, 1879, a new safety valve was put on the boiler, the ordinance was offered of any repairs having been done from the time of the new furnaces plates being put in September, 1877, up to the date of the explosion.

So much for the history of the boiler—a history which we think speaks for itself; let us next consider the evidence as to the manner in which it was set and the pressure at which it was worked. Mr. Thomas Bulling, of Batley, deposed that he set the boiler at Messrs. Graham and Hirst's in 1871. It was set on the brickwork of consolidation first passed along the side and then returned underneath. It was carried on two courses of firebrick, and he (Thicke) was not aware of any lime being in contact with the plates. Water accumulated in the centre flue, and six or seven months after the boiler was set a drain was made under this flue. This drain appears to have carried off the soil at the time, but John Oates, a flue cleaner, of Liversedge, deposed that he went into the flues of the boiler four or five months ago, and that in the bottom flue the water then stood half-way up the brickwork. And Charles Smith he (Oates) told Mr. Hirst (who has been for some time the managing partner in the firm) that the flues of the boiler required cleaning out, but Mr. Hirst would not have it done. Mr. Hirst, in his evidence, said that Mr. Oates, formerly for two years engineman to Messrs. Graham and Hirst, that in the time (about four years) that the boiler was about 14 in. out of level, and that he had to carry the water high to keep the water level. A witness, Abraham Jr. Pickles, fireman of Newtown, Leeds, who was engineman to Messrs. Greenhow and Hirst, from May, 1877, to May, 1878, of the boiler, also deposed that at that time the boiler was fastened at the bottom, and he called the attention of Mr. Graham and Mr. Hirst to it. The pressure was not of any great extent, and he believed that it had been caused when running the engine with the safety valve on.

As regards the working pressure we have already stated that the boiler was worked at 40 lbs., when the Halifax Flour Society parted with it in 1870. Previous to that time experiments had been made with the boiler when first started at Messrs. Graham and Hirst's was worked at a pressure of 70 lbs., to 75 lbs., but it was soon reduced and risen to from 40 lb. to 45 lb., and occasionally 45 lb. In 1877 it was worked at a pressure of 50 lbs., but when Messrs. Greenhow and Hirst purchased it in 1877 it was a new boiler was put in for supplying steam to the engine, and the old boiler was reserved for supplying steam for heating purposes, the working pressure being then considered to be about 45 lbs. We say "nominally" because it was proved that this pressure was habitually exceeded. Mr. Inspector Frederick Appleyard, depositing that he was the last inspector of the boiler, and that he had been during the four years; about six months ago he saw it at 75 lb., and that steam was not then blowing off. This witness added that he had never seen the safety valve lifted when he had inspected the boiler. On the Saturday before the explosion he saw the pressure at 70 lb., and in addition to the weight he had seen a steam test to see safety valve. The evidence as to the steam was corroborated by Mr. John Lawrenson, of Batley, and by James Sheard, a plaiter, both of whom had been at the mill in August, 1878, and were soon after removed to the mill. Sheard deposed that he had seen Hirst about having the safety weight on the safety valve, and Hirst had replied that he considered half-a-pound blowing off the engineman was always trying to get more steam than allowed him."

Such is a summary of the main facts elicited in the inquiry. The liability apart from Mr. Waugh's report. The boiler had been subject to no inspection beyond that of the engine tender who cleaned it. A reference to Mr. Waugh's report will show clearly the cause of the explosion. The boiler was extensively and seriously corroded, and it was simply in such a dangerously weak state that it was utterly unfit for work. Mr. Waugh adds that its condition could never have been readily ascertained by proper inspection. In the face of this evidence the Batley jury on Tuesday last returned the following verdict: "The jury are unanimous in returning a verdict that the deceased persons were accidentally killed by the explosion of a boiler at Brighton New Mills, Batley, and that the said explosion was caused by over-pressure. At the same time they desire to express their strong opinion that the proprietor of the premises (Mr. Hirst) is highly censurable in not having the boiler examined by a competent person." We have on page 198 of the present issue, in the course of an article on the Paddock explosion, expressed the opinion of such verdicts as these, and we only add here that it is utterly hopeless to put an end to the recklessness of a certain class of boiler owners so long as explosions are investigated by tribunals which are composed not of men of the class that which occurred at Batley, as "accidental." With the rapid increase which is going on in the number of boilers in use in our cities and towns, the time has arrived for a drastic compulsory legislation on the subject is most urgently, efficient, and those who are promoting such legislation deserve the most earnest public support.

THE ANTECEDENTS OF THE PHOTOPHONE.—No. III.

We have in previous articles referred to the early experiments of Mr. Willoughby Smith upon the action of light upon the electrical resistance of Selenium,* as well as to those of Dr. Werner Siemens and the simultaneous researches of Messrs. W. Grylls Adams, F.R.S.† In the present notice we shall review the continuation of Professor Adams's researches which were brought before the Royal Society in May, 1876, by himself and his pupil, Mr. R. E. Day, and were subsequently published *in extenso* in the Philosophical Transactions.‡ The special objects of those researches were: (1) To determine whether the changes in the resistance of selenium are in direct result of radiation, and if so, whether the dark rays, the luminous rays, or the ultra rays produce the greatest changes. (2) To compare the action of radiation in the selenium in its exposure to light from different sources and also to light which has passed through various absorbing media. (3) To determine whether the action is instantaneous or gradual, and to measure as far as possible the intensity of the action. This was necessary to the character of the electrical conductivity of selenium when kept in the dark and (4) To determine whether light could actually generate an electric current in the selenium, and be of the same nature as the currents Professor Adams adopted a Wheatstone bridge arrangement in which the four sides were respectively the selenium whose variation in resistance was to be measured, a variable resistance box of from 1 to 10,000 ohms, a fixed resistance of 4 ohms, and a coil of 9000 ohms. A reflecting galvanometer was placed in a circuit joining the junction of the selenium and the coil to the junction of the two other resistances, and a battery was included in a circuit which connected the other two junctions. A rough arrangement of circuits is illustrated by the diagram Fig. 7, where B is the battery, G the galvanometer, S the selenium, and

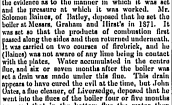


FIG. 7.

O D and E the several resistances. The circuits examined in the earlier experiments was the same specimen which had been first used by Mr. Willoughby Smith, and consisted of a rod about 1·4 millimetres long, 12 millimetres broad, and 3 millimetres in thickness. This was enclosed in a glass tube which was fixed in a box so as to be very similar to the apparatus shown in Fig. 1,* with the exception of being furnished with a sliding bastard of a hinged cover.

In arranging the apparatus for the measurement of resistance according to Fig. 7, the box containing the selenium was placed on its side and close against it was fixed a screen having in it a rectangular aperture which could be closed by a shutter or by pieces of coloured glass or other absorbing media through which the light from a source of illumination could, when required, be allowed to fall upon the selenium bar. The resistance of the latter, when in the dark, was then balanced by the usual process, care being taken that the current was not on for any length of time, which would cause it to increase its resistance. The cover of the box was then removed, light being allowed to fall upon the selenium for about fifteen seconds, by which its resistance was diminished, increasing again the moment that the light was again eclipsed, but Professor Adams found that the heating as well as the polarisation effects of the current are elements in the phenomenon and modify the results; he also found, as Dr. Werner Siemens had done, that the selenium is considerably more sensitive to the influence of light when first exposed after having been kept in the dark for some time than it is after repeated exposures, a fact which renders accurate measurement exceedingly difficult and complicated, for after each experiment the selenium has received a temporary injury to its sensitiveness, to which the name "fatigue" was very aptly applied by Dr. Siemens, and this fatigue renders it extremely difficult, if not impossible, to compare with any degree of accuracy the early experiments in a research with those which follow later on. Professor Adams found that the resistance of Mr. Willoughby Smith's bar of selenium was diminished by the light of an ordinary wax taper at a distance of 200 millimetres by as much as 15½ per cent of its resistance when in the dark, and in a series of experiments with the same bar making a gas jet was the source of radiation, the diminution of resistance amounted to from 10 to 25 per cent of the whole resistance.

In experiments belonging to this stage of the investigation Professor Adams found that the fluorescence fringe presented exceptional conveniences as a source of radiation, for by simply opening or closing a single hole of the burner the fringe can be made non-luminous or luminous at will, the heat remaining while the radiant heat emitted by the non-luminous flame, as measured by a delicate thermo-pile apparatus, was very nearly but not quite as great as that from the luminous flame, the respective values being as 100 were very different upon the resistance of the selenium bar; the non-luminous flame producing but little or no effect, while the comparatively cool luminous flame diminished the resistance in the selenium very considerably, amounting in some cases to as much as 25 per cent of the whole resistance of the bar.

This very interesting result led Professor Adams and Mr. Day to investigate the effect produced upon the electrical resistance of selenium by the dark heat rays of the electric light. For this purpose a screen was placed at such a distance of about two feet from the electric arc, the luminous rays being cut off by Faraday's method, a battery of boron plates of smoked rock-salt and alum, and although the experiment was carried on for hours, no effect could be observed upon the resistance of the selenium bar. As, however, the luminous rays alone in the beam would be to cut off the heating or actinic rays, while that of the smoking of the rock salt would be to eliminate the luminous rays; for clear rock salt, although it absorbs a considerable quantity of the luminous rays, while clear alum is transparent to light but almost perfectly opaque to heat, the interposition of the smoked rock-salt alum produced the same results as that of boron, viz., a perfect blankphilic of carbon of sufficient thickness to be opaque to luminous rays, the luminous rays were repeated in various ways under various conditions and invariably with the same result, leading these authors to the conclusion that "heat rays do not act powerfully in reducing the electrical resistance of selenium."

From this series of experiments it was but natural that Professor Adams and Mr. Day should be induced to take up the investigation of the effects produced upon the resistance of selenium by the chemical or actinic rays of the spectrum, and with this object glass of various colours so as to obtain spectra of such solutions were placed between the source of light and the selenium, but the results were not altogether

* See ENGINEERING, page 1, *ante*.
† *Ibid.*, page 12, *ante*.
‡ Proceedings Royal Society, vol. xxv., page 113.
§ Philosophical Transactions, vol. clxvii., page 313.

diminution of resistance depended rather upon the intensity of illumination than upon the presence or absence of the chemically active rays, the maximum effect on the resistance of the selenium being produced by rays coming from the colours in the spectrum between the yellow and the red, or a little further from the maximum heat region of the spectrum than was estimated by Lieutenant Sale.* After a long series of experiments in which the selenium was exposed to radiation not only proceeding from various regions of the spectrum, but from light emitted by various incandescent metallic vapours, Professor Adams and Mr. Day came to the conclusion that "the luminous rays are the cause of this peculiar behaviour of selenium, and that the dark heat rays and the chemically active rays have very little if any, share in producing it."†

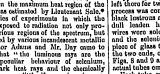

FIG. 8.

By exposing the selenium to the radiative influence of a constant source of illumination placed at different distances, Professor Adams found that the change in the resistance, as measured by the deflection of the galvanometer, is exactly as the square root of the illuminating power. In the following Table the figures represent scale readings of the galvanometer when the source of illumination was placed at the distances from the selenium as are indicated at the top of the columns.

Sources of Illumination.	Distances from Selenium.			
	1 metre.	1 metre.	1 metre.	2 metres
Argand lamp	...	170	82	39
Ditto ...	...	120	58	28
Ditto...	...	85	41	20

In continuation of this investigation, Professor Adams repeated the experiments by a somewhat different method, by varying the illuminating power of the light at its source, and by keeping its distance from the selenium constant, and the results given in the next Table show, as the former, that the change in the resistance is directly proportional to the square root of the intensity of illumination.

Number of Candles Measured by Photometer.	Galvanometer Deflection.
1	90
4	180
9	270
16	360

We may, however, here point out that this conclusion does not necessarily contradict the theory which Dr. Siemens gathering ground, that the ultimate physical action of light upon selenium is an electrolytic one, by heat, thus to light, for the researches of Mr. Crookes seem sufficiently to show that the same conditions of one force than distinct and opposed energies.

All the experiments of Professor Adams and Mr. Day to which we have yet referred have been made with the bar of selenium which had previously been experimented upon by Mr. Willoughby Smith, but in the subsequent researches of those investigators a large number of selenium specimens were tens a large number of selenium specimens were tens a large number of selenium specimens were described by Professor Adams in a paper which he read before the Royal Society. In this paper, which was read on the 15th of December, 1876, Professor Adams described the various methods employed by Mr. Werner Siemens which we figured and described in our last article,‡ and also those which were used for placing them in a test tube which was maintained at a uniform temperature of from 150 deg. to 180 deg. Cent. for several hours in a bath of paraffin, and was allowed to cool down very slowly, but by far the greater number of the experiments were made with the selenium cells of the form shown in Figs. 8 and 9.

Before is throughout this interesting research nothing more remarkable than the great diversity in the resistances of selenium cells prepared in precisely the same way, and apparently under precisely the same conditions. The following Table gives the results of a series of measurements made on a dozen of such cells on two consecutive days in the year 1876. The battery power employed was that of a single cell, and the deflections of the galvanometer are in degrees of the battery being in all cases connected to the marked electrode of the tube.

No. of Cell.	May 8.			May 9.		
	Temperature in Centigrade.	Resistance in Ohms.	Temperature in Centigrade.	Resistance in Ohms.	Temperature in Centigrade.	Resistance in Ohms.
1	19° C.	1,515,000	47° C.	6,87,10	19° C.	1,510,000
2	"	1,510,000	"	6,87,10	"	1,510,000
3	"	7,000,000	"	2,325,000	"	2,300,000
4	"	1,510,000	"	6,87,10	"	1,510,000
5	"	153,000	"	68,000	"	117,000
6	"	153,000	"	68,000	"	117,000
7	"	1,510,000	"	6,87,10	"	1,510
8	"	1,510,000	"	6,87,10	"	1,510,000
9	"	1,000,000	"	1,150,000	"	1,150,000
10	"	55	"	22	"	17
11	"	55	"	22	"	17
12	"	55	"	22	"	17

It is impossible to look at the above Table without being struck with the enormous differences of resistance between cells which are, to all outward effects, differences so great—amounting in some cases to several millions of ohms—and even at ordinary temperatures to over three millions of ohms—that the wonder is not that these differences of electric resistance should have not been met with by all workers with selenium, but that they should have been of very important elements of disturbance as at work investigating the data.

At this point we cannot but draw very special attention to the remarkable selenium cell "No. 10," the last in the above Table, and which is the one illustrated in Fig. 9, because it comprises a very conspicuous position in the history of selenium and among the antecedents of the Photophone. In the very interesting paper in which the invention of the photophone was first announced by Professor Graham Bell and Mr. Sumner Tainter, and which we published *verbatim et literatim* as far back as Sep-

All accounts are payable to the publisher, Mr. CHARLES WYMAN, 74, Great Queen-street, Lincoln's-inn-fields. To prevent "Town Sales," Cheques should be crossed "London and County Bank, Chancery-lane." Post Office Orders to be made payable at 427, Strand, London, W.C.

Foreign Subscribers, requiring their subscriptions to be forwarded to them by post, should remit the amount for the transmission of one year, or for a shorter period, in advance, which it is made payable. If this precaution be omitted, some difficulty is very likely to occur in obtaining the name of the defaulter.

Office for Publishing and Advertisements, No. 35 and 36, Bedford-street, Strand, W.C.

ENGINEERING is registered for transmission abroad.

Binding Cases.—Binding cases for containing twenty-six numbers of ENGINEERING may be had of the publisher or any newsagent. Price 4s. each.

NOTICE TO AMERICAN SUBSCRIBERS.

We beg to announce that we have appointed Mr. Lemcke and Buechner, 30, Park-place, New York, the sole agents for ENGINEERING in the United States, and all subscriptions for the United States and Canada should be sent to them. Messrs. Lemcke and Buechner have also prepared to receive advertisements for ENGINEERING, and will afford full information as to terms, &c., on application. Subscribers in the United States will please remember that the price in the United States is 10 dol. U.S. currency payable in advance.

NOTICES OF MEETINGS.

INSTITUTION OF MECHANICAL ENGINEERS.—Thursday, April 21st, and Friday, April 22nd, at 32, Great George-street, Westminster. The chair will be taken for the meeting at 7.30 p.m. on each day. The following papers will be read and discussed: "On Steering Apparatus," by Mr. Thomas Brassey, M.P. "On the Application of Experiments on Riveted Joints," by Mr. John Fernie. "Results of Experiments on Riveted Joints," by Professor A. B. W. Kennedy, F.R.S. "On Steam Jacketting," by Mr. Thomas Wrigley, of London. "On Means for Measuring Small Flows of Water," by Mr. J. J. Taylor, of London. "On the Insane System of Dredging," by Mr. J. S. Langley, of London.

THE MECHANICAL SCIENCE SCHOLARSHIP, the Gold Medal, and Prize of Books, founded by the late Mr. Whitworth, will be awarded in connection with the Institution of Mechanical Engineers. The subjects will be each: "On the Frequency and Duration of Rain," by Mr. Whichert Slingen. "Results of Experiments made at the New Testing Establishment, Elswick," by Mr. Andrew Noble, C.B. "On Wrought Iron," by Professor A. B. W. Kennedy, F.R.S. "Remarks on Mr. Leigh's Table of the Barometric Height at London, with regard to Periodicity," by Mr. E. Whipple, Edin., F.R.A.S., F.M.S.

The Publisher desires to draw the attention of Manufacturers and Purchasers to the advantages offered by the INTELLIGENCE AND ADVERTISING COLUMNS OF ENGINEERING. *These columns are read every week by the heads of nearly forty of the principal English and Foreign technical journals, and the circulars and catalogues of the leading firms in every branch of engineering are to be found regularly on the publication. A limited arrangement of the same advertisements can also appear either simultaneously or from time to time in* ENGINEERING *at terms worked out for advertisers. Manufacturers are invited to communicate their catalogues and circulars, which will be inserted and placed in the hands of the trade.*

NGINEERING.

RIDAY, APRIL 15, 1881.

AL EDUCATION OF NAVAL ARCHITECTS.

n of Naval Architects has already to the country and the profession ich it brought to bear on the ifteen years ago, in favour of School of Naval Architecture, arkably good work, a fact orroboration from the eminent position occupied by several of its pupils, and the excellent contributions which they continually render to the Transactions of the Institution. It is in no small degree due to the efforts of the Institution, and the teaching at the school, that naval architecture has ceased to be the empirical art which it was twenty years ago, and has become one of the most exact of the applications of science.

The School of Naval Architecture is, however, essentially a high school, intended only for pupils of somewhat advanced knowledge. It is, moreover, at present not appreciated by the mercantile marine, the great majority of its pupils going into the Government service. The question naturally arises, What facilities exist in the country for the elementary training of naval architects, especially of those whose future career will be in the construction of merchant ships? We fear the answer to this question is not very satisfactory. The present condition of education in naval architecture resembles that of a country possessing excellent universities, but with most inferior elementary, and absolutely no advanced schools. The sole systematic course of elementary instruction to be had in this subject is that obtainable by the classes which prepare for the examinations of the Sciences and Art Department at South Kensington, and it is greatly to be feared that these examinations are of so antiquated a type, and so limited in their scope, that they attogether fail to enlist the sympathy of mercantile shipbuilders, and consequently do not exert the beneficient influence on the training of students which they might do, were they brought more into conformity with the wants of the age.

Mr. W. Denny, of Dumbarton, has brought this question under the notice of the Institution of Naval Architects, by reading a paper at the session just held, "On Local Education in Naval Architecture." Mr. Denny's experience of these examinations is considerable, for in his own town of Dumbarton much advantage has been taken of them, and the local teacher is the chief draughtsman in the employ of his firm. The chief charges brought against the examinations are, that too much attention is devoted to the obsolete subjects of wooden and composite shipbuilding; and that the questions set in the final stage, or honours division, regarding ships' calculations, are not of sufficient difficulty to entitle the student to the distinction of honours; and also, that many of the most important questions relating to naval architecture are totally neglected, such, for instance, as the strength of sections of steamers, involving the calculation of their moments of inertia; the stability of vessels with reference to the metacentric height, and its alterations by reason of changes of draught and alteration of the positions of weights; the speed and power of steamers; Mr. Froude's law of proportional resistances; Mr. Inglis's application of the law to actual results of speed trials; and, lastly, the question of the trim of merchant steamers as affected by the distribution of cargo, the consumption of stores, and the addition or removal of ballast.

Regarding the first of these charges, it is alleged that in the two first stages of the examinations, it is *obligatory* on students to answer questions relating to wooden and composite shipbuilding, while in the third or honours division, although no such questions are obligatory, it is nevertheless the case that in some years all the questions relating to laying off have reference to wooden or composite ships, and consequently unless a student has devoted much time and trouble to acquiring a knowledge of those nearly obsolete arts he cannot pass in any one stage of the subject. It is greatly to be feared that knowledge of this sort, got up merely for the purpose of an examination, must necessarily partake largely of the character of pure "cram," with the additional evil in wrought of taking away the student's attention from other subjects, neglected it is true by the examiners, but which will be of vital necessity to him in his after career.

Mr. Denny does not content himself with criticising, but makes various proposals for the improvement of the examinations, which, we venture to say, if adopted will do much to extend the usefulness of those examinations, and to enlist for them the sympathy of the shipbuilding community. He proposes that they should extend over four years instead of three as at present. The first stage would include questions on the details of iron construction, and on the calculations necessary to produce an ordinary displacement curve, and to find the vertical centre of buoyancy. The second stage would embrace questions relating to the nature of iron and steel, their resistances to tests, and to the calculations for finding the longitudinal and transverse moments. In the third stage, the examination would be on the strength of riveted joints in calculations repeating trial, and the working out of examples showing the use of the longitudinal metacentre. In the fourth or honours year, the questions might relate to the calculation of the moments of inertia of scantling sections, and to calculations of stability showing the use of the transverse metacentre. Mr. Denny is convinced, from his practical knowledge of the progress which drawing-office apprentices are capable of making within a given time, that the above scheme is not too difficult; and on this point, to judge by the tone of the discussion which followed the reading of his paper, the majority of his audience agreed with him. Speaker after speaker arose, and deplored the shortcomings of the present examinations; while, at the same time, they fully endorsed Mr. Denny's views. So unanimous, indeed, was the opinion of the audience, that, if we are rightly informed, the Council of the Institution will again endeavour to influence the Government to give effect to the views expressed. If they would further succeed in obtaining for the best students in each year scholarships of such value as would enable the holders to continue their studies at the Royal Naval College, we have no doubt that they would thereby greatly increase the popularity of the examinations. It is, we believe, no secret, that the scheme for selecting Whitworth scholarships does not work quite satisfactorily, and has not hitherto produced the results which Sir Joseph Whitworth himself sought to attain. We venture to suggest that some of this fund might be wisely spent than in enabling the best competitors in each year to complete their studies, at the only school where it is now possible to obtain a complete education in the subjects of their profession.

ELECTRICAL TORSION.

IT is a surprising fact that we can accomplish so much with electricity, and at the same time have so little of its real nature. We have just conceptions about heat and light, and sound; we can explain to ourselves the modes of motion in air or other which give rise to them; but if we attempt to do the same for electricity, the ideal light is suddenly extinguished and the imagination is left groping in the dark. We cannot even tell whether it be a fluid or not; and yet we can work more wonders with electricity than with either light, heat, or sound.

The principal reason for this want of knowledge is that hitherto we have not been successful in research capable of enlightening us upon the molecular changes which electricity produces in its passage through a body. The electrometer and the galvanometer, sensitive as they are, will only show effects in mass, so to speak; they have no analysing power. In the indirect method of Professor Hughes, however, we have at length found a far more subtle tool of quest, and though the skilful use of it by its inventor, we are likely soon to learn something of the true character of electricity. With its coils and telephone it bears to that mysterious agent a relation similar to that which the microscope with its prisms and telescope bears to the rays of light; and it affords a means of investigating the molecular structure of those materials which, though opaque to light, are permeable by the electric current.

For some time past Professor Hughes has been experimenting with the induction balance on the electrical effect of torsion applied to wires of iron or other magnetic metals, a subject which has been previously studied by Matteucci, Thomson, and others. He was led to this inquiry by the anomalous behaviour of iron in his original tests with the balance. He then found that no two pieces of iron, even though they were cut from the same wire, would accurately balance one another. To discover the cause of this discrepancy he passed a soft iron wire through a hollow coil, as shown in Fig. 1, and connected it in circuit with a telephone. An electric current from a battery B, interrupted in a definite rhythm or cadence by a clock-work fleetone I, was sent through the coil, and he found that when the wire was perfectly free from torsion no current was induced in it by the coil, and no sound was heard in the telephone. The slightest twist

THE TELEPHONE.

The Telephone is now in full operation at Huntington. It is contemplated to extend it to Dewittville and Ormiston, if adequate substantial aid is given by the residents of these two places. The nearest is a distance of 16 miles to Hemmingford.

To be a general benefit however, it must reach Montreal, the market town of that District.

Mr. C. F. Sise, vice-president and managing director of the Bell Telephone Company, and L. H. McFarlane, manager of the eastern division, have recently been spending a few days in the city of St. John, N.B. Their visit there has been of special interest to Mr. J. H. Wagstaff, who has for only a short time been spared for the company, and who by close attention to business, both in the interest of the Company and the subscribers, has so improved the agency as to win the confidence of the managers, and has been rewarded by the appointment of the managers, and has been rewarded by the appointment of the position of district superintendent, which covers the management and inspection of the Maritime Provinces, with the head office at St. John. Mr. Wagstaff will continue to control the affairs of the St. John agency. There seems to have been earned within ten months and without any previous experience in the business, and is, therefore, more to be valued.

The Company will shortly remove to new offices in the Boutwick building, which are being specially fitted up for them, and, when finished, will be very complete and comfortable.

The Bell Telephone Co. are busy stringing in Montreal, a superior new steel No. 12 wire.

The Bell Telephone Co. exchange office at Toronto, which occupies the southern wing of the Mail building, was burned out on the morning of the 24th May. The Bell Telephone Company employ about eighteen young women to answer calls and make telephone connections, six of whom were on duty at the time of the outbreak, their names being Miss Clarke, Miss Mackenzie, Miss Murphy, Miss Leitch, Miss Porter, and Miss McCarthy. Naturally they were very much alarmed at seeing the smoke, and did not care to leave the office. Had they done so and passed by the elevator to the iron doors leading to the composing room which were closed but not locked, they could easily have escaped by the north stairs without going through the experience which they afterwards met with. Mr. Hambly of the Mail editorial staff, re-entering his room, found the telephone girls at the windows at their office, which overlooks his, but one floor higher up. They called to him for help, and he begged of them to keep calm and he would get assistance. Some of them were preparing to take a jump diagonally to the roof of the white building adjoining The Mail building, and knowing the hazardous nature of such a leap, and by clutching at a batch of wires, and sliding along them reached the roof in safety. The other girls then went to the windows overlooking King Street, and screamed for help. Mr. F. Thompson, of The Mail business department got a ladder on the roof of the white building, and resting it against the parapet of The Mail building, the girls were enabled to creep along one by one and passed into safety. The men were only just in time in doing this, as the girls had become terribly excited, and one of them was preparing to jump into King Street, which had she done she would have met with certain destruction. The reaction on her was such that when she was got down in safety she immediately fainted. The Bell Telephone Company suffered the most, and their hundreds of subscribers will be put to some little inconvenience for the next few days. It is expected the two hundred wires are now in working order again, the men working day and night to make the connections under the energetic direction of Supt. Nelson.

The Bell Electric Light Co. were burned out in the Mail building fire, at Toronto on the 24th May.

The Bell Telephone Co. of Toronto have leased new quarters for their Exchange at 116 Bay Street.

ELECTRICAL INDUCTION IN UNDERGROUND AND METALLIC CONDUCTORS.

BY F. S. GISBORNE, C.E., F.R.S., *Supt. of Dom. Government Telegraph Lines*, OTTAWA, 1881.

The Paper read before the Royal Society of Canada at its meeting on Wednesday afternoon, 23rd May, at Ottawa, by Mr. F. S. Gisborne, Superintendent of the Dominion Government Telegraph Service, possesses peculiar interest at the present time in that it deals with the phenomena of induction in electrical circuits to compensate the effect of which, many and various means have been from time to time suggested, but the inefficiency of which to eliminate the evil, has been declared before the Committee appointed to meet at present in session at Albany, N.Y., to consider the question of the practicability of placing electrical conductors under ground. Mr. Gisborne's paper was descriptive of a new system devised by himself, by overcome the difficulties referred to, diagrams were presented which graphically explained the condition obtained in neighboring circuits, and comparisons were made between two or more circuits arranged as heretofore considered best and the same circuits arranged according to his system. Proofs of the efficiency of his system were given in the proposition with respect to any other conductor or pair of conductors in the neighborhood. The philosophy of this device is, that a current passing through any such circuit has necessarily to pass down one wire and up the other, and it is evident that the positions of both with respect to a neighboring circuit, being the same as above stated, the inductive effect of the current passing down one wire is neutralized by the inductive effect of the same current passing up the return wire. It would appear therefore, that Mr. Gisborne's system is in reality one in which the phenomenon of current induction does not obtain rather than one by which the effects are neutralized. Considerable interest in this connection has already been manifested and it is understood that letters patent are about to be issued in Canada and the United States to the gentleman in question.

In connection with the International Electrical Exhibition to be held in September, it may be well to say that the meeting of the American Association for the Advancement of Science, which will be held this year in Philadelphia, and the expected presence of many representatives of the British Association, which will meet this year in Montreal, will attract a numerous and influential scientific gathering in Philadelphia during the time of the holding of the exhibition; and in order that so exceptional an opportunity to promote the interests of science shall not be lost, Congress has been requested to authorize the holding of a National Conference of Electricians, to convene in Philadelphia at this time.

sum he petitions to have repaid him together with a profit of 20 per cent. to cover his profit as contractor, and an allowance of 50 per cent. on the total cost of the works, to repay his failure as an engineer and inventor, bringing up the total amount to £9,137,5, a sum which will be he alleges quite unremunerative, stating that his time could have been better employed elsewhere. But he expresses his willingness to accept 40,000*l.* down rather than incur further delay. If Mr. Emery succeeds in his application he will fare better than English inventors would do on the hands of this Government. It may be interesting to note that the drawings for this machine cost 1200*l.* It will perhaps be remembered that the testing machine was ordered by the United States Government for the proof of the cannon, and was used for all persons who might desire to use it, upon the payment of a suitable fee, the scale of charges being adjusted to cover as nearly as possible the actual costs of the tests. An illustrated report is appended of the Gardner machine gun, the machine of which could not be described without the aid of drawings. Experiments showed that a velocity of 1230 ft. could be obtained, and in a range of 1000 yards 65 per cent. of hits were recorded, the average number of shots fired were 437 per minute. A limited number of these guns were recommended to the service for further trial.

In 1879 a series of trials were conducted by Captain Crozet, U.S.A., on the relative efficiency of the Martini-Henry and the Springfield rifles, especially in reference to initial velocity, range, penetration, accuracy, and flatness of trajectory. The targets used were of white pine. It is claimed that the Springfield gave superior results in all points except that of penetration, but as this rifle has a penetrating power of 9 in. at a safe range, it fully meets all the requirements of the United States service. The long-range firing was at 2000, 2200, and 3200 yards; and some excellent shooting was done by Lieut. H. T. Hare, who hit the 6 ft. pine target repeatedly at the latter range. At 2200 yards the Springfield and Martini both penetrated the 3 in. target, the former with an elevation of 8 deg. 14 min. 2 secs., and the latter 9 deg. 48 min. 57 sec. At 2500 yards the Springfield passed through 5.35 in. pine with an elevation of 10 deg. 33 min. 21 sec., and the Martini through 5 in. with 13 deg. 20 min. 18 sec. Also, at 3200 yards no hit was made out of 300 fires with the Martini, and with the Springfield 55 rounds with the Martini, and with the Springfield 55 per cent. of hits were made, the penetration being about the same as at the 2500 yards' range. The Springfield bullet weighed 500 grs.; the initial velocities were respectively 1951.2 ft. and 1020.8 ft. Four very interesting trials were recorded as to the curve of flight of the bullets at long ranges by means of the telephone. In the experiments two telephones with Blake's transmitter were used, one being placed within a few feet of the gun, and left open to receive the sound of the discharge. The other was in the shelter about 30 ft. in front of the target. A stop-watch beating fourths of a second was employed, and when the discharge was notified by the telephone the watch was started. With a little practice the readings were taken easily and with great accuracy. Four rounds were fired at a 3500 yards' range with the Springfield long range and the Martini. Out of 40 rounds the former hit and penetrated the target once, the latter did not reach far enough. Neither were any hits made with the Springfield service rifle, although a round was occasionally over the target. The concluding appendix in this volume contains a set of Tables and plates showing the principal dimensions and elements of fire of the larger rifle guns existing, proposed, or experimented upon at the beginning of last year, and being constructed in Sweden and Norway and in the also of the various Governments and Companies in European service. This report is illustrated with

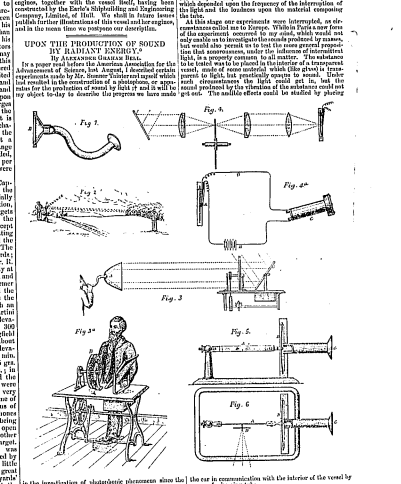
ENGINES OF THE ASSYRIAN MONARCH.

We give this week a two-page illustration and also an engraving on the opposite page, showing general views of the engines of the s.s. *Assyrian Monarch*, these engines, together with the vessel itself, having been constructed by the Barle's Shipbuilding and Engineering Company, Limited, of Hull. We shall in future issues publish further illustrations of this vessel and her engines, and in the mean time we postpone our description.

UPON THE PRODUCTION OF SOUND BY RADIANT ENERGY.*

By ALEXANDER GRAHAM BELL.

In a paper read before the Philosophical Society of Washington for the purpose of describing the experiments recorded certain experiments made by Mr. Sumner Tainter and myself which had resulted in the construction of a photophone, or apparatus for the production of sound by light and it will be my object to-day to describe the progress we have made as successes as this diaphragm. The first experiments made by myself in this direction were undertaken with the hope of obtaining articulate speech, and of course material which (like glass) is transparent to light, but practically opposite to sound. Under such circumstances the light could get in, but the sound produced by the vibration of the substance could not get out. The audible effects could be studied by placing



in the investigation of photophonic phenomena since the date of this communication.

In my Boston paper the discovery was announced that the sonorous vibrations of many different substances could be produced when exposed to the action of a rapidly interrupted beam of sunlight. The great variety of substances on which these experiments led me to believe that sonorous vibrations could be produced would be found to be a general property of matter.

At that time we had failed to obtain audible effects from the vapors of the various substances which were exposed to the rapidly interrupted beam of sunlight, but before the completion of this photophone, let this failure be explained upon the supposition that the sonorous vibrations produced by the light were totally inappreciable by the ear. The subsequent development of the experiments the ear in communication with the interior of the vessel by means of a hearing tube.

Some preliminary experiments were then made with the view of ascertaining if the results were so promising that they were communicated to the Royal Society at London on January 26, 1880, in a note read for me by Mr. Augustus Stroped.†

† Action of an Intermittent Beam of Radiant Heat upon Gaseous Matter," Proceedings of Royal Society, January 26, 1881, vol. xxxi., p. 156.

Sonorous effects were obtained with vapors from the interior of the receiver, but the results were so promising that they were communicated to the Royal Society at London on January 26, 1880, in a note read for me by Mr. Augustus Stroped.†

TELEPHONIC NOTES.

Mr. Max Ehser, general manager of the Pan-Electric, is fast getting things in shape in this city. The wires are nearly all strung, the switch-board has arrived, and it is expected everything will be in working order within ten days.

The Molecular Telephone company of Texas, is about being organized in Denton. This company uses cork in the place of carbon in the transmitter and hand phone, and claims that articulate speech is transmitted by the "molecular vibration of cork."

Mr. W. T. Bostick, manager for the Erie company in this city was taken very ill about the fifteenth ult., and in consequence, his marriage which was to have taken place at Round Rock on the 18th, was postponed. We are pleased to be able to state that he is now recovering rapidly, and if he receives no backset, will don his swallow-tail and kids in Round Rock on the 10th inst.

The Anniston (Ala.) Blast of the 18th ult., contains a column and a half devoted to a description of the Pan-Electric Telephone Exchange which has lately commenced operations in that city. The notice is very fluttering to the Rogers transmitter, and declares that the Pan-Electric is the coming telephone. The Blast of the 25th ult. contains a challenge from the president of the Alabama Pan-Electric Telephone Company to the Bell Company for an attack through the courts.

The examiners in chief of the Patent Office rendered their decision in the celebrated telephone interference case last week in favor of Alexander Graham Bell. Case G, contained the main point at issue, and practically covers telephonic invention, it being an application for a telephonic receiver, consisting of combination in electric circuit of a magnet and a diaphragm supported and arranged in close proximity thereto, whereby sounds thrown upon the line may be reproduced accurately as to pitch and quality.

The parties were Bell, McDonough, Gray and Edison. After an exhaustive review of a great mass of evidence adduced upon this point, and stating at length the reasons leading to the conclusion, the examiners say, "From the whole McDonough's proofs cannot be held to be sufficient to overcome Bell's record of dates. We have seen that a party contesting right of patentee must show completed and perfected apparatus. That McDonough did not have this, is clear. Had a patent been granted to him for it as described in his application, as experimented with in June, 1875, the public would have been no wiser than before. It still would have been ignorant of the method and apparatus for speech transmission, for no instrument working upon its principle of making and breaking a contract can accomplish that result. In this respect McDonough gave no more to the world than theirs. It is said by Justice Lowell in American Bell Telephone Co. vs. Spencer, a century of McDonough would never have produced a speaking telephone."

Accustics—Telephone and Phonograph.

The beautiful inventions of the telephone and the phonograph, although in the main depending on principles long since established, have imparted a new interest to the study of Acoustics. That former, apart from its uses in every-day life, has already, in the hands of its inventor, Graham Bell, and of Hughes, an instrument of first-class scientific importance, while the latter invention is still in some respects obscure, as is shown by the comparative failure of the many attempts to explain it. In connection with some explanations that have been offered, we do well to remember that molecular changes in solid masses are insensible in themselves; and can only be manifested to our ears by the consequent changes in the motion of the external surface extending over a sensible area. If the surface of a solid remain unaltered, no sound, however tall something of what goes on in the interior.

In theoretical acoustics progress has been steadily maintained, and many phenomena, which were obscure twenty or thirty years ago, have since received a satisfactory explanation. If some important practical questions remain unsolved, one reason is that they have received little attention. Almost everything in connection with the delicacy of our senses presents peculiar difficulties to scientific investigation. Some kinds of information with regard to their surroundings are of such paramount importance to numerous generations of living beings, that they have learned to interpret indications of the most subtle character. Many are of the simplest character, every day we are in the habit of recognizing, without any difficulty, the quarter from which a sound proceeds, but by what steps we attain that end has not yet been satisfactorily explained. It has been proved that when proper precautions are taken we can distinguish perfectly whether a pure tone (as from a vibrating tuning-fork held over a suitable resonator) comes to us from before or behind us. This is what might have been expected from a priori point of view: but what would not have been expected is that with almost any other sort of sound, from a clap of the hands to the clearest musical tone, the discrimination is not only possible but easy and decisive. In these cases it does not appear how the impression on the ear helps us through there is some evidence that it may; and even when sounds come to us from the right or left the explanation of the ready discrimination which is then possible with pure tones, is not so easy as might at first appear. We should be inclined to think that the sound was heard much more loudly with the ear that was turned towards than with the ear that is turned from it; and that in this way the direction was recognized. This, however, is impertinent, we find that, at any rate with notes near the middle of the musical scale, the difference of loudness is by no means so very great. The wave-lengths of such notes are long enough in relation to the dimensions of the head to forbid the formation of anything like a sound shadow in which the averted ear might be sheltered.

Sun — Sept.

THE TELEPHONE IN RUSSIA.—Although the telephone has become an established fact in several of the largest Russian cities, notably, St. Petersburg, Moscow, Odessa, Riga, and Warsaw, it is making but little progress elsewhere in the country. St. Petersburg itself is traversed in every part by at least 1,500 versts of wire on the Bell system. The principal factories in the quarters of Viborg, Peterhof, and Okhta, St. Petersburg are all in connection with the central portion of the city, as are the large government offices with the Admiralty, police courts, and prisons, so that orders from headquarters can be instantaneously communicated and carried out. The wires now extend to the fortresses of Cronstadt and Peterhof, and the large rambling works of Pontilow and Alexandrovsky, some eight or ten versts distant, correspond directly with the Nevsk Perspective and the Monskoi. An office has been opened for the public, who can send a message for 25 copecks.

The Elec. Era. Phil. Sept. 20, 1884

Telephone Exchanges.

In the issue of August 9th, 1884, the London, Eng., *Electrical Review*, unsolicited, published the following editorial on one of America's leading telephone companies. As it is a Philadelphia organization, born and bred, we take great pleasure in reproducing the article in our columns.

Perhaps no, piece of telegraph apparatus offers more scope for ingenuity than telephone exchange switches. The methods which have been designed for affecting intercommunication between subscribers are very numerous as the records of the Patent Office testify. To a great extent the ingenuity displayed has been thrown away, partly in consequence, no doubt, of the inventors failing to thoroughly understand the actual requirements of the exchange system, but more in consequence of that absence of a competition which would practically compel any telephone company to provide the best system available, or cause it to be superseded by a more energetic and enterprising rival. In London it is generally admitted the room for improvement in the matter of quick intercommunication is very great indeed, and we believe that any energetic rival who would introduce and work a rapid intercommunication system, combined with low rates, would be most welcome to the business community. A very great deal depends upon the personal attention of the switch clerks at the central stations, and systems which are dependent for their quick working almost wholly upon the prompt action of individuals who have practically no incentive for displaying unusual alacrity, are sure to be unsatisfactory. Personal attention cannot be wholly dispensed with, but it can be reduced to a minimum by the use of apparatus which is partially automatic in its action, as, for instance, in the "Clay" system, which we described in the last number of the *Review*. Apparatus which endeavors to affect inter-communication almost wholly automatically cannot, we believe, be included in the range of practical telephony; it is by the judicious combination of automatic with personal action (as in the system referred to) that the best results will be obtained. In connection with the general question of telephone exchanges a somewhat curious point is referred to by the Boston *Transcript*, as regards the expense of working large systems :—"From present appearances (says the journal) the problem can only be met by advancing the local rates of telephone exchange subscribers. It costs to operate an ordinary telephone exchange, including rentals paid the American Bell Telephone Company, about 40 dollars per annum per subscriber, and the annual compensation received is from 42 to 43 dollars, and some additional compensation in the way of charges for extra territorial connections. Now, the greater the business, instead of reducing the expense per subscriber, increases the expense *pro rata*, as the number of the connections and the particular service to every subscriber is increased by a new subscription, this can be well illustrated by the supposition of a telephone exchange attempting to connect all the people in a certain State, say a million. Several hundred dollars a year would not cover the expense of the service that each subscriber might demand of the exchange; but this million of people could be sub-divided into many exchanges, and each person served in his own locality for a comparatively small sum of money. The problem of how to limit the growth of local telephone exchanges, either by sub-division of exchanges or by increased rates is yet to be solved." Even in London, with its small number of subscribers, the necessities for considering the best maximum radius for local exchanges is quite apparent, but before any such town can be telephonically served, as its importance deserves, the present difficulties must be grappled with, and an arrangement which admits of constant extensions adopted.

Jan. — 11, 1885

EXTENSION OF THE TELEPHONE.

THERE is always a pulling up of roads and side-walks, as the Americans say, going on in London; but for its last six months unusual energy has been displayed in taking up pavements, both in the City and West-end, by those borrowing destroyers of our duties and tempers. The evil, however, which has been borne, we hope, if not patiently, at least generously, will not be without its compensation in the additional supply of telephonic communication between the various parts of the metropolis. We are informed that at the end of the present month all the West-end exchanges of the United Telephone Company will be kept open all night as well as during the day. The convenience of this to the district subscribers will be very great, as in the event of any need of communication with a doctor, or with the police, or a fire station, or in any other emergency, the requirements can be satisfied by this arrangement with a rapidity and expeditiousness unattainable by any other means. In Paris the public call system, which was permitted by the Ministère des Postes et Télégraphes in the like manner with the concession granted by the English Post Office, has already been fruit. Call stations have been established there, through which, for a small fee, the public can have telephonic communication. These call stations are two at the Bourse, and the others respectively in the Rue des Halles, Rue de Grenelle, Saint-Germain, Place de la Madeleine, and at the Grand Hôtel. The night communication in London at the West-end is a step in the right direction, but it cannot be accepted as a reason why, if Paris can avail itself of the public call system,

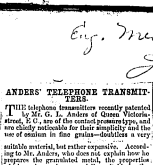
ANDERS' TELEPHONE TRANSMITTERS.

THE telephone transmitters recently patented by Mr. G. L. Anders of Green Victoria-street, E. C., are of the contact pressure type, and are chiefly noticeable for their simplicity and the use of osmium in fine grains—doubtless a very suitable material, but rather expensive. According to Mr. Anders, who does not explain how he prepares the granulated metal, the properties which render osmium especially suitable for the purpose are great hardness, infusibility, and



sensitiveness to microphonic action. In some instances he employs aluminium for one surface, and osmium for the other, because of its high conductivity for heat and electricity, which prevents overheating, its liability to fusion at the point of contact, &c. Both of the above-named materials, moreover, are free from the defect of producing a non-conducting film easily formed coating by exposure to the air or under the action of the current.

Fig. 1 is a side view, partly in transverse section, of part of a transmitter.

Fig. 2 is also a side view of another form, while Fig. 3 illustrates a modification. A is the diaphragm, which may be made of any suitable material, B B are the electrodes, preferably formed of any metal not easily oxidised or fused. One very advantageous manner of carrying the invention into practice consists in placing granulated osmium between two discs or plates forming the electrodes and inclosed in a tube or sleeve of indiarubber, cork, or other suitable material, as in the instrument shown in Fig. 1. In this instrument one of the electrodes B is attached to the centre of the diaphragm or soundboard by a screw-stud C, or by other suitable means; the electrodes are kept apart by rings or other pieces inclosed in and kept in the case or sleeve apart by the tube or sleeve C. The space D between the discs or bottoms is filled or nearly filled with grains of osmium. The conducting wires E are connected with the electrodes B as shown. The instrument shown in Fig. 2 has the above specified parts in duplicate, the outer ends of the electrodes B being connected by a small bar or plate B'.

Semilious the patentee employs a small quantity of granulated osmium intimately mixed with aluminium leaf or foil by rubbing them together. In this instrument either metal can be used in place of aluminium to form the electrodes B as the principal part of the microphonic action takes place between the mixed grains of osmium and aluminium. In this modification of Fig. 1 one electrode is attached to a diaphragm or sounding board, the other electrode may be prevented towards it by known weights. If desired, the two electrodes may be set firmly in the ends of a glass or other tube with sealing-wax or other cement, and the whole mounted upon a diaphragm or sounding board. According to another modification one electrode is attached to the diaphragm of the transmitter, and about its free end is either or tube of cork or similar material F, Fig. 3, into the end of which the other electrode is screwed. A space is left between the two electrodes in which is placed a short cylinder or disc of aluminium, the surfaces of which are purposely impressed with fine particles of osmium to which they adhere. The electrode should be faced with platinum or other insoluble metal. The cylinder or tube must fit tightly enough on the electrode on the diaphragm to enable the electrode to support the other parts. An adjusting screw-thread into the back of the case serves to vary the pressure upon the electrodes. This form of my

instrument is shown in Fig. 3. G G are pieces of aluminium which have the grains of osmium pressed into them and which are inclosed in the tubes C and between the electrodes B. The inferior or upper electrodes are connected by the wire or rod H. As the aluminium is sufficiently soft to permit particles of osmium to be readily united thereto by pressure, the patentee sometimes uses the osmium at the tip or point of an electrode formed of aluminium, and forms both electrodes of aluminium. Although Mr. Anders' experiments indicate that the best results are obtained by the use of aluminium in the manner described, yet other metals possessing to a greater or less degree the valuable properties mentioned in this specification may be employed in combination with osmium.

Engineering - Feb. 13/85

INDUCTION ON TELEPHONE LINES.

After the first flush at the success of the telephone its application was found to be, like other mundane matters, far from an ideal. Whatever may be the proper limitations to the term induction it is trusted that the same mind which invented the telephone may yet devise some means to annihilate the disturbing influences which limit its application. Mr. W. W. Jaques, one of Professor Hall's coadjutors, has been making investigations upon underground lines, and finds the empirical rule that when the product of the static capacity of the line in microfarads by its resistance in ohms is less than 18,000, it is feasible to use the telephone for commercial purposes, but when this product amounts to between 18,000 and 30,000, then the transmission is imperfect and nothing can be understood except by skilled operators. No telephonic signals can be transmitted when the product exceeds 30,000.

Dron — Jan. 16, 1886

A MECHANICAL TELEPHONE.

ANOTHER telephone, called by its inventor, Mr. A. G. Miller, of Layden, New York, a "mechanical telephone," has been added to the list of talking machines. The mechanical or acoustic telephone is stated to transmit and receive speech with great clearness and naturalness of tone. The mouthpiece has a central aperture for the passage of sound waves to the diaphragm, whose edges are secured within a rabbet of the mouthpiece. The diaphragm is about 7 inches in diameter, and is made of spruce wood, which possesses great sonorousness combined with strength sufficient to sustain the tension of the line wire. The mouthpiece and diaphragm are held to the wall on a bed plate by the tension of the line wire. The bed piece is recessed at both sides, and centrally perforated to the passage of threads connecting the line wire to the diaphragm. The front recess affords a space between the diaphragm and the centre of the bed piece for free action of the diaphragm, promoting clearness of enunciation when the instrument is used as a receiver, and the rear recess secures a small marginal support for the transmitter, thereby avoiding a large contact with the wall, and preventing excessive vibration. Threaded holes, tect articulation and the ringing sounds common to acoustic telephones, the line wire is connected to the diaphragm by silk cords, which are twisted about the end of the wire to obtain a firm connection therewith, and which diverge into three or more strands that are secured to a metal ring, between which and the diaphragm a rubber or leather ring is interposed. The line wire is made of strands twisted together and coated with varnish to bind them, and prevent them rubbing upon one another. This construction of the line wire makes it strong, and protects it from the weather, and, combined with the silk cord connections, is said to aid largely in clear transmission over line wires of considerable length.

Engineering - Feb. 13/86

Dron — Jan. 9, 1885

THE BELL TELEPHONE IN CANADA.

The Minister of Agriculture of the Dominion of Canada sends a decision on January 26, which wrecks the Bell Telephone patent in Canada. The patent laws among other matters require that the subject of a patent must be manufactured within two years, in order to preserve the patent, and it has been the custom to import portions of manufactured articles in such stages as the state of manufactures in the Dominion suggests, and the final construction and assemblage of parts has been regarded as complying with the law. The matter at issue is an attempt to decide how far back from the finished material it is necessary to go in order to constitute manufacturing. Can the sheet brass of an article be rolled and stamped elsewhere, where there are ample facilities, or is it necessary to go back to the ores of zinc and copper and tin? This is no factitious analogy, because a prominent patent has been prosecuted against on the ground of importation of stamped brass portions. Shall a patent requiring the brains of inventors and the persistence of capital be suddenly declared void because it is put together with imported screws? The principle must set forth patents no other interpretation. If such ideas are carried to their farthest extremes the result will work injury to that portion of Canadian business, fostered by patent laws which were drawn in a spirit of liberality and wisdom for the purpose of increasing the prosperity of the Dominion of Canada.

A NEW TELEPHONE.

EXPERIMENTS were made recently on the large wire of the Postal Telegraph Company between New York and Mendeville, Pennsylvania, a distance of 320 miles, with a telephone devised by Professor Webster Gillett, of Ypsilanti, Michigan. Owing to the storm and atmospheric conditions, the magnetic bell was kept ringing by the induction alone, but there was little difficulty in carrying on a conversation. Professor Gillett used what he calls a 10-point instrument. In its transmitter a needle is attached to a rubber disk, coming in contact with granulated carbon, held under compression to increase the conductivity for taking up loss by friction and other causes. Most instruments have solid carbon buttons. Each point is like adding another telephone in power. The feature of the receiver attached to the telephone is the increased magnetic surface presented to the diaphragm. Chicago, a distance of 1,000 miles, including a cable containing twenty-two wires, has been reached satisfactorily with the 10-point instrument. The single-point instrument has been operated for from 75 to 100 miles. The 10-point instrument was during the experiments reduced to six points, and communication was still kept up. The plan is to construct an instrument that will open communication by cable across the ocean as well as covering long land distances. We hear that a 20-point instrument is making for the purpose of ascertaining the distance it will reach. Professor Gillett states that the French cable is 2,430 miles long from end to end, and the resistance is 2·09 ohms. The resistance of the wire used during the tests experienced is 14 ohms, but as satisfactory results have been obtained from the smaller copper wire, the resistance of which is 6 ohms.

A NEW TELEPHONE.—We learn from *Nature* that M. Marcel Deprez, the well-known electrician, is not confining his labours exclusively to the transmission of electrical force to distant places. In conjunction with others, he has patented a new telephone based on a new principle of vibration, and dispensing with the use of voltaic elements. The lease of the Compagnie générale des Téléphones being about to expire, the municipal council of Paris have held a general meeting on the question whether the lease should be renewed or not. In the course of the discussion it was proposed to grant the renewal of the lease provisionally for a month in order to give the new apparatus a fair trial. The further discussion of the question has been postponed.

ON CAUSES OF DISTURBANCE IN TELEPHONIC COMMUNICATIONS.

ACCORDING to the observations made by M. D'Arsonval, it appears that the nerve of the frog, which has always been regarded as the most perfect of all galvanoscopes, is far from the most sensitive than the telephone. But the experiment of M. D'Arsonval proves that the nerve of a frog's leg placed on the platinum terminals of a telephone, in the circuit of the corresponding receiver, and the platinum touching the nerve and muscle forming the loop, we must attribute a considerable portion of the results obtained in telephony to the perfection of the organs of hearing.

Whatever may be the causes of this extreme sensitiveness, it is certain that it does not tend to the solution of the problem, as we shall, on the contrary, find the disturbing effects which diminish or diminish the power of the voice.

The causes of these disturbing actions exist either at the transmitting station, on the line, or at the receiving station, but very often at all three of them at the same time, so that an analysis of the phenomena which occur, says Mr. W. Le Conte Stevens, in *Telegraphic Journal*, becomes absolutely necessary.

Taking into account only the essential parts, a microtelephonic station comprises a microphonic transmitter with battery, a bell box with or without battery and a telephonic receiver, and a purely telephonic station; a call bell with battery and a telephone serving at once as transmitter and as receiver.

Most generally all this apparatus is essential upon one board, which is fixed to one of the walls of a room where the speech is transmitted and received.

In long as we have a perfectly insulated communication, this mode of grouping all the elements of a station has no disadvantage; but when the arrangement is used for a microtelephonic station, inconveniences may result in certain cases, as we shall see directly.

The microphone most generally used for telephony is the Leclanché, with porous cell. It is composed, as we know, of a glass jar containing a solution of chlorhydrate of ammonia, in this is immersed a porous vessel which contains a mixture of carbon and peroxide of manganese, surmounting a piece of carbon. This latter forms the positive pole of the battery, and the amalgamated zinc rod forms the second in the solution of chlorhydrate of ammonia.

Without describing accurately all the reactions which take place during the passage of the current, we may say that there is, on one hand, a formation of oxychloride of zinc, and on the other the production of the peroxide of manganese with disengagement of ammonia. It is easy to see that the many causes that tend to polarize the battery quickly exist to annul its working properly. We must avoid insulating the mixture contained in the porous cell: for a too strong imbibition of the carbon and peroxide of manganese would result in preventing the disengagement of ammoniacal gas and the escaping subsequent of the chemical.

In this case the battery would not work as well, the current strength would be diminished, and consequently the speech in the receiving apparatus would not be so loud. We think that it is best to have the liquid in the glass vessel one-half of the height of the porous cell.

Certain precautions must be taken generally in order to consider the rather numerous cases of batteries which may be found in the circuit of a microtelephonic station, although, for several reasons, it should be specially attended to in installations of this kind.

If we now examine the phenomena which occur in a battery in the normal state of construction and mounting, and which is placed in a position where the temperature is more or less high, we shall soon see that the chemical reactions which take place therein, upon the one hand, and upon the other, are:

Following this examination more attentively, we observe that these crystals are not of the same nature, and whilst the first are formed of chlorhydrate of ammonia, chloride of zinc enters into the composition of the second.

The following experiment, which may be made for this purpose, completely proves the difference of substances of the crystals which are deposited upon the vessel and upon the zinc.

Having thrown chlorhydrate of ammonia into a glass vessel containing water up to one-third of its height, and placed in a room having mean temperature of about 10° C., we may observe, at the end of the third or fourth day, the formation of the crystals of the salt, forming a band above the surface of the liquid. This band increases continually in width, and after about a month reaches the top of the vessel, and then redescends in a progressive manner upon the outside of the receptacle, and reaches the bottom in about two months and a half.

Whilst the band is developing and rising, the deposit of salt which forms it, and which appears at first like a sort of dew, offers successively more abundant and more regular crystals, with considerable fine creeping salts. These crystals, in fact, actually along the surfaces of the cells, and as soon as a slight deposit is produced, by the evaporation of the liquid which has risen by capillary attraction between the walls and the salt already deposited, forms, arranges and regulates them by it, after having prospected in this manner, we combines the experiment by immersing a rod of zinc in the solution of chlorhydrate, we perceive to change in the phenomena which reveals as they were. The chemical action is manifested by any change of color, and sometimes there are any crystals deposited upon the zinc rod.

It results from these facts that the crystallizations which we observe on the vessels are different from those upon the zinc, and that the first, which are produced in a liquid containing only chloride of ammonium, can only be formed from this salt.

Those, on the contrary, which cover the zinc, and which only exist in batteries which have already worked, are formed of the chloride of this metal, or M. Wurtz said, in his dictionary of chemistry.

The last point is key, moreover, explained as follows:—The chloride of zinc which is produced in the battery under ordinary current requires, in order to be dissolved and crystallized, a certain elevation, and as soon as the temperature is sufficient it is deposited in the form of crystals falling to the bottom of the receptacle. The formation of the crossing salt, which impoverishes the chlorocitrical liquid intended to dissolve the salt of zinc, and therefore, the zinc is deposited upon the crystals.

Therefore, in order to have a good representation of the battery, we know that it is important that the battery be in special conditions, which, although not exactly preventing the formation of the crystallized salt, nevertheless retards it.

The presence of these salts, in fact, leads directly to a diminution of the electromotive force, and hence causes during the working of the battery the formation of crystals upon the zinc, which prevents it from being attacked, and increases the resistance of the element.

We have seen that a certain degree of heat usually favours the production of crystals of chloride of ammonium and zinc, and that the cold is necessary for obtaining them in such a manner as possible in placing the battery in a place where the temperature is low. It follows, therefore, that by grouping up in the same box all the apparatus of a microtelephonic station, including the battery, the considerations mentioned above cannot be realized under all circumstances.

We have now to tell us on the subject of disturbances caused by the special conditions of the battery.

We will now study the microphonic transmitter, which forms the second apparatus of a microtelephonic station.

The most important element which enters into a comp osition is certainly the carbon, of which the transmitting disk is composed, and the resistance upon the hardness and cleanness of the speech.

It must not be powdery, for instance, for by the vibrations, which are, so to speak, continual, to which the apparatus is subjected, the molecules of carbon are accumulated between the contacts and produce a disagreeable crackling which accompanies the voice.

Other organic powders dry, like the finest powders, moreover, fit somewhat, and thus the battery is constantly deranged by a few sharp blows given upon the box containing upon the back of the disk, under where these derangements appear.

Very often M. Carbon is pulverizing, compressing, and subjecting to a high temperature, the mixture of carbon very rare also in fine powder, calcined sagebrush, and syrup of sugar.

On examining with a lens a carbon thus prepared we find a certain number of small white pearls, apparently formed of crystals of sugar not entirely carbonized. They emit, laterally regularly, a fine powder of carbon. This factor, in the series with a rigid diaphragm, which by their nature they extract from the microphone, and Edison's is even followed by the disappearance of the cracks and the formation of a band of which is very loud to detect from the ear.

In order not to be obliged to do this too often, it is necessary to avoid, as much as possible, the formation of the said powder, by the use in every case at the white points by perfectly polishing the surface of the carbon, so as to give it the appearance of a metallic body.

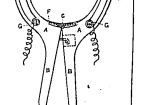
These remarks now only a very little to be said about the bell, the line, and the telephone, which are the last parts to be examined. As regards the bell, we have to the magnetic bell the preference should be given to the polarized bell, on account of that working with or a battery, because of the numerous advantages which it possesses, amongst others, the ensuring of better contact. This is numerous cases of weakness of voice which occur rather frequently in up-to-date when the bell is constantly used in an imperfect manner. The line is also a source of many disturbances, especially when it has a very or badly-soldered joint, for the resistance of the circuit increases, and the intensity of the current is consequently diminished. It may happen, also, that the wire touches a conductor in communication with the earth, and, line, for instance. In this case, the leakage that takes place at the point of contact diminishes greatly the circuit and increases the total resistance, by which is divided at the point of contact in inverse proportion to the resistance of the apparatus used. Consequently, the current which actuates the receiving apparatus is always weaker than when the line is in the regular condition—that is to say, when there are no abnormal leakages. A similar weakening of the current may result from the bad state of the line, from bad connections, as well as from the employment of a bell of communication with earth. As regards the telephone, we may say that the only defect which it can present is an insulation which the ebonite plate taken when the apparatus is kept in a damp place, or when it serves as a transmitter. In these cases, the plate, which is generally covered with a thin coat of wax, no attracts the metal and whatever vapour it may be covered. At the point where moisture is formed—that is to say, at the ends—a leakage is produced to manganese—the plate isn't longer in its normal condition, and, especially, the combined action of this dampness and the attraction of the magnet of the armature results in the production of the apparatus.

The considerations which precedes causes the plate such as the magnet, and protection all speech. It is necessary in this case to heat the apparatus, to

BARRAUD'S TELEPHONE RECEIVERS.

THE telephone receiver shown in the annexed sketches is one of the most powerful of the two-diaphragm type, and is constructed to combine as much as possible the maximum sound, with the minimum amount of battery power. It is patented in this country on behalf of D. G. Barraud, of Ilkley, Caledon, N.Z., and is the result of this adjustable double receiver. Fig. 1 is a transverse section of the receiver, which absorbs the rays emitted therefrom. Fig. 2 is a rear view of the diaphragm with the magnet removed. Fig. 3 is a rear view of the receiver magnet. Similar letters of reference indicate like parts in each figure. In the centre of the receiver between them the bond of the user of the instrument, is a magnet with handles, A, and an adjusted together at the upper ends of the handles by a screw, B. On the two ends of each pole piece, C, is secured two curved metallic arms D, D', which are fixed at their free ends to the rim, E, of the receiver, which pass through the arms D, D' to the diaphragm, forming pivots upon which the coils may swing, and which fix themselves to the ears of the case. The two ends are connected with the terminals of the telephone binding head screws to conduct the telephonic current through the sides of the diaphragm coil, one to each of the arms D, of the opposite sides, one connected with each other by a wire low-spring F, which conforms to the

general curve of the levers A, and draws them towards each other, and, at the same time, serves as an electrical conductor between the bobbins of the diaphragm coils. The ends of the arms D, D', which are connected to the levers A, are prolonged towards the rim, E, and provided at their ends with the adjusting posts G for receiving the usual telephone connections. When the diaphragm coils S are drawn towards each other by the spring F, the handles A are separated, and so limit the movement of the levers A. A book c extends from one handle into a recess in the other, in position to engage a pin or pinning



transversely through the recess when the handles are separated. The diaphragm coils E each contain a A, surrounding the end of a permanent magnet, J, which is curved in a spiral to bring it within the compass of the coil. The magnet J is clamped by screws J' against the fillet K, and lead in the diaphragm coil. The diaphragm coil E contains the usual diaphragm A, which is opposed to the magnet, and is held secured by the aperture cap A. The adjustable telephone receiver is applied to the ear by means of the

diaphragm coils E, by pressing on the handles B, then placing the head between the ears, and relieving the handles B, when the spring F may draw the diaphragm coils against the ears. When thus applied both ears are used, and all extraneous sounds are effectively shut out. By thus counteracting the volume of sound is greatly increased, and faint sounds are rendered more effective. This receiver thus facilitates telephonic communication in noisy places, and permits of receiving telephonic messages in a manner not to operate the ordinary receiver effectively. It is therefore especially adapted to long distance telephony, where the currents arriving at the receiving end of the telephone line are not in a fraction of the current sent out by the transmitter.

A NEW WRINKLE.

A Mode of Telephoning or Telegraphing Without Batteries.

For three years past T. H. Brown of Fort Worth, Texas, has been at work on an invention on which a patent was allowed last week, but which has not been issued yet at the request of Brown to his lawyers in Washington. The invention is a magnetic telephone and telegraph without batteries, a new system of transmitting and receiving human voice without using batteries of any kind. Brown has had a hard time perfecting his invention, being refused aid by [illegible] to whom he applied. A short time ago Mr. W. P. Masterson, a lawyer of much [illegible] and a man of means, saw Brown's telegraph and telephone one day, saw the instruments tested it and at once wrote to a director of the Western Union Telegraph company and president of the Gresham Telephone company, setting forth the wonderful workings of the invention. The Western Union sent Mr. Norvin Green to see Brown Tinker and asked him to have instructions to some experienced manager in a Texas office as regular Fort Worth to have the instruments tested over the Western Union lines and report to headquarters. Mr. Tinker replied, handed the instructions, and General Superintendent Clowry of the Texas lines. This [illegible] visited Mr. Fraser, Mr. Brown's lawyer, Mr. Masterson, J. H. Murphy and Robert L. Moore, operators, were in the Fort Worth office. Mr. Umsinger, an operator, was in the Dallas office, and Mr. Osborne, words in the Cleghorne office. The batteries on the line were cut off from the wire [illegible] mile long, and the magnetic transmitter and receiver attached at both ends of the line. For two hours the test went on, all parties talking, and all operators, by the telephone system, receiving and sending telegraphic to the Cleghorne office and receiving an answer in the same manner. The voices of the Cleghorne parties were very distinct, and a marked feature was the absence of all ringing or other noises on the line, and of any other apparatus. After the test was completed General Tinker was telegraphed to

Inventor to your letter of June 15, but made over a three-mile-wire circuit worked satisfactorily with the batteries of Brown's invention instead of batteries.

"The instrument used today was composed of, two ounces of wire and a half-pound of steel, and can be made for $6 cents. The transmitter is simply a horseshoe magnet, either pole being covered with fine wire, through which the voice, striking on the steel, agitates which the voice is thrown is transmitted through the magnets to the wire. The receiver is similar, with another magnet. It is claimed by the inventor that he can transmit the voice around the world or across the Atlantic ocean, there being [illegible] to the wire, and the only limit being the increase in the size of magnet. The one used today, weighing half a pound, was capable of transmitting the voice seventy-five miles. The cost of batteries is said to be $1000 yearly, which would be saved by this invention. In telegraphing battery and ordinary instrument is used, but in telephoning very little noise would be made. The receiving operator would have a disk attached to his ear, hung by a hook in a cup or stopped around his head. The noise now incident to the telephone would be done away with. He can send and receive information unlimited to pool-rooms, stock exchanges, etc. The telegraph would be absolutely secret. The inventor says, further, that the instruments could be carried 50 miles, and, in case of breakage, a temporary connection could be made by a telegraph wire and noise given to any station just where the accident had occurred. He says, etc., and this done in a few seconds. He also says a miner or river could take an instrument, attach it to an insulated wire, go into a mine or under the ocean with it, converse with a friend at the other end. Messrs. Brown and Masterson go to New York this week, when Mr. Brown will make arrangements to obtain patents in France, Germany, and England. Those being secured he will return to Texas and visit the country. It is possible the Western Union will buy the patent.—Chicago Tribune.

TO REVOLUTIONIZE TELEPHONING.

The Wonderful Invention that Came to a Fort Worth Man in the Dead of Night.

From the Fort Worth Democrat.

Over three years ago Fred H. Brown began the work of studying out a telephone on an idea which occurred to him that a telephone and telegraph instrument could be made which would work without a battery. For three years he toiled and thought, encountered no scorn for the goal that was to be attained, until one night in February last, about 2 o'clock in the morning, he awoke suddenly from sleep and found the invention in his mind. Cold as it was, he jumped out of bed, lighted a lamp, and began to work. In a few months he had perfected an instrument and tried it at home. He at once determined to go to Washington, procure a patent, and the right to England to Spence, Gaines J. Frazier and G. H. Shuttler to France and Germany. Mr. Brown's son, who is a wood engraver, accompanied Mr. Brown to Paris.

The electricians of Mr. Gould and Mr. Mackay and the Western Union Telegraph Company and Bell Telephone Company are all interested, and it is learned if the invention could not be patented, but Mr. Brown had provided against all contingencies, and has secured patents in every land. The immense value of the invention was seen by A. J. Rudwig, a capitalist, who brought it to the notice of Mr. Masterson, a lawyer of means, who formed a company, and the multitude, who bought the right of the United States for one hundred dollars, raising $250,000 in 30 days in small dollars. Mr. Brown is secretary of the company of Houston, Mr. Masterson is president, Fort Worth capitalists every one. Several offers were here, and on Thursday night left with his instruments for New York and Washington.

When in 1876 Alexander Graham Bell was negotiating for Canada, which is held by the Dominion Telegraph Company, Mr. Brown offered that a hundred such company instruments was willing to say a dozen sets for it, which will further illustrate Professor Bell's invention. Mr. Brown left Fort Worth three days ago, after their interest in the invention had been sold to Jay Gould, Jersey and Frazier, to run in New York, and will leave in a few days for Europe.

The test in New York and New York a cable test will be made over 3,000 miles of cable, being the distance across the Atlantic. Instruments will be placed in the cable office in London and Paris, and messages will be transmitted over the 6,000 miles of wire and the instruments worked as clear as a bell. In a few days 200 miles of wire will be stretched on Long Island for tests of the instruments.

As soon as possible the company in New York will get to work and organize sub-companies in all the States, and the telephone and telegraph will be superseded. All under control.

This invention is a magnetic telephone and telegraph instrument, by means of a new and peculiar method of using [illegible] for sending without using batteries of any kind. Brown has had a hard time perfecting his invention, being refused aid by those to whom he applied. A short time ago Mr. W. P. Masterson, a lawyer of means, and well-acquainted with prominent Eastern telegraph and telephone men saw the instruments tested, and at once wrote to a director of the Western Union Telegraph Company and President of the Gresham Telephone Company, setting forth the wonderful workings of the invention. The Western Union sent Norvin Green to see Brown. Tinker and asked him to have instructions to some experienced manager in a Texas office as regular Fort Worth to have the instruments tested over the Western Union lines and report to headquarters. Mr. Tinker replied, handed the instructions, and General Superintendent Clowry of the Texas lines. This [illegible] visited Mr. Fraser, Mr. Brown's lawyer, Mr. Masterson, J. H. Murphy and Robert L. Moore, operators, were in the Fort Worth office. Mr. Umsinger, an operator, was in the Dallas office, and Mr. Osborne, words in the Cleghorne office. The batteries on the line were cut off from the wire [illegible] mile long, and the magnetic transmitter and receiver attached at both ends of the line. For two hours the test went on, all parties talking, and all operators, by the telephone system, receiving and sending telegraphic to the Cleghorne office and receiving an answer in the same manner. The voices of the Cleghorne parties were very distinct, and a marked feature was the absence of all ringing or other noises on the line, and of any other apparatus. After the test was completed General Tinker was telegraphed to

Inventor to your letter of June 15, but made over a three-mile-wire circuit worked satisfactorily with the batteries of Brown's invention instead of batteries.

"The instrument used today was composed of, two ounces of wire and a half-pound of steel, and can be made for $6 cents. The transmitter is simply a horseshoe magnet, either pole being covered with fine wire, through which the voice, striking on the steel, agitates which the voice is thrown is transmitted through the magnets to the wire. The receiver is similar, with another magnet. TESTING TELEPHONE WIRES.

Electric Currents Measured and Recorded by Delicate Instruments.

The Telephone Exchange is the scene of experiments daily, due to the perfection of the system, and to the genius of its inventor, L. Bailey, an electrician from New York, was found by a GLOBE-DEMOCRAT reporter yesterday surrounded by batteries, testing machinery in a large room in the top story of the Mechanics' bank building, and busy making tests. Mr. Bailey said:

"The telephone business in some localities is generally run by a sort of rule-of-thumb method. The people of each place are only considered a necessary to make a connection, thinking that their construction is good enough for telephone work. That doesn't answer for us, and we have to make a study of each locality. Mr. Bailey, the present company's general manager, is an electrician, having had a large experience in telegraphy, and has brought the results of Prof. Varley's visit to America when he made his last, and report about Varley's work. Mr. Bailey says that Varley's work was really the starting point of the successful operating of the Western Union system of duplex speaking. This company relies on Varley's report as being one of the greatest improvements in telegraphy, and on its power to regulate the resistance of the wires, etc., from which all tests are made. Before a line is put up, it is carefully tested, and received either in the wooden or iron shed. The wooden shed is the one in use in the city, and is the one in which the instruments are kept and tested. The iron shed is the one in use in the country, and is the one in which the instruments are kept and tested. The iron shed is the one in use in the country, and is the one in which the instruments are kept and tested.

PATIENT INVESTIGATION.

There are a number of minor points which are developed in telephonic business which don't occur to the public, and which require a long and patient investigation, and require a long and patient investigation of tests, which are to be supplemented by new experiments and improvements. Before a line is put up, it is carefully tested, and received either in the wooden or iron shed. The wooden shed is the one in use in the country, and is the one in which the instruments are kept and tested. The iron shed is the one in use in the country, and is the one in which the instruments are kept and tested.

MEASURED RESISTANCE.

There were some slight sensations yesterday in the line of the Telephone Exchange, and the line was found to be in good condition, and the line was found to be in good condition, and the line was found to be in good condition.

Journal, Albany, N.Y. 1885.

TELEPHONE CHARGES.

AN EXHAUSTIVE REPORT BY THE ASSEMBLY COMMITTEE.

Rates Reduced from $150 to $100 for Business Houses, and from $100 to $80 for Residences—Why the Telephone Company Escapes Legislation—Over $5,000,000 Already Invested—A Mass of Valuable Information.

Chairman Ainsworth of the telephone investigating committee appointed last year by the assembly presented a report this morning more voluminous than the New Testament. It begins with reciting that on April 27, 1885, the assembly passed a resolution directing the appointment of a committee to ascertain the status of all companies doing telephonic business within the State of New York; the amount of the capital stock of each; the cost of the plant of operation; the amount of the earnings of each, and their dividends. The resolution appointed Messrs. committee Messrs. Ainsworth of Oswego, Hedley of Franklin, Saxton of Wayne, Dickey of Rockland, and Grocer of Whitchester. Mr. William H. West of Marion, N. Y., was appointed as counsel. The meetings of the committee were held in Albany, Rochester, Utica, Troy, Syracuse, Buffalo, Binghamton and New York. The affairs of all the companies doing business were investigated. The report covers but a volume; one and detailed statement of the information obtained, etc. It was signed by Messrs. Ainsworth, Dickey, Wilcox, Hedley and by Chairman Ainsworth. Assemblyman T. Bolton and F. C. Hedley of the committee. A brief summary of it is as follows:

THE AMERICAN BELL COMPANY.

The American Bell telephone company is a corporation organized under the laws of Massachusetts with a capital of $10,000,000, which, by subsequent judicial decisions, on and restricted rights under it to use upon telephonic instruments in the United States, the invention and any of the instruments manufactured under its patent, but loses them by failure to increase at an annual rapidity of $11 per cent of instruments, excepting the Metropolitan company of New York, which is exempted by the city of Troy, which is exempted $10 respectively, reserving the right to increase the rental of instruments at its pleasure. By the terms of its original with the local companies those instruments are delivered to the local companies on the condition that they pay to the city of Boston. In addition to these royalties the company receives from licensees for manufacture in the United States of a duration of 33 per cent of the capital stock of its licensees. It also exacts a commission upon all extra territorial and telegraph business of the local companies, 45 per cent to the former and 50 per cent of the latter.

THE BELL COMPANY OF BUFFALO.

The Bell telephone company of Buffalo embraces the counties of Erie, Niagara, Orleans, Genesee, Wyoming, Monroe and Livingston and was organized in March, 1878, and has a capital stock of $500,000, of which the American Bell telephone company of Boston owns $250,000. Dividends to the amount of that stock has been issued. The total cost of construction of its plant is $414,892.15, and its net earnings during the year 1884 were $84,-565.20; the percentage of net earnings to cost of construction, including franchise stock and preferred stock, is 19.60. The dividends paid by this company in 1884 were 12 per cent. The rule of charges, being based upon the bell system, cannot be given.

THE CENTRAL NEW YORK.

The Central New York telephone and telegraph company operates the counties in the central portion of this state, with [illegible] offices in [illegible], [illegible], [illegible],

1883. The capital is $1,000,000, divided into American Bell company's $10,000, issued as franchise stock. Its call certificates during the last fiscal year were $30,681.50.—The actual cost of construction to date is $1,000,000. The amount of outstanding is cost of construction is $1,000,000. This company paid no dividends during the year. Its average dividend has been $.17 per month. It has 1,420 exchange subscribers, at an average annual rental of $36.00. Its net receipts from exchange business during the past fiscal year were $39,276.00, making the total net earnings to cost of construction 3.9 per cent. It has 826 subscribers at an average rental of $48.00.

THE EMPIRE STATE.

The Empire State telephone and telegraph company operates that portion of the line between the Buffalo and Chester New York companies, and has a capital stock of $500,000, divided into 5,000 shares, and of which the American Bell telephone company owns a franchise stock $60,000. The net earnings during the past fiscal year were $17,167.50, of which its city business furnished $1,750.41, while its toll line or country business contributed $15,412.05. Its total cost of construction to date is $25,000. The percentage of net earnings to cost of construction is 67 per cent. It has 826 exchange stations, the average rate being $41.25.

THE TROY COMPANY.

The Commercial telephone company of Troy operates principally the city of Troy and is owned principally by the Western Union telegraph company. It was organized January 1, 1879, and has a capital stock of $100,000, part of which is franchise stock. The nearly remaining evils of the franchises issued under the Edison patent and its franchise ceased expire in 1891, when, by the terms of its contract, the Western Union telegraph company contracts similar to those held by the other companies of the state. Its cost of construction is $90,000. Its net earnings during the past fiscal year were $23,000. Its percentage net earnings to cost of construction is 25.5 per cent. It paid no dividends in 1879, 30 per 'ct. in 1880, 40 per 'ct. in 1881, 50 per 'ct. in 1882, 60 per 'ct. in 1883, the amount of which was derived from its earnings and the district messenger service. It has 1,200 subscribers, at an average annual rental of $60.00 per instrument.

THE UNION COMPANY.

The Union telephone and telegraph company operates the exchanges at Albany, Troy, Saratoga, Cohoes, Warren, Washington and Rensselaer counties. It was organized in 1881 and has a capital stock of $500,000, part of which has been issued and none of which is franchise stock. Its cost of construction is $400,000. Its net earnings for the past fiscal year were $40,000, showing a percentage of net earnings to cost of 10 per cent. It has 1,000 licenses of the Bidden river telephone company, to whom it pays a royalty of $20 per annum each instrument. It has 1,000 exchange subscribers at an average annual rental of $42. Its average annual dividend has been 5.5 per cent.

THE NORTHERN NEW YORK.

The Northern New York telephone and telegraph company operates the northeastern portion of the state. The officers of the company reside in Lowell, Mass., and refused to furnish an interview. The statement was furnished by the manager, Mr. W. W. Wright, of Plattsburgh, from whom it was learned that the cost of construction for the year, 1883, was $75,000. Its capital stock is $50,000, all issued, of which the American Bell company owns $10,000. Its net earnings were $19,000. The dividend for the past fiscal year was 7 per cent. The percentage of net earnings to cost of construction and 25 for business and profession. We are unable to give its cost of construction.

THE NEW YORK AND VERMONT.

The New York and Vermont telephone and telegraph company was organized in 1881, and has a capital stock of $50,000, none of which is issued, for the American Bell telephone company is a subsidiary of the Bidden River company. The cost of construction is $50,000. Its net earnings for the past fiscal year were $5,000, the percentage of net earnings to cost of construction being 10 per cent. It has 200 subscribers, at an average annual rental of $25. It has never paid a dividend.

THE HUDSON RIVER COMPANY.

The Hudson River telephone and telegraph company operates the Hudson river valley, and a portion of Pennsylvania and New Jersey. It has a capital stock of $500,000, $150,000 of which has been actually issued. Its cost of construction is $300,000. Its net earnings for the past fiscal year were $45,000, showing a percentage of net earnings to cost of construction of 15 per cent. The interest company has never paid a dividend on its stock. It has been but a year and a half in operation. It has 2,000 subscribers at an average rental of $22.50.

THE NEW YORK AND PENNSYLVANIA.

The New York and Pennsylvania telephone and telegraph company, operates the southern tier of counties in New York and a portion of Pennsylvania. It was organized in 1882, and has a capital stock of $1,000,000, $250,000 of which has been actually issued. The American Bell company own, as franchise stock, $100,000. The cost of construction is $200,000, and its net earnings for its past fiscal year were $50,291.00, showing a percentage of net earnings to cost of 25 per cent. The annual dividend has been 4.5 per cent upon the issued capital. It has 2,000 subscribers at an average rental of $24.00.

THE WESTCHESTER COMPANY.

The Westchester telephone company operates principally in Westchester county, and has a capital stock of $100,000, all of which has been issued and $10,000 of which is owned by the American Bell company as franchise stock. The cost of construction is $75,000, and its net earnings for the past fiscal years were $18,000, showing a percentage of net earnings to cost of construction of 24 per cent. The capital stock has all been purchased by the Hudden River company. Its average dividend since organization has been 7 per cent. It has 1,000 subscribers.

THE STATEN ISLAND COMPANY.

The Staten Island telephone company operates Staten Island, and is an outgrowth of the Metropolitan company, which operates in New York and Brooklyn, having a capital stock of $125,000, all of which has been issued. Its cost of construction is $80,000, its net earnings for its past fiscal year were $6,474, showing a percentage of net earnings to cost of construction of 8.1 per cent. The Metropolitan company owns $45,000 of its capital stock issued to them as franchise stock. Its annual dividend has been 6 per cent. It has 372 subscribers, paying from $50 to $125 per year, depending upon distance from the central office.

THE NEW YORK AND JERSEY.

The New York and New Jersey telephone and telegraph company operates between Jersey City and various points. It was organized in 1881 with a capital stock of $2,000,000, $400,000 of which is franchise stock of the licensees of the Metropolitan company, which owns $200,000 of the stock. Its cost of construction is $1,000,000, and its net earnings during the past fiscal year were $100,000, showing a percentage of net earnings to cost of 10.5 per cent. It has 2,317 subscribers at an average rental of $75.

INEQUITY OF UNIFORM RATES.

This company has a special class of service furnished to the brokers who are large users, and pays a dividend, in one case of $720 per year. Free service is given by actual count for 70,000 connections with the Jersey City exchange, and from the cost of the instruments and the other items of service furnished the liability of these brokers' business hours, counting from the time the first bell rings in the morning until the last bell rings in the evening, it would appear that these illustrated the inequity of these uniform rates for equal service. These cases point to a loss marked degree throughout the state.

A COMPANY WHICH NEVER EARNED MONEY.

The American Union telegraph company, of Buffalo, was organized in 1865 with a capital of $750,000, and was the pioneer company, especially in the giving of telephonic conversations between different cities. It never earned any money, and was finally wound up under the provisions of the resolution appointing this committee.

THE METROPOLITAN.

The committee review the conflict between the Metropolitan Union telegraph company, owners of the Edison patent, and the Bell company as concerning the Edison Bell patent, and of the settlement of which, gave the Metropolitan company of New York, and the Metropolitan company of Brooklyn, each a franchise of $1,000,000, granted respectively by the Metropolitan telegraph company of New York, and Western Union telegraph company, in the two

DAN-DRAWBAUGH'S HOME

STORY OF THE INVENTOR'S TRIALS

INVENTED THE TELEPHONE AND MACHINE GUN

The Struggle of His Existence Worth and His Sufferings—Handicapped by Poverty and Created by the Press—Millionaire Bell, His Rival Works on His Farm—What His Neighbors Say.

HAMMONTON, Pa., April 12.—I have been over at the Second Valley of the Cumberland in the neighborhood of Dan Drawbaugh's workshop and residence of the Supreme Court of the United States say or think of the claims of this man in the federal courts. The courts have arrived at are that the state has authority, provided by its constitution of legislature, to impose taxes or regulations of doing business in this state; but that the regulations enacted by the full company of Boston *for the right to use its patents* are not subject to state control.

THE ONLY REMEDY IN INVENTED.

The remedy, therefore, for the attempted legislation of the states and the investigations made by their committees, is found in the decisions have been rendered in the New York, Pennsylvania, Ohio, Michigan, Minnesota, Illinois, Iowa, Arkansas and Texas with regard to this question, and review at length the decisions of the supreme position in Indiana and in effect in the states of Minnesota and the people. They treat of the question of the Bell patent that fix the cases. This is brought out in the decision of the American Bell company and the interference between the patent of Dr. Bell and that of Mr. Edison, according at the conclusion that at the option of the Bell company the Edison patent was the company upon telephonic instruments, practical use will extend for a period of 17. years from the date of the settlement of this interference. The only remedy to defeat this patent is to show that the invention of the person of a telephone which shall render communication possible by the use of the Bell apparatus, and that it breaks " sound well, electricians say, is extremely doubtful.

WHEN THE INVENTION MAY INTERFERE.

The committee think there is but one circumstance under which their judgment would justify legislative interference. That circumstance is when the Bell company shall so large that it shall be a burden to the world to use it and which shall produce a revenue disproportionate to the capital upon which it is based. It is not to be supposed that the company will be content to retain its present limits. That circumference is found in the cities of New York and Brooklyn, and in the latter, its franchise expires in 1893, when legislation is recommended for that city.

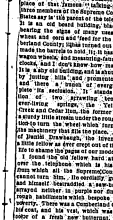
THE METROPOLITAN TELEPHONE CHARGES

The committee believes that the returns of the Metropolitan company are such that they may have a moral right to demand, and will probably get a bill making the charge in the city of New York $1.50 per month, with an additional charge of $1 per month for all points exceeding one half mile from any one of the present central offices.

THE EXPENSE INCURRED BY THE COMMITTEE.

The total expense of this investigation will not exceed $7,000, which appropriation has been paid by the individual members of the committee, owing to the fact that the attorney-general, at the request of the committee of the last session of the legislature refused to act, or sanction, provision for the expenses of a legislative committee of investigation.

The committee employed no counsel, acting themselves in that capacity.



THE OLD HOME.

"In this house, over 20 years ago," said Dan Drawbaugh, as he pointed to the old farm house, "I invented the telephone, and I have the models to prove it." Mr. Dan's wife corroborated the statement. "I remember," she said, "the night he came in from the workshop and told me that he had invented something which would enable people to talk to each other over long distances, so that they could hear the voice of the person at the other end of the line. I remember, too, that I was afraid to go to bed that night, for I thought he would get up and talk to himself all night." Mr. Drawbaugh is a man of about 60 years of age, and has lived on the farm where he now resides for 30 years. He is a man of medium height, with a full beard, and has a pleasant face. He is a man of few words, and modestly, yet firmly, asserts that he is the inventor of the telephone. He says that Drawbaugh did have an interview with Prof. Bell, but that the latter's invention was entirely different from his own. The principle upon which Drawbaugh's telephone operates is a diaphragm, or receiver, which is placed in the mouth of the speaker. This diaphragm is composed of tin, or tar or varnished cambric is concerned. Mr. Drawbaugh has been in the habit of making his own tools, and has a machine shop on the farm, where he has a complete assortment of machinery with which he can make anything he wishes. He

CAN GO UNDER GROUND.

What Telephone and Telegraph Companies Will Do in New York.

The Board of Electrical Control, consisting of Mayor Hewitt, Commissioner of Public Works Jacobus, Police Commissioner Matthews, Fire Commissioner Purroy, Commissioner of Parks Dowling, Commissioner of Docks Andrews, and Commissioner of Buildings Brady, met yesterday afternoon in the Mayor's office to hear the petitions of the New York and New Jersey Telephone Company, asking for the privilege of placing its wires underground, and to receive and battery-test, with a view to their adoption, the various systems of underground wires which have been submitted by the Western Union Telegraph Company and the Consolidated Telegraph and Electrical Subway Company. Mr. Bogart, the electrician of the Board of Electrical Control, was also present.

Mr. Bogart explained the various systems of underground wires which had been submitted, and the tests which he had made of them. He said that the Western Union Company had submitted two systems, one of which was the invention of Mr. Phelps, and the other that of Mr. Gilliland. The Consolidated Company had submitted the system of Mr. Van Depoele. Mr. Phelps's system consisted of a lead pipe, in which the wires were placed, and which was filled with paraffine oil. Mr. Gilliland's system consisted of a wooden trough, filled with paraffine oil, in which the wires were placed. Mr. Van Depoele's system consisted of a wooden trough filled with asphaltum, in which the wires were placed. Mr. Bogart said that he had made tests of the systems of Mr. Phelps and Mr. Gilliland, and had found that the insulation of the wires was perfect. He had not had time to make tests of the system of Mr. Van Depoele.

Mr. Bogart then explained the tests which he had made of the systems of Mr. Phelps and Mr. Gilliland. He said that he had found that the insulation of the wires was perfect, and that the induction was not sufficient to cause trouble. He had found that the wires could be worked as well under ground as overhead.

Mr. Bogart then explained the tests which he had made of the various systems of underground wires which had been submitted by the Consolidated Company

ELECTRICAL NEWS.

A New Telephone Appliance—The American Co. in the Field Again.

That able, forcible, pronounced exponent of the modern science and unsurpassing development of electrical appliances, the Boston Advertiser, does itself credit thanks of the electrical world by the following notice of the appearance of the New England Electrical Exchange, the manufacturing of these methods in wall discs, and last, but not in its degree and importance, boxes of Practical Electricity, which should be in the hands of every family in the land, as a matter of electrical economy, and to prove how true that "electrical companies agreements are reform, wire Dr. Austin should have the hearty co-operation of the press as well. Limited space in our columns prevents us from the comfort of writing more in regard to this matter, but we shall have more to say on the subject hereafter.

A "caretaker" invention that appears to have decided merit as well as novelty is a late improvement on the telephone, which is contained in a small box that is placed near to the "piano forte," or other musical instrument. The object of device is that of electrically conducting telephonic communications to "any paper inside the machine. If a person is singing or playing, present, the person speaking continues to sing or play, and the person who is listening can hear and see the wire in motion, and when dropped on the apparatus, which indicates that some one has been talking. Switch on the phone he cease the switch, when all that has been said will be recorded on the paper and the party is bound to silence as soon as the tone of voice and at the same rate of speed as when the paper are fast in, and the wires and lines be placed in the machine and the sound be reproduced."

Mr. J. Hill, manufacturer of electrical apparatus, 26 Cortlandt street, has a fine assortment of lamps and batteries, 152 Greenwich street, is very busy on his specialties. He has recently issued a neat illustrated little catalogue, written in plain, conversational language how electricity is generated in a systematic manner.

If the electrical raising of sugar under the Louisiana sun is successful, as it seems to be, the sugar centralists is successful, as it seems to be, the sugar centralists is successful, as it seems to be, the sugar centralists

8 Merch, Recorder, Fayetteville, N.Y.

A Novel Telephone.

The Lovell electric-telephone has been put in Chicago, and is a combined transmitter and receiver. A hollow cylinder about four inches long is attached to the receiver, from the rest of which a small button protrudes slightly. The button is placed against the listener's head by vocal chords, and the receiver is held against the ear in the usual manner. When the operator speaks the vibrations of the throat are transmitted with, it is said, distinct clearness. The instrument is operated by the usual vibratory current that accompany the utterance of words. The inventor, James Lovell, is a young man of about twenty-five, and writing on the instrument for the first time. When he first applied for a patent, three years ago, the authorities at Washington thought him a crank, and refused to listen to him. He attached the instrument to wires in the office and asked over it: "What do you think now?" Back over the wire came: "I give in, it works perfectly." Our Chicago informant says it has been successfully operated between that city and Milwaukee, and in Pittsburg (Wrinkled over a line seventy-five miles in length, on which were twenty-five Bell instruments, a perfect success.

UN HOMME A FUSILLER

C'est M. Edison.

On nous écrivait peut-être un peu sévère pour cet inventeur de génie, auquel nous devons le téléphone, le phonographe, la lampe électrique et tant d'autres merveilles que nous ne pouvons nous empêcher d'admirer, et qui nous sentant près d'horreur et de rancune pour leur auteur.

M. Edison est tout simplement en train d'abréger les jours de l'homme et de lui rendre la vie insupportable. En fouillant les angles de la justice, je crois que l'on trouve un malfaiteur plus chargé de crimes, plus convaincu d'homicides plus coupable de drames mortels que cet Américain dont j'ose à peine prononcer le nom illustré.

Le téléphone! Quand le Parlement ajoutera-t-il un article au Code pénal pour punir les crimes du téléphone? Un mais, et l'autre brandissant le phonographe révélateur, qui répète toute heure de la nuit pour vous dire les dernières effusions de votre voix et les dernières phrases d'amour que vous avez prodiguées à votre femme, à votre maîtresse, à votre amant, à votre mari, à votre fils, à votre père, à votre mère, à votre fille, à votre sœur, à votre frère, à votre oncle, à votre tante, à votre cousin, à votre cousine, à votre neveu, à votre nièce, à votre petit-fils, à votre petite-fille, à votre arrière-petit-fils, à votre arrière-petite-fille, à votre arrière-arrière-petit-fils, à votre arrière-arrière-petite-fille, à votre arrière-arrière-arrière-petit-fils, à votre arrière-arrière-arrière-petite-fille, à votre arrière-arrière-arrière-arrière-petit-fils, à votre arrière-arrière-arrière-arrière-petite-fille, à votre arrière-arrière-arrière-arrière-arrière-petit-fils, à votre arrière-arrière-arrière-arrière-arrière-petite-fille, à votre arrière-arrière-arrière-arrière-arrière-arrière-petit-fils, à votre arrière-arrière-arrière-arrière-arrière-arrière-petite-fille, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-petit-fils, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-petite-fille, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petit-fils, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petite-fille, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petit-fils, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petite-fille, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petit-fils, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petite-fille, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petit-fils, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petite-fille, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petit-fils, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petite-fille, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petit-fils, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petite-fille, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petit-fils, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petite-fille, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petit-fils, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petite-fille, à votre arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-arrière-petit-fils, à votre arrière-petite-fille, à votre arrière-petit-fils, à votre arrière-petite-fille, à votre arrière-petit-fils, à votre arrière-

THE TELEPHONE LITIGATION.

There is naturally a great deal of interest in the telephone litigation, which many thought had come to an end by the recent decision of the Supreme Court in favor of the Bell Telephone Company, but which is by no means yet ended by the determination of Drawbaugh, the Pennsylvania inventor, to secure his rights in the patent in the microphone or carbon instrument, and by the demand of the Western Union Telegraph Company that the Bell Company shall keep to its agreement and not even appear to interfere and compete with the Western Union's business, and shall pay for its violation thereof.

The questions involved in this complex litigation are, first, whether Drawbaugh was not the original inventor of the telephone which, with but slight differences, was used by the Bell Company as Bell's invention, and by the Western Union as Gallier's invention, and in this is involved the question of the patent on the art of telephoning in general, by which both Bell and Edison have acquired wealth. Drawbaugh is still poor; and second, whether the Bell Company, having secured the sole right to the Hunning English patent, by which all the long distance telephoning has been accomplished, enabling it to "interfere and compete" with the Western Union's business, has violated its agreement with the latter, which was based on the joint use of an instrument of which Bell, Edison and Drawbaugh each claimed to be the inventor.

According to current statements, Drawbaugh invented his microphone in 1870, Edison does not claim his patent before 1877, and the Bell people have admitted that Drawbaugh's instrument was constructed in the year named. What judgment may be rendered in the dispute between the Bell and the Western Union people few readers will care, except to gratify curiosity; but, as the public sympathy is very apt to be with the under dog in a fight," there will be considerable anxiety to know how Drawbaugh comes out of this contest, and everybody will hope that the litigation will not be long drawn out for the behoof of the lawyers, but will be "short, sharp and decisive," to the end that justice may not be left to the enjoyment of the next generation only.

Boston is now engaged on a "fire alarm" machine, by means of which people will be able to see long distances. The "wizard" never fails in what he undertakes, and some of these days a man in Boston will be able to see his mother-in-law over a thousand miles away. Edison has done a great deal to bless this world and render life worth living.—Utica Herald.

A Far-Sight Machine.

Mr. Edison is reported, in a conversation with a reporter who solicited his ideas on the subject of the projected world's fair in New York, as saying that he would take an hour or more in such a fair and completely cover it with his inventions, of which he has no less than seventy new ones under way. "One of these," Mr. Edison, "is what I might call a far-sight machine." By means of this extraordinary invention he hopes to be able to increase the range of vision by hundreds of miles, so that, for instance, "a man in New York could see the features of his friend in Boston, with as much ease as he could see a performance on the stage. That," he added, "would be an invention worthy a prominent place in the World's Fair, and I hope to have it perfected long before 1892."

Electrical Review.

Gazette, Brooklyn, Mass.
June 1, 1889.

This "sportelectric" system will soon be shooting passengers from here to Boston inside of ten minutes. Mr. Edison proclaims that in three years you can see a man hundreds of miles away, by an invention of his. There will then be no excuse for those who go out between the acts to "see a man."

SEEING BY ELECTRICITY

LOOKING AT PEOPLE THOUSANDS OF MILES AWAY FROM YOU.

EDISON'S SUDDEN DEPARTURE TO AVOID THE INTERVIEWER.

MAN WITH THE TELEPHONE HAS BEATEN THE TELEPHONE, AND GOT AHEAD OF HIM.

EDISON'S NOTABLE PREDICTION UPON THIS POINT IN HIS AKRON VISIT.

LAST WINTER—YET ANOTHER INVENTOR OF THE WONDER.

The following special dispatch to THE BEACON from New York to-day has a local interest to Akron readers, as it goes to show that more than one mind was at work on a greatinvention during the time that Mr. Thomas A. Edison visited Mr. and Mrs. Lewis Miller in this city several months ago. THE BEACON dispatch reads:

"NEW YORK, Aug. 9 (Special).—It is given out that scientific circles in Edison's sudden visit to Paris is directly connected with the invention of the telephote by M. Courtenay, the well known Frenchman. Edison has been long studying the same apparatus which will enable people to see at long distances just as the telephone enables them to hear far-off sounds and moving words. This, it is claimed, is accomplished by the telephote, and it will further, it is averred, transmit luminous vibrations through any kind of obstacle on a wire for hundreds or thousands of miles. Courtenay promises to give full details of his discovery as well as public experiments inside of two months."

"The above dispatch recalls an interview to this effect, which appeared in the Akron BEACON last winter, after Mr. Edison, one evening, after the party had enjoyed the phonograph in Mr. Lewis Miller's home, during the inventor's recent Christmas visit in this city, Mr. Edison himself, operating the instrument to the delight of all. The newspaper man, in the course of the conversation, asked Mr. Edison, whether new thing he was next going to give to the public to astonish them. He spoke of various things that he was at work upon and then said: "The next time I come to Akron I will show you a machine that will not only reproduce the sounds of an opera, but that will also show you all the characters in it, in short it will be the same as though you went to the opera house." He said that the proposed instrument would show the performers as they came on the stage and all the motions during the entire evening, giving of each person as distinct in picture, that they would be readily recognized by all familiar with the characters employed. He was questioned as to the process, but he went into no special detail, beyond remarking that the delicate film of a soap-bubble and the resulting reflections thereon, and said that the whole scene on any stage could be caught up by his proposed invention so that every feature would be distinct and every motion would be seen in the image on a bubble. His declarations then of what we heard, but could not half realize, that the "Wizard of Menlo" should accomplish what he then promised to bring to Akron in due season, has a peculiar interest at present, inasmuch as another Buckeye man has made another discovery with a friend, formerly of Akron, in this same line in the East, who died of himself seeing in the home of a friend, a scene of remarkable intensity, a device for seeing the persons you talked with by telephone, as well as hearing them. In fact this gentleman himself tested the apparatus more than a year ago and being through a number of miles of wire what was transpiring in a room so distant and satisfied as to practical possibility that the sight was in any other way than over the electric wires by some mysterious method of transmission. Thus three minds, at least, have been on the verge of putting this marvellous invention into practice."

The wizard of the Menlo Park is going to surpass himself. Arabian magicians and conjurers of old time have developed extraordinary talents in the way of revealing to a lover in a drop of ink or a ball of crystal the sight of his mistress, no matter how many hundred miles she might be distant. Edison has tramped this by the invention of what he calls a farsight machine, by means of which he hopes to be able to increase the range of vision by hundreds of miles, so that, for instance, "a man in New York could see the features of his friend in Boston with as much ease as he could see a performance on the stage." He hopes to have the invention perfected long before 1892. Query, will the farsight machine add to the joy or the misery of the world?

Tribune, Rochester, Pa.
Aug. 9, 1889.

Edison's Machine.

Mr. Edison is reported, in a conversation with an interviewer who solicited his ideas on the subject of the projected world's fair in New York, as saying that he would take an hour or more in such a fair and completely cover it with his inventions, of which he has no less than seventy new ones under way. "One of these," said Mr. Edison, "is what I might call a far-sight machine." By means of this extraordinary invention he hopes to be able to increase the range of vision by hundreds of miles, so that, for instance, "a man in New York could see the features of his friend in Boston with as much ease as he could see a performance on the stage. That," he added, "would be an invention worthy a prominent place in the World's Fair, and I hope to have it perfected long before 1892."

Times, Scranton, Pa.
July 24, 1889.

We shall soon have perfected an instrument upon which Edison is at work, by which two persons can actually talk to each other from different cities, but see each other at the same time. We are getting there rapidly.—Unsentertain.

The new invention may not be as pleasant when you are "rung up" by the fellow whose bill is a little past due.

Mr. Edison says that one of the most possibly of possibility of the inventions he is now working on is the far-sight machine; he hopes with it to be able to increase the range of vision by hundreds of miles, so that, for instance, a man in New York could see the features of a friend in Boston."

In this connection it may be mentioned that Edison has invented an attachment for the telephone by means of which one may see the person to whom one is talking over the telephone.

Utica—Great Scott! Is that so?

Chris—Yes, I've fact.

Utica—You're pretty tough, then!

Chris—Because if it's so I want to be able to see the girl I'm talking to over the telephone.—Troy Times.

Voice—"see that Edison has invented an attachment for the telephone by means of which one may see the person to whom one is talking over the telephone."

Utica—Great Scott! Is that so?

Chris—Yes, I've fact.

Utica—You're pretty tough, then!

Chris—Because if it's so I want to be able to see the girl I'm talking to over the telephone.—Troy Times.

They've altogether too progressive for me.

Thomas A. Edison announced the other day that he is at work on a new invention by which sight as well as sound may be transmitted by electric wire. It seems, however, that a young German named Kornel has anticipated him. The Centralblatt für Electricität gives an interesting account of an exhibition recently made by this gentleman, in which two of his instruments, in different cities, were connected with a telephone wire. The features of the person standing at one end of the wire were distinctly seen in a glass plate at the other end, and the larger type in a newspaper held before the instrument in one city was easily read in the other city. Everything seen was greatly reduced in size, but this was because the glass plates were small, this phenomenon being governed by the laws of optics and not those of electricity.

The secret of this wonderful invention lies in the sensitiveness of selenium to the effects of light. When a ray of light falls on a plate of selenium, one electric conductivity of the metal changes. Mr. Kornel uses a plate covered with a composition which he calls bromide of selenium gelatine for "reading" the image of the person using the telephone, which is then transmitted by the same wire that conducts the sound of his voice and throws, apparently without the use of any further apparatus, on a glass plate at the other end. In this way the persons using the telephone can not only hear but see each other.

American Edition, N. Y. City
Aug 16, 1879

Mr. Edison, of electric and phonographic fame, promises the world an apparatus which will enable people to see at long distances, just as the telephone enables them to hear distant sounds and movements. The American inventor has a rival in a Frenchman, M. Constenne, who states that he will make public his discovery and perform experiments with his "Phonephote" at the end of the present year, so that Mr. Edison's claim may not be allowed to be first in the field. M. Constenne avers that his invention will be able to transmit luminous vibrations through any kind of obstacle on a wire not only for hundreds but thousands of kilometres.

Paramount, Idaho, Co
Aug 13, 1879

As now we see all to see long distances, as we telephone, M. Constenne has already perfected an electric invention for this purpose and Edison has gone to Paris to examine it. Edison thinks that the machine a man thinks he is working, will soon have power and control of him. Edison may be in love for a time and lose sight of his self, but soon he will have a machine that will see no more lost in distinctly and satisfied. His self could were he seated in the bed of his arrangement takes the place of the telephone between office and residence and the balance machine does all the work. Edison's machine is a wonderful invention.

Times, Petersburg, Va.
Aug. 15, 1879

Nothing can save the people of Germany from the consequences of their folly in the matter of the telephone. Edison has invented a device for the transmission of pictures by telegraph, and Constenne, a French engineer, has made a similar discovery. A new arrangement by which a person at a distance can be seen by the family at his home has been patented in Germany, and it is said that others have been under way in the same field, and one of these, Herr Kornel, of South Germany, has not only effected several important developments, but has actually brought down the invention to a working basis. The foundation of the apparatus is the ordinary house telephone. Above the diaphragm aperture is a lens, similar to the objective of a photographic camera, and above this a translucent glass plate is an elaborate frame. At the right and left of the objective are two incandescent lamps with silvered mirror reflectors. The lamps are lighted by a specially constructed battery. This constitutes the whole outward appearance of the apparatus. The objective serves for taking the picture of the person using the telephone, while the incandescent lamp illuminates his face. Upon the glass plate above is thrown the property of whatever is to be transmitted by the telephone. In the course of an exhibition of his system in Berlin, Herr Kornel connected his photoscope to a telephone, and had the central office connect him with a business friend in Potsdam, who likewise was provided with a photoscope. The moment the Potsdamer stepped to the apparatus the ground glass plate showed an excellent portrait of him, which, when connected with his photograph, was easily identified. The shape of the hand, the smile and the natural expression of the whole face was perfectly distinct.

In the course of a conversation with a newspaper man, who sought his views upon the subject of the projected "Electric Fair in New York city, Edison, the electrical wizard, is reported as saying that he would take as sure of space in such an exposition and completely cover it with his invention, of which he has no less than seventy now under way. "One of the most peculiar and now perplexing good results," said Mr. Edison, "is what I may call a far-sight machine." By means of this extraordinary invention he hopes to be able to increase the range of vision by hundreds of miles, so that for instance a man in New York could see the features of his friend in Boston with as much ease as he could see a performance on the stage. That, he added, "would be an invention worthy a prominent place in the World's Fair, and I hope to have it perfected long before 1889."

Years ago an American inventor announced that he was on the track of a discovery by means of which electricity could be made to do for the eye that which through the telephone it does for the ear, and persons, objects and scenes, however distant, could be made to appear upon a screen at the end of the "telephote" wire. The announcement made here a slight impression, and nothing has been heard of it since. The invention seemed to be in the narrative, and not in any actual apparatus. Now comes a report from Europe that what was then suggested as possible, is a part of the here actually accomplished, so far as this, that by some mechanism in the telephone, the persons of the person speaking appears on a screen at the other end of the wire. Mr. Edison, of course, is said to be working on the same problem.

One of the "late inventions in the use of electricity is that by which a person may be enabled to see an object at a long distance from him. In this way the likeness of a person talking through a telephone may be seen by the person with whom he is talking. It seems that a likeness may thus be transmitted many miles, and greater probably than the distance over which a telephone may be used. Edison is working on an instrument of this sort, but he is not the first inventor. A German named Kornel preceded him. This will rank with the phonograph as a modern wonder.

Edison is inventing a long distance telephone, so that you can see a fellow in New York or Boston as you talk with the boys do who tell their wives they were at the lodge. If they are in love the machine will turn down at the faro table by their loving spouses? [illegible]

American, Hackney, Conn
June 5, 1880

Edison is at work on a machine which he expects to do for the eye what the telephone has done for the ear and says it is possible for a man in New York to see the features of his man he is talking to in Boston.

The Wizard of the Menlo Park, Mr. Edison, is going to outdo himself. Another magnificent invention of his time have developed extraordinary talents in the way of revealing to a lover in a drop of ink or a ball of crystal the sight of his mistress, no matter how many hundred miles she might be distant. Edison has trumped this by the invention of what he calls a farsight machine, by means of which he hopes to be able to increase the range of vision by hundreds of miles, so that, for instance, "a man in New York could see the features of his friend in Boston with as much ease as he could see a performance on the stage." He hopes to have the invention perfected long before 1889. Query, will the farsight machine add to the joy or the misery of the world?

BELL'S PATENT SUSTAINED

THE WILLIAMSON CASES DECIDED IN HIS FAVOR YESTERDAY.

Justice Gray Delivers the Opinion of the Court—Justice Blatchford Dissents—Other Decisions.

WASHINGTON, March 19.—Mr. Justice Gray this morning announced the decision of the United States Supreme Court in the telephone cases. It is in favor of the Bell Telephone Company on all the points in every one of the cases. The opinion was rendered by only four Justices out of the seven, but the majority of one was, of course, enough to make it final. Justices Gray and Lamar did not participate in the case. Justice Bradley read a dissenting opinion, in which Justices Field and Harlan concurred. The cases now decided are five in number. The Bell Company has been plaintiff in seven cases, but two of them had been the defendants in the lower courts. The companies concerned are the Overland, the Drawbaugh, the Dolbear, the Scribner, the Johnson and the Globe-Gold, of New York.

The decision restores the original patent to Bell, it was alleged, obtained surreptitious information with respect to the invention of his assistant, and then amended, by new specifications. The Court holds that there is no evidence to support this charge, or to cast the least reflection upon the integrity of Bell or his attorneys. Justice Bradley, Harlan and Field dissent because they do not believe Drawbaugh's claim. They confine themselves to that point, and express no opinion as to the validity of Bell's patent in view of other claims to the invention.

The Court holds that the form of the instrument employed by Drawbaugh had reference to the transmission of sound, but is incapable, as a matter of fact, by multiplying its magnitude or otherwise, to transmit articulate speech. Bell's patent was in general that "the Drawbaugh claim is declared to be nonexistent. "If more had been said," says Justice Gray, "the expression in the Drawbaugh specification would be misleading."

In considering the question of the alleged anticipation by the invention of Daniel Drawbaugh, the Court holds that Bell's invention was not limited to the employment of steel, but that the apparatus described by him, present or absent, of intervening circuits, was sufficient to transmit articulate speech, and that the expression of the discovery which was made by Bell.

The Court considers that the Bell patent was not void for uncertainty in the description of the invention, and that the expression "undulatory current" was sufficiently definite. The Court holds that the invention was completed by Mr. Watson, Bell's assistant, when the latter heard the sound of the tuning fork through the telephone and not when Bell himself heard it. Mr. Watson, however, was employed by Bell, and the invention belonged to Bell. The Court holds that the Bell patent was not void because it was not put in practical use within two years after Bell's application for it

LE TÉLÉPHONE GOWER

à Royal-Institution

L. Rodanet

Nous recevons, d'un de nos correspondants de Londres, des détails sur la conférence faite à Royal Institution par le professeur de Parnsby sur l'ingénieux instrument que nous avons été les premiers à faire connaître au public français.

Londres, 29 mars 1878.

Le professeur Tyndall a fait ici, à Royal Institution, une conférence sur le téléphone Gower, conférence qui a obtenu un tel succès, que les membres de la royale société en ont demandé une seconde pour le lendemain. Le professeur Tyndall a développé, dans ses détails techniques, l'invention de M. Gower que tous nos lecteurs connaissent déjà après avoir présenté à l'auditoire M. Gower, le confidencier a montré quel pas énorme le jeune ingénieur avait fait faire à la science. Il l'a complimenté longuement sur la valeur de son appareil, qui donne de si merveilleux résultats dans sa simplicité même, et, sans pile, sans accessoire, produit les courants électriques, *sous la seule excitation de la parole humaine.*

B. MURRAY.

TELEPHONE WITH MAGNETIC SUPER-EXCITATION.

By M. Anon.

The new telephone is founded on the principle that if a slender blade of iron or steel is placed before the poles of a magnet, it is much more strongly acted upon if there is placed behind it a piece of soft iron than if this is not the case. Thus a greater sensibility is obtained by placing in front of the diaphragm of a common Bell's telephone, an iron disk, pierced in its center, with a hole corresponding to the mouth of the apparatus. Scientific Am. Nov 240

Talking by Telephone through the Human Body

Boston Journal June 1880

As the human body is a good conductor of electricity it may be expected that telegraphic messages may be transmitted through the same, and even the weak intensity currents of the telephone, and this without the person conducting the current perceiving any thing. This has been tested recently in Glasgow and the telephonic current led through a circle of persons who joined hands, and the expectation was fully realized, the human links in the circuit notwithstanding.

ux quand, arrivés à la véritable solution, ils remplacent x par la quantité trouvée et remontent à l'origine de leurs calculs, en les vérifiant l'un après l'autre.

Ils sciences naturelles, s'il est permis de se servir de l'hypothèse comme d'un point d'appui, ce n'est qu'à la condition qu'elle sera vérifiée séance tenante par l'expérience.

L'hypothèse peut servir de procédé opératoire ; elle ne doit jamais fermer la base d'une théorie.

C'est pourquoi je commencai mes recherches par le plus simple des instruments téléphoniques, le condensateur chantant.

Je découvris bientôt les sons secondaires produits dans ces appareils par l'influence des lames inductrices.

La construction d'un grand nombre de ces instruments me fit voir le rôle des résidants et des conducteurs, les effets produits par la distance des lames entre elles, leur nombre, enfin leur forme.

Je remarquai que si on réduisait un condensateur à sa plus simple expression, c'est-à-dire à deux surfaces conductrices infiniment petites séparées par une lame isolante, le chant était reproduit.

Mais deux surfaces infiniment petites ne sont autre chose que les extrémités de deux pointes, la lame isolante peut être une lame d'air; or, j'ai démontré expérimentalement que deux pointes placées en regard l'une de l'au re suffisaient pour reproduire le son.

Mais nous savons aussi que l'épaisseur des lames est sans influence. Supposons les extrémités des pointes sans aucune ép isseur, elles se réduiront à un point : donc une se le de points séparés par des lames d'acier reproduisent le son.

Le point réduit à l'infini, c'est l'atome.

La lame d'air réduite à l'infini, c'est l'intervalle moléculaire.

Or, les corps ne sont composés que d'atomes et d'intervalles moléculaires.

D'où je conclus (voir le numéro du 29 juin) qu'un corps conducteur n'est en réalité qu'un condensateur réduit aux dimensions at-omiques.

Cette constitution des corps conducteurs me permet de formuler dès à présent cette autre proposition sur laquelle je me réserve de revenir avec de nombreuses expériences à l'appui.

L'électricité se propage dans les fils conducteurs par induction et non par circulation; par décomposition successive du fluide neutre de chaque molécule à mesure que un courant ou tension excitant d'une source quelconque.

La pile ou l'électro-moteur n'est qu'un excitateur de molécules sur ces qui déconpose en polarisé par induction les molécules passives formant le fil de conducteur.

Il n'y a ni bons conducteurs, ni corps isolants; il n'y a que des corps plus ou moins conducteurs, et on ne doit accepter les mots conducteur, meilleurs conducteur, isolant, que comme des moyens de faciliter le langage.

Un corps pouvant être bon conducteur par rapport à un second, et isolant si on le compare à un troisième.

Mais revenons aux pointes placées en regard.

La conclusion précédente n'est pas le seul enseignement qu'elles puissent nous donner.

Si nous observons ce qui se passe au moment de l'émission d'un son, nous verrons qu'elles deviennent lumineuses; il y a production d'aigrette et d'étincelle.

D'où je conclus que :

Quand un courant électrique est assez fort pour traverser une lame gazeuse médiocrement conductrice, il le fait sous forme de lumière.

Donc, si nous intercalons dans le circuit un médiocre conducteur gazeux, ce médiocre conducteur gazeux deviendra lumineux sous l'influence du courant et nous avons tout lieu de croire que l'illumination présentera des caractères particuliers dus l'analyse pourra s'emparer.

Les résultats devront être très-précis, puisque ce sera le courant lui-même que nous saisirons au passage sans le secours d'aucun instrument intermédiaire.

L'expérience est venue confirmer mon hypothèse.

Un tube de Geisseler n'a-t-il autre qu'un médiocre conducteur gazeux ; si nous le plaçons entre les pointes mobiles, il s'illumine et constituera mon nouvelle électro-manoscopique.

Je vis du premier coup que l'illumination n'était pas la même pour les différentes notes.

Restait à trouver le moyen de tirer parti au point de vue de l'étude de ce résultat expérimental.

J'eus de suite l'idée d'imprimer au tube un mouvement de rotation.

Je sais que l'on me dira que cette expérience n'est pas nouvelle, qu'elle se trouve dans toutes les boîtes de physi ue amusante.

Oui, si on la répète telle qu'elle a été faite par M. Gaver dans sa conférence.

Non, si on l'exécute telle que je la décris.

Ce qui doit caract riser tout instrument scientifique, c'est d'être propre à mesurer deux ou plu-leurs phénomènes de même nature et d'être comparable à lui-même.

Les machines employées jusqu'ici pour faire mouvoir les tubes peuvent-elle remplir ces conditions?

Non, car leurs résultats ne sont pas comparables : or, qui dit comparaison dit mesure.

Mais si on mesure ne peut s'établir qu'entre quantités de même espèce dont l'une est prise pour unité.

Toute mesure peut s'exprimer ainsi :

Rechercher combien de fois une valeur connue prise pour unité est contenue dans une autre valeur de même espèce.

Quand nous disons qu'un sac d'argent contient 1,000 francs, nous exprimons que ce sac contient 1,000 fois l'unité monétaire, appelée franc.

Quand nous disons que d'un point à un autre il y a 152 mètres et demi, nous indiquons que cette longueur renferme 152 fois, plus une fraction, l'unité de mesure, appelé mètre.

Enfin, quand dans une expérience nous trouvons qu'un corps est à la température de 70 degrés, nous constatons que la température de ce corps est à une distance de 70 fois plus grande du zéro de l'échelle que celle d'un autre corps qui serait seulement à 1 degré, la distance 0 à 1 constituant l'unité thermométrique.

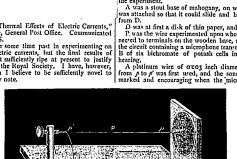
Les nombres 1,000 francs, 152 mètres et demi, 70 degrés ne sont que des quotients de division.

Comparaison : mesure et division ne sont donc que trois acceptions différentes d'une seule idée qui est la recherche d'un rapport entre deux phénomènes de même nature.

May 23.—"On some Thermal Effects of Electric Currents," by William Henry Preece, General Post Office. Communicated by Prof. Stokes, Sec. R.S.

I have been engaged for some time past in experimenting on the thermal effects of electric currents, but the final results of those experiments are not sufficiently ripe at present to justify my bringing them before the Royal Society. I have, however, obtained one result which I believe to be sufficiently novel to justify a short preliminary note.

Nature
June 1878



was spoken into. The articulation, though muffled, was clear, and words could easily be heard.

1. Experiments were first made to determine the length which gave the loudest sound and the clearest articulation, and, after repeated trials with every variation of length from 1 inch to 6 feet, it was found that a wire 6 inches long gave the maximum effect.

2. Experiments were then made to determine the diameter of the wire that gave the best effect, and after repeated trials with every gauge drawn from 0·005 inch to 0·001 inch, it was found that a wire of the diameter 0·001 inch gave the best effect.

3. Experiments were then tried with wires 6 inches in length and 0·001 inch diameter of different materials, viz., gold, iron, aluminium, silver, copper, palladium, and platinum, and they came out in the following order of merit :—

Platinum	...	...	...	Very clear.
Aluminium	...	...	...	Very variable.
Palladium	...	...	...	Clear.
Iron	...	...	...	Clear.
Copper	...	...	...	Faint.
Silver	...	...	...	Faint.
Gold	...	...	...	Very poor.

4. The effect of mechanical strain was tried. It was found not to vary the effect. When once the requisite tension, which varied with each metal, was obtained, further tightening up did not vary the clearness or loudness of articulation.

Gold would scarcely bear the tension required to reproduce sonorous vibrations, hence its low position.

5. Very thin carbon pencil, 0·025 inch diameter, was tried under compression and under tension, but no effect whatever was experienced unless a bad joint was made, when at once a faint intermittent effect was experienced.

6. No sibilant sounds whatever could be reproduced.

7. That the effect was due to heating and cooling was shown by the fact that it was possible to increase the current to such a strength as to render the temperature of the wire sensible to the touch, and then to make its elongation and contraction by regulating the current by hand.

It therefore appears from these experiments that wires conveying those currents of electricity which are required for telephonic purposes expand and contract as they are heated and cooled, and as the variations in the strength of the current are small compared with the strength of the current itself, the expansion and contraction vary in the same ratio as the condensation and rarefaction of the air particles conveying the sonorous vibrations which produced these vibrations.

The mechanical changes, or molecular vibrations in the wire, due directly or indirectly to telephonic currents, which result in the reproduction of sound, bear a close analogy to the mechanical changes due to the direct transmission of sound, but with this important difference, that while the vibrations due to sound are progressive along the wire, and their velocity is low and easily

The most striking facts elicited by these experiments are :

1. The extreme rapidity with which thin wires acquire and lose their increased temperature.

2. The excessive sensibility to linear expansion which fine wires of high resistance evince.

Now as the rate of heating, and therefore of expansion and contraction, varies very nearly directly as the increment or decrement of the current, when these vibrations are very small, it occurred to me that if a thin wire of platinum, platinoid, or gold-silver were attached to a sounding board or to the centre of a disk (such as one of those used for telephone and phonographic) and it formed part of a circuit conveying telephonic currents, sonorous vibrations ought to be reproduced.

The sketch shows the arrangement of the apparatus used for the experiment.

A was a stout base of mahogany, on which a brass support C was attached so that it could slide and be fixed at any distance from D.

D was at first a disk of thin paper, and then of thin iron.

T was the wire experimented upon whose loose ends were connected to terminals on the wooden base, so as to be inserted in the circuit containing a microphone transmitter M and a battery B of six Leclanché of potash cells in another room out of hearing.

A platinum wire of 0·0025 inch diameter and 6 inches long from *p to p* was first used, and the sonorous effects were best marked and encouraging when the microphone transmitter M

Nature, Mar. 25 1880

equal proportions from either sex. I exhibited copies of fifty-four of them (made by a camera lucida) at the Anthropological Institute on Tuesday, March 9, when I read a paper on the subject. The meeting was attended by several of my correspondents, who are well known in the scientific world, and who explained to the meeting their respective forms. They were Mr. George Hilder, B.C., the Rev. G. Henslow, Mr. Hogrt, Mr. Schuster, F.R.S., Mr. H. Woodd Smith, and Col. Yule, C.B. Two of these, namely, Mr. Henslow and Mr. Schuster, see the forms objectively; they can point to the direction in which at any moment any particular figure appears to them to lie, and when they move their eyes the form moves too. In the other four cases the close co-ordination between brain and eye does not exist, and their images appear in a sort of dreamland having no strict relation with external space. The form of each observer is quite unvariegable to the rest, having no meaning except to himself.

The language employed by persons in respect to some of the features of these forms is apt to be very similar. Phrases are frequently met with, such as "Ever since childhood I have always seen . . ." "I cannot account for their origin in any way;" "It is perfectly independent of the will." I have verbally questioned a great many acquaintances whether they see numerals in any particular way. They usually say No; they ask what I mean, then they sometimes say No; they ask what I mean, then profess inability to understand my object, and evidently think it some nonsensical fancy. But I get my reward in the proportion of cases I have mentioned. I have already become familiar with the quick look of intelligence on these occasions, and with the reply in words denoting that the right chord had been struck. Then the details are poured forth. I am frequently told how the habit used to be mentioned to relatives, but was ridiculed, and had ceased to be spoken about; or again, how some particular brother or sister had the same habit, but that one only, and so forth. The more I follow up the inquiries, the more the accuracy of the first replies becomes evident; thus, I ask for fresh sketches, and they correspond to the first. The general result is, that these statements bear all the marks one could expect of being the reports of what is clearly seen and what the writer is anxious to describe exactly. Among my foreign correspondents whose names are well known to the scientific world, and whom I am permitted to quote, are M. Antoine d'Abbadie, the traveller, and Member of the Institute, and Baron von Osten Sacken, the Russian entomologist.

Now for the results. These forms (as distinguished from the figures now seen upon them) are survivals of a very early mental stage, and must have originated before the child learns his letters. There is no nursery book or which written and printed things do not. They are more archaic than the alphabetical and historical forms used by the same persons, for these bear little or nothing to do their origin. The clock face has little or nothing to do with them, for its influence can only be traced in three cases. I believe the forms to have been mnemonic diagrams, invented by the children when they were learning to count *verbally*, the *names* of the successive numerals being associated with the successive points of the form. Also, that when the children began to read, the visual symbols of the numerals quickly supplanted the verbal ones, and established themselves permanently in their places. On this supposition we possess in these numerical forms a representation of the route along which the attention naturally travels in the mental field of view of the child. It is entirely the child's own way of working, and therefore true to his nature; and being natural, it persists through life and offers itself in the adult for our examination.

The characteristic run of the lines in each form has some general similarity to that of the correspondent's hand-writing, but it must testify more directly to his mental peculiarities than the latter. The form shows the mental pathways the mind most likes to travel by, but the handways that the compromise between what the writer desires writing is a compromise between what the writer desires to produce under the joint guidance of a mutual fancy, of his education and of fashion, with what the muscles of the hand can most easily effect. These forms or natural lines of thought are, I presume, analogous to those that instinctively prompt each species of animal to make his lair, instinctively prompt each species of animal to make his lair, instinctively prompt each species of animal to make his lair, burrow, nest, or other piece of domestic architecture, on no burrow, nest, or other piece of domestic architecture, on no burrow, nest, or other piece of domestic architecture, on no

Le Courrier
THEORY OF THE TELEPHONE.

EXPERIMENTS that I have recently made with a Bell telephone have convinced me that the sounds produced are the result of molecular change in the iron disks, and are the same in kind as those heard in the telephone of Reiss.

My experiments were made with a carbon transmitter and Bell receiver, using a small battery to generate the current. First I removed the bar magnet from the receiver, in accordance with a suggestion made by a writer in *Nature* some months ago. The effect without the magnet was the same as with it. It then occurred to me that the intensity of the sound might be increased by using two disks instead of one. Accordingly I cut two circles out of a piece of sheet iron, leaving a narrow strip of the metal to connect them, of sufficient length to enable the disks to lie on either side of the rod, so as to form, in fact, an armature to the electromagnet. On experimenting with this my anticipations were fully realized, the sound produced being more than double that of a single disk.

Now, while trying these experiments I held the disks loosely in my hand, without their being in any way fastened to the wood holding the rod, the effect being the same as if firmly secured. In the absence of a common dinner knife or a spoon of iron would you not expect if brought near enough to the core of the electro-magnet.

I have since constructed a very efficient telephone receiver out of a block of wood two inches square and three quarters of an inch thick. I then drilled a hole sufficiently large to receive the rod, and covered the face with thin sheet iron, it needs no further description, and forms the most effective telephone receiver that I have seen. But, still further to prove that the sounds produced are due to the magnetisation of the iron of the disk, and not to mechanical vibrations resulting from the electro-magnets, I made a set of the discs of which were two inches in diameter. Now, connecting the rod and plate as in circuit, the flanges of the reel gave out sound as clearly as in the Bell telephone. It was by this experiment rendered impossible to doubt that the sounds proceed from the magnetisation and demagnetisation of the iron, and are therefore precisely the same in character as those formed by a Reiss receiver.

St. John's Rectory, British Columbia. PLINIUS. 4/8/80.

Dating Association of the Telephone.—The [illegible] Bell Telephone Company, in Jersey City, [illegible] accurately the [illegible] which [illegible] effected by the [illegible] telephone in a [illegible] bridge, and [illegible] battery, and a [illegible] of the resistance [illegible] the liquid resistance [illegible] the electro-dynamic constants of the branches [illegible] very small; it further, a German silver [illegible] wire be used as measuring wire, it is found [illegible] in the position when the galvanometer shows no deflection, the tone in the telephone has a well-marked minimum of intensity. Supposing the liquid resistance has 2,000 units, a variation of even four units reveals itself in a displacement of the minimum position. A conversation was made, a few days since, by telephone between Plymouth church (Beecher's), Brooklyn, and the towns of Orange, Newark and Elizabeth in New Jersey, also several points in New York City, and all of which Beecher's church and the music were both heard. The transmitter was placed in front and below the pulpit. The farthest point was 17 miles distant.

La Lumière Pour Tous
L'emploi du téléphone dans les mines

La Chronique industrielle signale un nouvel emploi extrêmement curieux du téléphone dans les mines.

Une lampe de sûreté ordinaire a été modifiée de manière qu'on puisse lui adapter le système de l'harmonica chimique. Le tuyau chantant dans lequel brûle la flamme de la lampe se trouve relaiu d'un téléphone communiquant avec un autre téléphone au jour, placé dans le cabinet de l'ingénieur et à portée de sa main.

Si l'on place alors la lampe dans une veine à grisou, le gaz en brûlant modifie, comme on sait, la flamme suivant la proportion dans laquelle il se trouve mélangé à l'air de la mine. Il en résulte dans le tube des sons différents et qui sont transmis intégralement au jour avec toutes leurs variations par l'intermédiaire des deux téléphones.

L'ingénieur peut donc ainsi commodément se rendre compte à chaque instant de la quantité de grisou qui règne dans l'atmosphère de la mine à une profondeur quelconque, et sans avoir à se déranger de son cabinet.

M. Ader, [illegible] telephone receiver without diaphragm, composed simply of an iron wire called [illegible] and surrounded by a solenoid helix. [illegible] considered the sounds to be due to longitudinal vibrations, the core being lengthened and shortened by the magnetising current acted on did not act. With suitable apparatus he has now proved the important principle that all kind of magnetic nature submitted to [illegible] action of compression, tension, or traction, tend to recover their original molecular arrangement under influence of a current, magnetised body. (In these experiments the circuit was only closed momentarily.)

A New Telephone.

A feature in the new Ekenas telephone is its distance from the instrument at which conversation may be transmitted, without raised or to a perfect whisper. An exhibition was recently given in Montreal at which the Daily Witness says: "parties present stood at twenty paces from the mouth piece, and subsequently went into an adjoining room at least forty feet away, and the conversation was thence carried on, in both cases as clear and perfect as if within the usual six inches necessary in the Bell telephone, and without the slightest raising of the mouth piece, as in the case of the Edison. And this was done with the lock turned on the instrument equally as well as when facing it. Whispering messages were transmitted, the words coming sharp and clear from the instrument with perfect ease and distinctness. A Mr. Blake, of Montreal, has the sole appointment for the Dominion for the Ekenas telephone users, a very important central office system, by which subscribers could be put in instant communication or notified with the least possible delay by the central office. The improvement is to be made to introduce as soon as he has organized a sufficient exchange. It should be stated that the batteries and general appliances and the mode of operating are almost the same as in the Bell telephone, but, if anything, less complicated."—*Exchange.*

The Hoover Telephone.

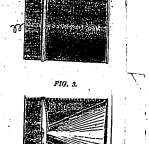
We give herewith [illegible] illustration of what may be called a mechanical telephone. It is not operated by either electricity or magnetism; but consists of a simple arrangement of metallic diaphragms, placed in intensifying drums and connected by a copper wire. The instrument is known as the "Hoover Telephone." It is being largely introduced and gives very good satisfaction over short distances. Hitherto it has not been used over a space exceeding one mile, but the proprietors have no hesitation in putting it up and guaranteeing satisfaction over any ordinary line. This telephone transmits the voice as faithfully and as distinctly as the Edison or Bell telephone, and costs much less, being furnished, with appliances for a call, at the [illegible] low price of $16 each, with an addition of five cents per rod for whatever wire is needed to make the connection between the two points. The costs of wire is also added for such fixtures, springs and battery as will be required in putting up and sustaining the wires. Insulators, five cents each. A complete telephone, without a call, is furnished for $6, the cost of wire, insulators, etc., to be added as in the first instance. Figure 1 represents a sectional view of a telephone complete, or rather of one transmitter of the same. As previously observed, is funnel-shaped, and will be used for speaking into the voice at the center of the diaphragm, from whence the vibrations are transmitted by the wire, as shown, to a similar instrument at the other extremity. In the lower portion of the instrument, as shown, there is a mechanical call, which, by the use of the spring, may be used at pleasure to cause a small hammer to beat rapidly upon the inner side of the diaphragm, the sounds from which are conveyed by the wire to the telephone at the other extremity, where they are repeated so loudly and so distinctly as to arrest attention almost as readily as the ordinary [illegible] bell. Figs. 2 and 3 represent a perspective and sectional view of the instrument without the "call." The only method of calling with these instruments is by a rapid tapping of the pencil on the diaphragm. Such a call answers very well for short distances, and where the call is not expected to arrest the attention at any great distance from the instrument.

For connecting an office or store with a factory, a physician's office or store with a residence, a private residence, an upper with a lower floor, and for many other useful instruments as well, even every practical purpose, it is cheap and can be sent by express, C. O. D., to any part of the country, with all necessary directions for putting it up and operating. We have one of these instruments to connect our editorial rooms in the front with the composition rooms in the rear of a long building, running from street to street. Quite a number are also in use in various parts of the city and in Oakland. Sold by the Hoover Telephone Co., room 54, at 526 Montgomery St. Send for circulars, which will give all particulars.

FIG. 1.

FIG. 2.

FIG. 3.



THE HOOVER TELEPHONE.

On the 26 inst. an outbreak was announced in the City Council of Chicago, looking to placing all telegraph and telephone wires in the ground. It was referred to committee.

CINCINNATI, July 31.—A company, the capital stock of which is chiefly owned by the Bell Telephone Company, has been formed in Cincinnati with the purpose of testing experiments for submitting the Edison telephone with Europe. A Bell telephone to French capitalists will be secured. The arrangements, it is thought, will be completed in a few days. The process upon which the proposed system is to be done is based upon the Orangfengh invention a year ago by the French Khoun physicist. Ample capital has already been raised for completing the plan. Several Eastern capitalists are reported to be interested in the enterprise. The trials will be made from New York City. Only the combination of the Bell, the Edison, and the Gray patents, the exclusive use of the Bell, the Edison, or any of the instruments now in active use, as the case may require, so that they are actually infringing upon many claims of invention, and the question will probably be fought out in the United States courts. It is believed that the Bell Telephone Company has already [illegible] by the [illegible] of the experiment is $200,000.

The Electrician, June 11th 1881

THE ORIENTAL TELEPHONE COMPANY (LIMITED).

The first ordinary meeting of the Company was held on Friday, June 3rd, and a full report appeared in our Special Edition of June 6th. The Chairman (John Pender, Esq., M.P.) referred to the great progress already made by the telephone, and spoke very hopefully of its future. The work of the Company would be first developed in Egypt, and he trusted that early in the winter months telephones will be at work in Cairo and Alexandria. A concession has been obtained from the Egyptian Government which was very satisfactory. In India the Company has a free field for development. The Oriental Telephone Company and the Telephone Construction Company, Limited, are working. The Hon. C. S. Hubbard also referred to the work in Egypt, and hoped interest shown in telephonic matters. Hesolute was also passed, as containing 100 subscribers to the telephone system. A vote of thanks to the Chairman was proposed, seconded, and carried unanimously.

ON SOME THERMAL EFFECTS OF ELECTRIC CURRENTS.*

By WILLIAM HENRY PREECE, Assoc. Inst. C.E.

I HAVE been engaged for some time past in experimenting on the thermal effects of electric currents, but the final results of these experiments are not sufficiently ripe at present to justify my bringing them before the Royal Society. I have, however, obtained one result which I believe to be sufficiently novel to justify a short preliminary note.

The most striking facts elicited by these experiments are :—

1. The extreme rapidity with which thin wires acquire and lose their increased temperature.

2. The excessive sensibility to linear expansion which fine wires of high resistance evince.

Now as the rate of heating, and therefore of expansion and contraction, varies very nearly directly as the increment or decrement of the currents, when these variations are very small, it occurred to me that if a long wire of small diameter and high resistance were attached to a sounding board, or to the centre of a disc (such as one of those used for telephones and phonographs) and it formed part of a circuit conveying telephonic currents, sonorous vibrations ought to be reproduced.

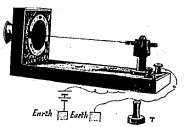
The sketch shows the arrangement of the apparatus used for the experiment.

It consists of a stout base of mahogany, on which a brass support was attached so that it could slide and be fixed at any distance from the upright at the further end of the base board.

A disc of thin paper, and then of thin iron, was mounted on the upright.

The wire experimented upon had its ends connected to terminals on the wooden base, so that it could be inserted in a circuit consisting of a microphone transmitter, T, and a battery of six bichromate of potash cells in another room out of hearing.

A platinum wire of 0·003 inch diameter and six inches long from end to end was first used, and the sonorous effects were most marked and encouraging, when the microphone transmitter, T, was spoken into. The articulation, though muffled, was clear, and words could easily be heard.



1. Experiments were first made to determine the length which gave the loudest sound and the clearest articulation, and, after repeated trials with every variation of length from one inch to six feet, it was found that a wire six inches long gave the maximum effect.

2. Experiments were then made to determine the diameter of the wire that gave the best effect, and after repeated trials with every gauge drawn from 0·005 inch to 0·001 inch, it was found that wire of the diameter 0·001 inch gave the best effect.

3. Experiments were then tried with wires six inches in length and 0·001 inch diameter of different materials, viz., gold, iron, aluminium, silver, copper, palladium, and platinum, and they came out in the following order of merit :—

Platinum	...	...	Very clear.
Aluminium	...	...	Very variable.
Palladium	...	...	Clear.
Iron	...	...	Clear.
Copper	...	...	Faint.
Silver	...	...	Faint.
Gold	...	...	Very poor.

4. The effect of mechanical strain was tried. It was found not to vary the effect. When once the requisite tension, which varied with each metal, was obtained, further tightening up did not vary the clearness or loudness of articulation.

Gold would scarcely bear the tension required to reproduce sonorous vibrations, hence its low position.

5. Very thin carbon pencil, 0·025 inch diameter, was tried under compression and under tension, but no effect whatever was experienced unless a bad joint was made, when at once a faint microphonic effect was apparent.

6. No sibilant sounds whatever could be reproduced.

7. That the effect was due to heating and cooling was shown by the fact that it was possible to increase the current to such a strength as to render the temperature of the wire sensible to the touch, and then to make its elongation and contraction by low sounds evident to the eye.

It therefore appears from these experiments, that wires conveying those currents of electricity which are required for telephonic purposes expand and contract as they are heated and cooled, and as the variations in the strength of the current are small compared with the strength of the current itself the expansion and contraction vary in the same ratio as the condensation and rarefaction of the air particles conveying the sonorous vibrations which produced those vibrations.

The mechanical changes, or molecular vibrations in the wire, due directly or indirectly to telephonic currents, which result in the reproduction of sound, bear a close analogy to the mechanical changes due to the direct transmission of sound, but with this important difference, that while the vibrations due to sound are progressive along the wire, and their velocity is low and easily measured, those due to thermal effects are practically instantaneous, and therefore affect simultaneously the whole length of the wire.

VOL. 1, NO. 1. CINCINNATI, OHIO, U S. A., AUGUST, 1880. MONTHLY. $4.00 PER YEAR.

The Blake Transmitter.

The Microphone is the most abused instrument in the business. Half the inspectors don't get the swing of the thing, and don't seem to care to. If the gas meter is taken away and breaks the ground, a new microphone is suggested. If a switch lever strikes wood and leaves line open, something is "off" with the microphone. If a line wire contracts with the positive,—"just put in a new microphone." Two battery wires are short cut by one staple, and the microphone needs adjustment.

The fact is that not one microphone out of a hundred is wrong. Not one out of hundred which seems wrong need be run in for repairs. We propose here to explain the dark points of the microphone and explain the method of showing its fault if the fault is really in it, and also the method of locating the faulty spot, if it is in the microphone, and that with the tools, &c., always carried by an inspector.

The cut on this page shows the essential bowels of a microphone, arranged for easy explanation.

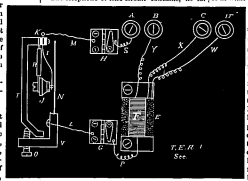
DESCRIPTION OF MICROPHONE.

Battery wire comes to binding post B. The circuit goes to primary coil F, composed of a few layers of coarse wire, thence by curl P to hinge G, thence by wire L to back frame V, thence through screw O, and adjusting bar T to spring R, on the end of which is a weighted carbon button J, thence through carbon button and platinum bead to spring I, which is insulated at K, thence by wire M to hinge H, thence by curl S to binding post A, thence to battery, thus forming a short local circuit, including a battery, a primary coil and a delicate carbon and platinum contact. The insulated diaphragm N bears against the platinum bead, and any movement of the diaphragm, by the voice or otherwise, alters the degree of pressure between the platinum bead and carbon button. Any alteration of pressure alters the conducting power at this point, and thus varies the intensity of the current which the battery is sending through the primary coil F. Under the jarring effect of the voice the contact at J is constantly altering, and thus giving a series of impulses to the current passing through the primary coil.

Notice that this battery circuit is entirely local, and does not go to line or to anything which has not been mentioned.

The line wire with telephone and other apparatus in circuit goes to binding post D, thence by curl to secondary coil E, composed of many layers of fine wire wound outside of the primary coil F, thence by curl to binding post C, thence to ground or continued line.

The telephone or line circuit contains, so far as the microphone is concerned, only the secondary coil. When a current passes through the primary coil wire it induces a strong current in the secondary coil wire, and thus sends the microphone impulse to the line. This induced current is the same as is produced on a telephone line by a telegraph line running near it and parallel with it.



In the microphone the wires are simply coiled on one spool for the sake of compactness. Such a rig is called an induction coil.

NEW MICROPHONES.

New microphones may be put up without any test or adjustment whatever. Seldom one needs anything but proper connection. They should be fixed perfectly plumb and against a solid wall or partition. As we are saying nothing about call boxes now, we will presume that the microphone is in good shape and properly connected up, and that trouble happens, and that the microphone is suspected.

FIRST EXAMPLE.

Bells ring all right, answers come all right, but the whole microphone and telephone business seems dead.

Questions. Is the fault in the microphone? If so at what point and how can it be fixed.

Procedure:—Disconnect the outer wire from the posts C and D, and splice the wires together. Now call up and use the telephone, for talking and listening. If it won't work the fault is *not* in the microphone and it must be tested for in the call box. If the telephone does work all right the fault *is* in the microphone. To locate the faulty spot, set up the battery near the instrument so as to be handy. Run a short wire from battery to binding post C. Disconnect the telephone from the call box and connect one telephone cord to the battery. Listen at the telephone and touch the other telephone cord tip to the binding post D. The telephone should remain silent when you make and break. If you hear noises in the telephone you have made a mistake in the former test which put the fault on the microphone, in such cases connect up in shape and try again, for the microphone is not at fault. There should, if the fault is in the microphone, be no noise as you make and break when testing for the spot. Now, with a knife skin back the silk where the curl wire W goes under the binding post D, and touch on naked wire. If you get a noise you have the fault located. The curl wire W does not make good connection with the binding post D. Investigate, repair and try touching on the binding post D. You should get noise.

WORLD-WIDE EXTENSION.

An Improvement Destined to Revolutionize the Present System of Working Submarine Cables—Dear prices of the Marvelous Machine.

[Special Dispatch to the Chicago Tribune.]

Boston, Sept. 21.—The Daily American to-morrow will publish a description of an improvement destined to revolutionize the present system of working submarine cables. Arrangements have been perfected for the purpose of introducing and carrying out these improvements, was formed in New York about three ago. The chief general have of that State, and all composed of capitalists prominent in that city, with several Bostonians. It has been quietly and secretly at work for more than a year, and its existence is rumored to-day only because the submarine cable, connecting New York City directly with Brest, in France, commences. It is an American enterprise, and the invention, under lieutenant of the American work, which have received the recommendation of Prof. Torrelliby, of Harvard; Prof. Silliman, of Yale; Prof. Bolbest, of Yale, and other scientific men of note. The invention has been patented with great secrecy, and from time to time it has been examined by several scientists; and during the meetings of the American Association in this city, by several of the most prominent members. The instruments, all constructed in this city, have been set up in large rooms in the Equitable Building, and a connection with a submarine cable has been established, and tested by the invention and electricians of recognized reputation. The various apparatus form a new and complete system for working submarine cables and land line, and they are: A submarine repeater relay to be used in connection with the submarine repeaters, and by means of which the weak current, after it has passed, and the submarine system will be strengthened and renewed, so that it may be increased many fold over the present feeble impulses of mechanical construction which are capable at their full capacity of polishing fifty-eight Roman letters per second, or 3,480 per minute, or, allowing six letters for the average word, 580 words per minute. The speed at which the printed record is determined by the clip at the operator only; and instruments for working the submarine system on cables of the several inventions. Most important is the submarine repeater, to be submerged in the ocean. This consists of a bronze globular zone six inches in diameter, molded at a material which is supposed to be able to resist the rust of the sea-water for many years. In the case or globe, hermetically sealed, is the complete mechanism which performs the functions of an ordinary two operators at the bottom of the sea in mid-ocean without the aid of human intelligence at that point. In the use of the submarine repeater, a cable of any length, say 2,000 miles, may be divided in the center into any number of lengths of 1,000 miles each, and a repeater of the kind described be used between each of the lengths. Therefore, four three greater than on a circuit or cable of 2,000 miles. Consequently, one cable connected by the submarine repeater would be equal to four cables worked in the usual present Atlantic cables. Another important feature of the submarine repeater is to make it practicable to operate a cable twice the length of the present Atlantic cable—3,000 miles in length, which is supposed as present cables are worked. Thus a cable might be worked between San Francisco and China, where the distance is nearly 6,000 miles, and would be put practicably or paying speed by the present. The system of working the submarine cables and receiving are to be used in connection with the submarine repeater. The parts are an entirely new principle. The syntax of working the submarine instrument is most simple, more so than the Wheatstone, of the so called "Fast Rapid." The number of keys is but two, and over a cable by these new instruments is limited only by the number of impulses which can be sent through and in the case of this new company's cable it will be over 4,000 [illegible]

TELEPHONE EXTRAORDINARY

Conversation Across the Atlantic.

The Loose of an Ocean Cable.

Cincinnati Enterprise Again Ahead.

In this busy world of ours devoted, as in outward appearances it may be, to the most practical details of every day life, there is a poetry as genuine as any ever sung or written in the so-called heroic eras. In fact, it is often the lack of antiquity alone that sheds the light in which modern poets weave their fancies. There are numbers who will dwell with delight upon descriptions of the Palace of Xerxes at Shushan, or the hanging gardens at Babylon, but who would ridicule the idea that any modern work of man's hands could present a theme for poetry or supply food for the exercise of the imagination. Nevertheless it is undoubtedly true that it is in the union of the most practical knowledge that true fancy finds the richest germ. Modern science is full of a poetry of the thoughtful and loving care of the legends of the past, and the ancient poets as all the traditions upon which even Homer founded the Iliad, as delightful as the best medieval stories of fairy land, as charming as the Oriental tales of Fatima and Scheherazade, splendid as they are in all the luxuriance of the Oriental imagination of Haroun Alraschid and the Nights of Arabian literature.

The latest truth is that in all their fertility, in all their marvelous inventions into the realm of that which, in them, was the transcendental, intangible and invisible domain of the unknown, the ancients had but a faint hint of "all the wonders that were to be." Their greatest minds, in the solemn air of their misty fairyland, had but a dim conception of the wonders to-day, and the ever nature is to-unlevel them to the light of day. Even the "winged words" of the mighty bards of Greece were but vague and indefinite shadows of the truth which is now being unfolded before us in the possibilities of the telephone. Dupe said, speaking of Homer, that England, by means of

> Many things there are that mighty be,
> But none are mightier than men,
> For he can cross the stormy sea,
> And speak the truth in Ilyria.

Shakspere, in *Hamlet*, followed, in a measure, perhaps, the same train of thought, when he said:

> There are more things in heaven and earth,
> Than are dreamed of in our philosophy.

As the transmission of articulate sound by the telephone is among the latest and the most extraordinary marvels of the age, so it is one of the most wonderful facts in the history of the development of science that lines which have already by fifteen years been in practical use for the transmission of messages spasmodically by telephone, even its most rudimentary form, Page said, something perhaps precisely:

> Repeat the swift intercourse from soul to soul,
> And as a flash from heart to heart be told."

This is very nearly true of the telegraph; in its latest, most perfected form, the telephone. Even in its infancy, Mr. Bell, therefore, is favored in some of words-wire interest a clergyman, who, in a sermon, said that the latest development of the telephone is that consisting in itself interest for the scientific and the practical, yet possibly millionaire and the statesman, to make sure how wise known how to gild with the golden light of poetry the mysteries of the most severely practical application.

It so happened, then, that in the different mechanical, gifted with a particular bringing his peculiarity in peculiar circumstances, was the Cincinnati Enterprise, which, on Thursday, Tuesday, Tuesday, Tuesday, Tuesday, Tuesday, of what was then known of electricity, and was the most wonderful of all machines. Before the banana absorbed in his work, nothing, animated, but so much by the desire to win a wife, as by the love of science, he had invented an improvement on one of the telephones then in use, the guiding star of all his investigations. He perceived the idea of the propagation of sound in the spiraling coils of the telephone, and he set to work to [illegible] for this he knew was then [illegible] for the wife and family that made his [illegible] happy. The invention was [illegible] Bell's telephone, and [illegible] for [illegible] in the middle of all nations. [illegible] ever, no sooner taken possession of his mind than his whole nature seemed to undergo a change. He was no longer the [illegible] he was before. During the process of [illegible] competition [illegible] inventing, which [illegible] his wife left him, [illegible] of the most [illegible] of [illegible] July friends, they should be called—removed [illegible] [illegible] [illegible] [illegible] seem to tell him that at last the [illegible] Hutchison had fulfilled his promise, [illegible] was the largest room in the city. [illegible] lessons and students were already [illegible] [illegible] [illegible] [illegible] [illegible] by the old or "vibrating-needle." Both was, indeed, the first, and the Stenograph [illegible] [illegible] [illegible] [illegible] [illegible]

There is an immense spring near on the West Dolores, about six miles from Rico, just across from the head of Horse gulch and near the base of Cullen peak, that has an ebb and flow that is quite singular. The basin is about 25 feet in diameter and in the morning is always full of water, but in the evening it is perfectly dry and empty. The water is cold and apparently of good quality, and the basin gradually fills to overflowing when it as slowly recedes, effervescing violently all the time. The discovery was made by a prospector who passed it in the morning when full (the basin was full, we mean) and returning at night it was empty. He watched it with the result mentioned above. It is exciting considerable curiosity in that region.

SWANSEA.—The British Association formally opened the telephone line between the Guildhall, Swansea, and the waterworks (8½ miles). Whilst they were in Swansea, the president congratulated the contractor on its success, and spoke very highly of the instruments used (Gower-Bell). It is expected that a Gower-Bell Telephone Exchange will be shortly established at Swansea.

THEILER'S PATENT TELEPHONE TRANSMITTER.

FIG. 1 represents the outside appearance of the instrument, the dimensions of which are only 5 in. by 6 in. by 1¾ in., so that the whole apparatus, containing induction coil, microphone, automatic switch and bell push, is of very small bulk. The transmitter may either be screwed or hung against a wall like a picture, and as its appearance is by no means clumsy or awkward the instrument may be fitted up in a drawing-room without disfiguring its surroundings.

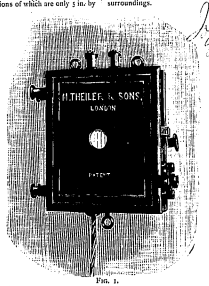


FIG. 1.

There being no adjustment of any kind, variation of temperature, &c., cannot disturb the position of its component parts.

The funnel which is required for speaking into with other transmitters is entirely dispensed with in the new transmitter. The use of such a funnel, particularly in those transmitters which require rather loud and close speaking, is not free from objection.

FIGS. 2 and 3 represent the inside of the transmitter, and show the peculiar form of microphone which, after innumerable experiments with every other possible form, was found to be the best.

It is a diaphragm of Swiss pine wood or of cork. The former substance makes a highly sensitive diaphragm, while the latter is more remarkable for the great distinctness of articulation produced.

To this diaphragm two cylindrical pieces of any conducting substance, B B (fig. 3), are cemented in a parallel line, and a connection is made from these cylinders to the battery and primary circuit of an induction coil, I I, in the usual way. The circuit is closed by the rod, A (which is also cylindrical), suspended on a silk thread from the diaphragm at an angle of about 25 degrees. The nearer this suspension approaches to the perpendicular the more sensitive the transmitter becomes, but as extreme sensitiveness also includes the transmission of any, even the feeblest, noise, and imparts to the articulation a peculiar metallic twang, it was avoided by suspending the rod, C, at an angle of 25 degrees.

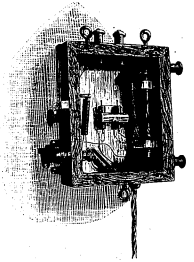

FIG. 2.

It will be seen that the incidence of the suspended contact piece with the fixed ones forms mathematically four sharp points, which are, however, free from the great liability to breakage or wasting away which *actual* sharp points would possess.

This feature was found to be essential to the production of a clear articulation. As there is no friction of surfaces in this arrangement, that grating rasping articulation so peculiar to common microphones is totally absent in this transmitter.

The contacts, as well as the points of suspension, being all on the diaphragm itself, it does not at all matter whether the tension of the latter be altered by change of temperature, &c., or not. If the fixed contacts should, from any such cause, change their position, the suspended contact would follow them, and their relative position would practically not be altered.

If the diaphragm is vibrated very violently (by shouting against it), the suspended piece, C, would separate from B B altogether, and produce a harsh sound in the receiver. This can be entirely prevented by the stop, S (fig. 3), which is adjustable in the bridge, B, and does not allow the piece, C, to separate from B B entirely. It is not as immaterial as is generally believed, or has been asserted, what kind of battery is used with a microphone transmitter. On the contrary, the results obtained will

Amer. Gas Eng. Telephone in Coal Mines.

Oct. 11 1879

London *Iron* has the following upon this subject: — "There are different connected with the application of electric lighting to coal mines, which, however, are not insuperable; but there can be none to the use of the telephone as a means of communication between the miners and the upper world, as well as with the authorities underground. The advantages of the telephone would be manifold in the ordinary routine of the pit. In the untimely accident to which, however, it is in use, the engineer above is able to satisfy himself as to the condition of the pumping machinery in the parts of the works the most difficult of access, by merely listening to the sounds given out by the valves, etc., independently of the advantage of sending immediate advice or instructions on an emergency; and it is evident that, in case of an explosion, were the wires properly protected, the communication they would afford with workmen suddenly entombed alive would be of the utmost importance.

On this last account the establishment of means of instantaneous communication with those employed in mines has, we are informed, been already enforced by one of the Australian Legislatures."

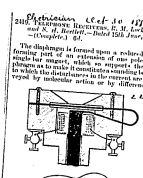
2402. TELEPHONIC RECEIVERS. *E. M. Locke and S. A. Bartlett.*—Dated 15th June, 1878. (Complete.) 6d.

The diaphragm is formed upon a reduced arm forming a part of an extension of one pole of a single bar magnet, which so supports the diaphragm as to render it capable of vibration according to which the disturbances in the current are conveyed by molecular action or by difference in



degree of polarity in different parts of the pole, to which it is connected, rather than by any mechanical vibration of the diaphragm due to its attraction to and repulsion by the coil. The figure shows the diaphragm at the end of the magnet.

2465. NICKEL PLATING. *J. Wetter.*—Dated 19th June, 1878. (Complete.) 4d. *Engineering*, 7 June, p. 1.

This consists, first, of a metallic electro-deposition solution to which benzoic acid has been added; secondly, of a metallic electro-depositing solution to which citric or other salicylic acid has been added; thirdly, of a metallic electro-depositing solution to which sulphic or pyrosulphic acid has been added; fourthly, of a combination of the above solutions; fifthly, the combination with the solutions, either or elements of nickel or nickel salts, of an electro-depositing metal; sixthly, of the single or double salts of nickel to which benzoic acid has been added; seventhly, an electro-depositing nickel solution to which potassium or sodium has been added either with or without the bisulphite of soda.

Telegraph Journal

Mr. H. C. Page, of Springfield, Mass, has lately patented a Dental attachment for telephones, by means of which persons having defective hearing can hear. The arrangement consists of a disk of rigid sound-conducting substance, such as wood or hard rubber, connected with the centre of the diaphragm, or with a disc attached to the centre of the diaphragm, and is supported by an elastic fulcrum attached to the mouth-piece of the telephone. The further end of this disk is held by the teeth of the deaf person, and the vibrations can thus be transmitted to the auditory nerves. The under surface of the disk is provided with an elastic coating which prevents the vibrations from affecting the teeth of the lower jaw.

THE phenomenon lately discovered by Hall of the action of a magnet in altering the path of a current of electricity in the conductor which carries it, has formed the starting-point for two investigations, which have appeared separately in the *Wiener Anzeiger*, by Bottomson and Von Ettingshausen respectively, in which they point out that this discovery may be applied to determine the absolute velocity of electricity in a conductor.

TELEPHONING ABROAD.

Electrician Oct 30 1878

The Belgians Take to the American Innovation—Novel Objections to Housetop Wire-Running—A Queer People's Queer Ideas—The "Rail-roader" Among the Flemings.

ANTWERP, BELGIUM, Aug. 19.

Telephoning is attended with a good many drawbacks, it seems. Everything has gone along smoothly with the International Company (Hubbard's) until lately, when the other concern (Bell's) commenced intriguing so much that parties who allowed the putting up of frames on their houses protested, and, in a good many instances, what had been erected was taken down, and the wires had to find other directions. The concession for the International Company has not been obtained yet, and, considering the influences and leagues brought to bear, it may take some time yet to get it. All the subscribers, and many others, signed a petition to the government to obtain it; but, on the other hand, Bell and his people got parties to protest, and among the protestations is that of the pigeon-flyers, who pretend that the net work of wires keeps the pigeons from flying; that a good many have been killed on account of it, and that it destroys the appearance of the city's architecture, &c. Others protest because the wires pass over their houses, (though not touching) such alleging that the volume of air above his property belongs to him, and is interfered with on account of the wires passing through it.

The Burgomaster is favorable to the intentions; but in the Council are gentlemen who are adverse, and the "telephone question" looks as if it might be the matter of two new political parties—the telephones and anti-telephonists. Where it will end, I don't know. Wherever established, the instruments give the very highest satisfaction, and I have heard people say that they would not be without the telephone for 5,000 francs. The people heretofore have a good deal to learn yet, and they can't accept progress without discussion.

Secrets to the Railroaders. It is a very interesting paper. Possibly I may be able to do something for you in the way of subscriptions. Many of the railroad employes speak and read English. Q.

[A few words in explanation of the above: Two companies are undertaking to do a telephone business in Antwerp, the commercial City on the European continent. These are the International Co., of New York, introducing the Bell and Blake instruments, and the Bede Co., who have exact copies of the Bell and Blake apparatus. To transact a business of this kind legally, a "concession" must be obtained from the government. This, the international people, after six months' endeavor, have yet been unable to procure. Nefarious competition of no ordinary sort account. So the contest is one of long-continued haggling between the International Co. and the Belgian government. Besides, the Bede people are comparatively poor, are inexperienced, and do their work clumsily, but have, over from the government, and patronage from the people on the ground that theirs is a Belgian company. So it is—highly Belgian—for it is based on piracy. But the Belgians naturally regard foreign innovations with a jealous eye and Bede is gaining popular sympathy. The fight is going on throughout the Kingdom, and is making considerable excitement. Meanwhile the Americans are spending money like the wind, and will keep up their end as long as the "beer" holds out.

The pigeon-flyers of Antwerp are a numerous body and possessed of some influence. "Antwerp carriers" are famous as the fanciers in the world.

The old, quaint and interesting architecture of Antwerp is indeed disfigured by the wooden "standards" of the telephone companies. Many of them are of enormous size, such as are nowhere erected in the United States, and resemble derricks more than anything else. The whole town has been made to look like a mast yard. It is no wonder that citizens are indignant.

All employes on Belgian railways speak two languages—Flemish and French. Many of them speak German and English also, and trainmen more or less familiar with half a dozen languages are not uncommon. Most of the notices to the public, in the cars and at the stations, are printed in Flemish, German, English and French.—ED. RAILROADER.]

[From the Scientific American.]

Some Experiments with Small Batteries.

M. L. Baxter, M.D. Elect 1 1878

To illustrate the capacity and sensitiveness of the telephone, I tried a small battery made in a common tumbler with a carbon and zinc pair, and a solution of ammonium muriate as an exciter. The common salammoniac will answer all purposes.

This battery I included in a circuit with a Hughes microphone and a telephone; and instead of the monotonous ticking of a watch or clock, I used a musical watch with quite a range of tone. By the use of this watch the capacity of the microphone for transmitting high or low tones with their complimentary overtones may be studied and regulated.

With the battery above described I obtained all the tones clearly and well, and tried with it what effect different depths of immersion would have. One of the claims in Professor Bell's first patent on undulatory currents covers varying immersion as a means of varying the current, but I found very little difference in the operation of the telephone when the carbon plate was withdrawn, so that merely a corner touched the surface of the liquid in the battery. This led to the withdrawal of the zinc plates also, until only its corner touched the liquid. Under these circumstances the diminution in volume of sound was very slight, the tones coming out full and clear. The zinc plate being held clear of the solution a dead silence resulted, and the transition from this to full tone ensued with the slightest possible contact.

These phenomena led me to construct very minute batteries, and the progress step by step was very interesting. One arrangement of a pair shows the battery in, to me, a new light. It is this: Make up a circuit of a microphone, a telephone, and a continuous copper wire, and, of course, there is silence in the telephone. Cut the copper wire, and to one of the ends attach a bit of zinc. Bring the ends together again and silence ensues as before; but allow the bundredth of an inch clear space to intervene and bridge the gap with a drop of battery solution, and the telephone at once finds its voice, not loud, to be sure, but clear and distinct for most of the notes.

Such a "battery" as this may be even concealed in the connecting wire by being covered by the usual cotton or silk insulating covering, two or three thicknesses of tissue paper between the ends preventing metallic contact. A gum cap battery with zinc and sulphuric acid gives a strong current for the microphone circuit.

Discarding the zinc, as being too readily consumed, I have made pairs with carbon and gold, carbon and platinum, platinum and gold, zinc, and in no case have I failed in getting results; but the currents are too weak for practical uses. Two pieces of carbon, even, have diffusive enough in their structure to determine a slight current appreciable by the telephone. The study of these combinations, though not of apparent importance, is interesting, and, where all are groping, may shed a ray of light upon something else.—Washington, D. C., June, 1880.

In connection with the subject of telephonic communication, we may mention that one of the largest brewery companies of Wurtemberg, Germany, ago completed a telephonic line of 30 miles, and this stimulated the idea, and now, everywhere tried the Government telephone service, [illegible] have them applied generally on their system.

1329. **Telegraphic and Telephonic Apparatus;** W. U. Labo, London.—*E. Davis, Cambridge, Mass., U. S.*—Dated March 29, 1877.—*To Sir Henry Bessemer.*

This invention consists in the arrangement of electric current indicators, consisting of an electromagnet with two or more armatures, and mechanism actuated by the movement of the said armatures, and so constructed that the movement of any one armature will not interfere with any of the others, but each armature can be set so as to sound a local alarm on any one of the instruments, or to sound a local alarm on any one of the instruments, and to signal in any one of the instruments, by the movement of the said armatures, and to signal in any one of the instruments, by the movement of the said armatures, and to signal in any one of the instruments, by the movement of the said armatures

NEW TELEPHONE.—A new acoustic telephone has been recently introduced by E. F. Edgecomb, of Mechanics Falls, Maine. When in connection with the compound wire, of three strands, which is also made by Mr. Edgecomb, conversation can be easily carried on. The ticking of a clock 20 ft. from the instrument can be heard at the other end of the wire, the diaphragm of the instrument is so sensitive. We also learn from a Boston journal that Prof. Hosmer, of Cook's College, Medford, Mass., has invented a telephone that promises a great improvement over those in general use, and immunity from many of the chronic disorders of present systems.

London Times Oct 29 1878

EDISON'S TASIMETER.

With the first news which reached us respecting the observations made during the recent eclipse there came an announcement which perplexed even some of the astronomical elect. We were told that Edison—"the modern magician," as his fellow-countrymen call him, the inventor of the phonograph and of other instruments only less wonderful, the man who "to amuse himself," as he said, had shown how a hole might be talked through a deal board—had announced with his tasimeter the heat of the sun's corona. Few European astronomers know precisely what manner of instrument Edison's tasimeter might be; some even had not heard of it. Electricians were better informed. Edison had been somewhat loudly calling their attention to the instrument, under a mistaken impression that his ingenious fellow-countryman, Professor Hughes, had borrowed his ideas and exhibited a similar instrument here. But even electricians were not able to give a satisfactory account of the method by which the tasimeter had indicated the heat of the corona. A brief description of the instrument, or rather of its general features, and an account of what it has done and promises to do hereafter will, we believe, be interesting to our readers.

The property on which the invention depends seems to have been discovered by Edison independently about the year 1873. It was, however, recognised so far back as 1866, if not earlier, by Clerac, electrician of the French Government Telegraph Department. It is this: that the electrical resistance of carbon varies to a marked degree under very slight variations of pressure—in other words, if a current of electricity has a circuit, part of which is formed by a piece of carbon, then very slight pressure applied to that piece of carbon will cause the current to pass more readily, appreciably diminishing what is technically called the resistance of the carbon to the passage of the electric current. This property, as we have said, is not an original, though doubtless it was an independent discovery of Professor Edison's. The practical application of the property to measure very small changes of pressure, and thus to measure changes of temperature, moisture, and other conditions, by causing these changes to produce changes of pressure, must be regarded as wholly Edison's.

The simplest form of the tasimeter (the tension, or pressure, measurer) may be thus described:—A flat button-shaped piece of compressed lamp-black, forming what we shall call, for convenience, the carbon button, is held between two discs of platinum. One of these is the head of a screw fixed into a stout upright and holding against that upright a larger and thicker disc of vulcanite, through whose centre the screw passes. The other platinum disc is retained in its position against the carbon disc by the outlying ring of vulcanite. Thus there are three small flat discs, the middle one of carbon, the two outside ones of platinum, imbedded in a larger disc of vulcanite, which is held against the upright by the screw projecting from one of the platinum discs. It will be understood that a certain thickness of vulcanite intervenes between the last-named disc and the stout upright, except, of course, where the screw pierces the vulcanite. The thickness of this interposed part of the vulcanite is about the same as that of each platinum disc end of the carbon button between them. The entire thickness of the vulcanite is equal to rather less than four times the thickness of these several discs, so that the outermost face of the outer platinum disc lies a little outside the face of the vulcanite disc. This outer platinum disc bears, opposite the screw of the other, a metallic cup. One end of a horizontal strip of whatever material is to be tested or employed to produce varying pressure on the carbon button rests in this cup. The other end of the strip rests in a cup supported by another stout upright, by turning which screwhead this cup may be made to advance or recede horizontally in such sort that the pressure on the carbon button may be suitably adjusted to begin with. If the reader has followed this description, he will see that the strip of matter to be tested or used in the experiment is supported in a horizontal position between two stout uprights projecting from a rigid base, and that, at one end rests in a cup carried by a platinum disc in contact with the carbon button, any expansion of the strip in length must increase the pressure on the carbon button, while any contraction in the strip must diminish this pressure. The carbon button and its platinum neighbours are imbedded in the large vulcanite disc, simply that any such change of pressure may be freely communicated to the carbon button, while yet the strips can be freely interchanged, the vulcanite holding the small discs in situ without interfering with the pressures which the outer ones exert on the central one.

So far the description relates only to mechanical adjustment. The carbon button is so placed that it will undergo greater or less pressure according as the strip of material between the uprights expands or contracts. It is now necessary to make the carbon button part of the circuit along which an electrical current runs, so that the property discovered by Clerac may come into play. To this end, a wire from one pole of a galvanic battery is brought into connexion with one of the platinum discs, while a wire from the other pole is brought into connexion with the other platinum disc. So soon as this is done the current passes from one pole along one wire, through the carbon button, and along the other wire, to the other pole. A galvanometer is made to form part of the current's track, or, in other words, the current on its way passes round and round a coil of wire surrounding a magnetic needle (or rather, one of a pair of opposed needles which exactly neutralize each other so far as terrestrial magnetism is concerned), and the intensity of the current is measured by the deflection which the needle experiences while the current is passing. It will be manifest, then, that since carbon possesses the property of varying in resistance to the electric current as it is more or less compressed, the needle of the galvanometer will respond to any changes in the condition of the carbon button. If the button is compressed its resistance will diminish, and the needle will indicate the passage of a stronger current, or its index end will move further from the zero point. If the pressure on the button is diminished, the needle, by moving towards the zero point, will indicate a weaker current, in consequence of increased resistance by the carbon button.

Those who are familiar with the use of the thermo-electric pile (for convenience called the thermopile) to indicate small changes of temperature will understand how the tasimeter, in the form just described, may be compared with the thermopile. The thermopile itself is formed of bent strips of bismuth and antimony combined together in such a way that when heat falls on one face of the thermopile, an electric current is caused to flow along a wire connecting the first of the antimony strips with the last of the bismuth strips. A galvanometer is made to form part of the circuit, as in the case of the tasimeter, and by testing the indications of the galvanometer the strength of the current is ascertained, and hence the degree of heat to which the face of the thermopile has been exposed. Having, then, a galvanometer of a certain degree of delicacy, we take the two wires of a thermopile—one from the first antimony strip, the other from the last bismuth strip—and bring them into connexion with the coil of the galvanometer; then we expose the face of the thermopile to various sources of heat, noting the indications of the galvanometer. Next, separating the galvanometer from the thermopile, we make it form in turn a part of the circuit of the tasimeter,

as above described ; then we expose the strip of matter between the uprights to the same sources of heat to which we before exposed the face of the thermopile. If the galvanometer indicates similar degrees of deflection, the teatimeter and the thermopile are least measurers of similar delicacy. If, however, greater or lesser degrees of deflection are produced when the teatimeter is used, the teatimeter is much more delicate than the thermopile, and vice versâ if much the greater deflection is produced when the thermopile is used.

Thus tested the teatimeter shows a very marked superiority over the thermopile. The *Scientific American* states that when a thin strip of hard rubber was used, the expansion caused by the heat of the hand held a few inches from the rubber sufficed to produce a deflection of several degrees in the needle of a galvanometer as "ordinary" (that is, as inferior in sensitiveness) that it was not affected in the slightest degree by a thermopile facing and near to a red-hot iron. From another source we learn that with a similar galvanometer a gas jet five feet away caused the needle to move four degrees. A match burning at a distance of six inches caused a deflection of 21 degrees. Breathing slightly on the rubbing caused a deflection of 20 degrees. Those who have attended Professor Tyndall's lectures on "Heat" will remember that he exhibited with the thermopile experiments scarcely known for more surprising. The minute quantity of heat generated when a piece of cold brass was rubbed once along the surface of a cold piece of wood caused strong deflection, even when the brass was brought for an instant only in contact with the face of the thermopile. And, as the lecturer said, would have brought the needle into violent contact with the stops, and destroyed the magnetism, if the brass had been allowed to remain in contact a single second. But the greatness of the deflection was due to the extreme sensitiveness of the galvanometer employed by the lecturer. With the galvanometer used by Edison in the experiments we have described, no effect whatever would have been produced by the slightly-heated brass brought against the face of a thermopile. With the galvanometer used by Tyndall, the heat of the burning match at a distance of ten yards would have sufficed to throw the needle against the stops. In our experiment Edison's little finger produced with the teatimeter an effect six times greater than a red-hot iron with the thermopile, the distances being the same in both cases.

With the teatimeter, even in this form, slight degrees of pressure produced effects much more than by heat can be readily measured. Thus in one series of experiments Edison interposed a film of gelatine between the uprights to measure increase of dampness produced by three inches of water on the tip of the finger, held five inches away, deflected the needle 17 degrees. A lighted cigar at the distance of nearly a foot dried seven degrees in the opposite direction from the preceding one, because the gelatine contracted in this case.

With a very slight modification of form, also, the teatimeter is a very delicate weighing machine. The pressure produced by the weight of a tiny shred of paper produces a sensible deflection of the needle. The weight of the smallest insect can be measured, while a tobacco worm causes the sound made by the insect's feet to be clear. We do not dwell, however, on these applications of the instrument, because it is not here that the originality of Mr. Edison's teatimetric researches resides.

Although the teatimeter in the form above described is far more delicate heat measurer than the thermopile, the power of the instrument can be greatly increased when still more delicate investigations are to be made. For this purpose the part first described remains unchanged, but the ordinary galvanometer used for conventionally rough researches is replaced by one of Sir W. Thomson's reflecting galvanometers. This marvellously delicate measurer of the galvanic current was originally devised, as our readers will remember, to indicate the feeble electric currents transmitted through the Atlantic cable when it was being laid. As in the ordinary galvanometer, a needle-shaped steel coil of wire surrounds a magnetic needle, but the coil consists of a far greater number of turns, and the magnet is not only far more delicately poised, but its movements are indicated in a much more obvious manner. The magnet itself is made of a piece of fine watch-spring about 1-inthe of an inch long, and not weighing more than a grain. It carries a tiny mirror slightly concave. Facing this mirror, and about a yard from it, is set a horizontal graduated scale, beyond which is placed a lamp, the rays of which, shining through a hole below the scale, fall on the mirror, and are by it reflected to the zero or middle point of the scale. This tiny point of light is virtually the extremity of an index 360. long, extending from the mirror. The least movement of the mirror causes the point of light to traverse a considerable arc of the graduated scale. Thus, when a current traverses the coil which would be far too feeble to affect the needle of an ordinary galvanometer, and which even affects the needle of the reflecting galvanometer so slightly that ordinary vision could not detect its motion, the mirror, sharing in this slight motion, sways round the converging light-beam which forms its long index, and the point of light, perhaps, one ray say), and the point of light moves in a manifest manner along the graduated scale.

Such a galvanometer largely increases, of course, the delicacy of the teatimeter. To introduce it effectively another change must be made. The current must be regulated so that the light beam of the reflector may initially fall exactly upon the zero of the scale. For this purpose the contrivance called a Wheatstone's bridge and a Rheostat are introduced into the circuit. The teatimeter, thus reinforced, as to speak, is able to indicate the minutest changes of pressure, and, therefore, of temperature, moisture, or any other conditions affecting so readily the pressure exerted on the carbon button. It is hardly necessary, perhaps, to point out that the very delicacy of the combination, while rendering the movements of the index so obvious, increases the necessity for care in the use of the instrument, and caution in drawing inferences from its indications. When a very feeble source of heat, for instance, has to be detected, the slightest currents of unequal warmth by multiplied trials under different conditions must be carefully excluded. Thus, if the source to be dealing with, and be generated by bring the heat from that source to bear on the strip of vulcanite or other substance the expansion of which causes increase of pressure on the carbon button. Even with the thermopile extreme care is necessary in delicate researches. For instance, an astronomer who was endeavouring to measure the heat received from a star of the first magnitude found at the beginning of his researches that when by shifting of the telescope he brought the light and heat of the star upon the face of the thermopile the galvanometer very obviously indicated heat ; but he soon found that this heat was due in the main to the movements of the telescope, not to the rays of that remote sun. Since Edison expects (potentially, in our opinion) to be able to measure with his teatimeter the heat from a star invisible in the very telescope used to survey the star's heat to the teatimeter-strip, it will be understood that the utmost care must be used to prevent the access of any heat resulting from mechanical movements. Edison is, of course, fully sensible of the difficulties arising from the extreme delicacy of his teatimeter. How he proposed to overcome some of them during the recent eclipse will be seen from the following account of his original plan, which, however, he was unable to carry out in all its details in practice :—A fasimeter of smaller size, and having its framework of brass, was to be enclosed in a receptacle of tin, which, in turn, was to be placed within another receptacle of the same metal. The space between the two was to be filled with boiling water to preserve evenness of temperature, because boiling water attains no higher temperature than the boiling point, and the boiling point at any given station undergoes no appreciable change in any short time. Moreover, a complete pressure is changing with altogether exceptional rapidity.

Edison was defeated during the recent eclipse, so far as the measurement of the corona's heat was concerned, in a different way, though the extreme sensitiveness of his instrument was in reality the cause of his defeat. So soon as he allowed the adjustable image of the corona to fall on the platinum strip (which he used in preference to vulcanite, as more sensitive to heat), the index-point of light which had been set to the zero of the scale sped right off the scale. The image of the corona was immediately shifted from the platinum strip, but it was too late. Before the index returned to the scale totality was over. A result less sensitive would unquestionably in reality have served much better, but, of course, Edison had not any means of estimating beforehand what amount of heat might be expected to reside in the rays of the corona. Professor Young, of Princeton, also failed to obtain satisfactory results from a teatimeter with which he had been provided by Edison. But, not to be foiled, he used a thermopile, and, though he was unable to measure the corona's heat, he obtained evidence agreeing with Edison's in showing that the heat of the corona is not enough to be made manifest without using contrivances of exceptional delicacy.

It is not solely, or chiefly, however, for astronomical purposes that Edison proposes to use the teatimeter. He has already taken steps to use the instrument for the measurement of vessels at sea. The carbon button can be arranged to act as a highly sensitive thermometer, and enclosed in a case connected with the keel of a ship. Wires will run from this case to a galvanometer in the captain's room. Thus any change in the temperature of the water will be at once indicated. The approach of an iceberg would be known long before there was any danger of collision. The teatimeter might also be arranged to act as an exceedingly delicate barometer, to give warning of fire, to indicate slight changes in the humidity and temperature of the air, and in physical researches for which the thermopile has been used with but partial success. In fact, we venture to predict that before many years have passed the teatimeter will be found among the most effective of those instruments by which science has endeavoured to solve the mysteries of molecular physics.

THE TIMES, TUESDAY,

NOVEMBER 5, 1878.

THE TASIMETER.

TO THE EDITOR OF THE TIMES.

SIR,—Mr. Edison having recently been good enough to send me the latest form of his teatimeter, the first, I believe, that has made its way to Europe, it may be of interest to some of your readers to have independent testimony as to the extraordinary delicacy of this novel instrument.

The principle of the teatimeter, as explained in the recent article in *The Times* on the subject, consists in slight changes of pressure upon a button of carbon, producing variations in its electric resistance, revealed through the indications afforded by a delicate galvanometer. The secret of success in this instrument, and in the carbon telephones which depends upon the same principle, consists in obtaining a sufficiently conducting mass of finely divided carbon. By a happy accident Mr. Edison hit upon some lamp-black deposited on the chimney of a smoky petroleum lamp, and this material into a button answered the purpose admirably. Hence it is from this source that all the carbon buttons are at present made.

It has been stated that Mr. Preece was the first to discover the electrical effect of pressure on carbon, but I have not met with any reference in support of this statement. H. Gilme made artificial resistances, or rheostats, of tubes filled with charcoal for telegraphic purposes ; but with this material no change in resistance of any utility in telegraphy can be obtained by variations in pressure. A well-known French electrician—the Count du Moncel, I believe, the first to notice that some slight difference in the resistance of the circuit was produced by pressing surfaces in sterile contact more or less closely together ; but this observation had not attracted much attention until recalled by Edison's invention in 1876 of the carbon "relay," the progenitor of his carbon telephone, carbon tlosetral, and micro-tasimeter. All these instruments depend upon the principle, which Edison, I think, was unquestionably the first to discover, that certain in a state of fine division undergoes a considerable diminution in the electric resistance when slightly pressed. That squeezing the particles of a semi-conducting powder more closely together should augment its conductivity is what might have been anticipated ; but that any appreciable variation in conductivity could be produced by so minute a variation, or by the movement of a screw through a space of, say, a millionth of an inch, entirely transcends all expectation, and yet this is the case. The microphone is a very remarkable instrument, and it is evident that Edison was familiar with the true principle of the microphone when he produced that "noise maker" ; for as yet it is little more, was made known by Professor Hughes in the early part of the present year. In fact, twelve months previously Mr. Edison, it seems, had to all intents and purposes discharges microphones, and rendered them unsuitable for telegraphic purposes. As however, this remarkable man, in his eagerness to press forward, has published no account of the modicum of experiments that have led up to his many and valuable inventions, Professor Hughes is entitled to all the credit of having independently discovered and first published the simple and novel arrangement that constitutes the so-called microphone—a word, by the way, first used by Wheatstone in 1827 to designate a simple acoustic apparatus he had devised for detecting or locating feeble sounds. Those of your readers interested in pursuing this subject I would refer to the fuller description and illustrations that will appear in the forthcoming and succeeding numbers of that excellent periodical *Nature*.

Returning to the tasimeter, in its present form the instrument differs considerably from that described in *The Times* a few days ago, although the essential parts are the same. The object of this modified arrangement is to insure greater sensibility and protection from accidental sources of disturbance. A sketch of the instrument will

---

THE UNSEEN UNIVERSE AND THE TASIMETER.—The extreme delicacy of Edison's teatimeter has been proved during the recent solar eclipse, and we now hear that the latest pressing project of Mr. Edison is to employ it in exploring those blue fields of the night sky, which to the eye are void of stars, in order to discover the unseen orbs which transit them. His plan is to adjust the teatimeter in the focus of a telescope, then attach it to the exploring telescope, when, if in any particular direction of the heavens there is a marked and invariable deflection of the teatimeter, it may safely be inferred that there is an unknown world in line. "Seeing," says the *Scientific American*, "that the teatimeter is affected by a wider range of etheric undulations than the eye can take cognisance of, and is with all far more acutely sensitive, the probabilities are that it will open up hitherto inaccessible regions of space, and possibly extend the range of our real knowledge as far beyond the limit attained by the telescope as that is beyond the narrow reach of unaided vision. Possibly too, it may bring within human ken a vast multitude of newer bodies—latent out suns or feebly reflecting planets—now unknown because not luminous.

6

be given in the next number of the *Telegraphic Journal* (Nov. 15), but meanwhile the following brief description may be of interest to some of your readers:—The carbon button is held fast within an insulating cup in the centre of a small but massive brass base; resting on the button is a light metal disc which supports a slender strip of vulcanite, about an inch long and a quarter of an inch wide. Vulcanite is used on account of the comparatively large dilatation it undergoes when warmed, but a strip of blackened zinc is more prompt in its indications. The upper end of the vulcanite strip abuts against the base of a vertical screw, capable of an extremely fine motion by means of a worm-head gearing into a second horizontal screw. Attached to the milled head of the latter is a small pointer moving over a graduated circle. Each division in this circle corresponds to a motion of the fifty-thousandth part of an inch imparted to the vulcanite strip, and thus a corresponding small degree of pressure can be brought to bear upon the carbon button below the strip. A platinised cone converges radiation upon the vulcanite, which is enclosed in a metal casing except on the side opposite to the cone. The upper and lower faces of the carbon button are in metallic communication with a cell or two of a constant voltaic battery and with a delicate reflecting galvanometer of low resistance. A Wheatstone's bridge and resistance coils are also included in the circuit to balance the resistances of the carbon; and at first a "shunt" of thick wire is necessary to derivate through itself the greater part of the current, and so ratio the motions of the galvanometer needle. When the proper balance is obtained—the fine adjustment being made by turning the micrometer screw that presses the carbon—the shunt is removed and the instrument is ready for a test experiment.

The best radiated from one finger held near the cone is more than sufficient to drive the galvanometer under right across and off the scale. In a letter relating to this instrument, Mr. Edison writes to me as follows:—"By holding a lighted paper several feet away I have thrown the light right off the scale," and by increasing the delicacy of the galvanometer, "the instrument may be made so sensitive that the heat from your body, while standing 6ft. from and in a line with the coil, will throw the light off the scale, and the radiation from a gas jet 100ft. away gives a sensible deflection."

These statements—less extravagant than those that have appeared in some newspaper reports—are quite consistent with my experience of the instrument, and they show that the tasimeter is a marvellously delicate thermoscope, and as such, or as a means of detecting minute variations in pressure, it is a really valuable addition to the cabinet of the physicist. It is not, however, likely to displace the thermopile, electric pile in experiments on radiant heat; albeit, when the small area on which the radiation falls in the tasimeter is taken into account, it no doubt a more delicate thermoscope. In fine, owing to the narrow linear surface it exposes to the radiation, it will probably do good service in such researches as the study of the spectrum of lunar and solar spectra, and in registering the variations in the solar spectrum. But as regards delicacy, characteristic of the man, Mr. Edison has shown how the tasimeter may be used as an instrument for detecting the presence of moisture in the atmosphere. All that is necessary is to remove the carbon button from its cup, and in a strip of gelatine extended across the cup, when it becomes an hygrometer of surpassing delicacy. Other applications of the tasimeter, which, perhaps, Mr. Edison will allow me to suggest, is for detecting variations in the pressure of the atmosphere, and a new form of aneroid barometer it would doubtless give with extreme promptness and delicate indications, and thus be of considerable use to meteorologists. The application of the instrument for detecting minute changes in the length of a body is obvious, but I am not sure that, save in its use in very special native experiments, further information is necessary, and several minor modifications of the present apparatus are possible.

I am, yours obediently, W. F. BARRETT.

Telegraph Journal July 11878

EDISON'S THERMO-PILE.

One of Mr. Edison's latest inventive effusions is the carbon thermo-pile.' It is based on the principle of the carbon telephone, now so well elucidated by the microphone. The sensitive part consists of a cube of prepared carbon or charcoal, confined between two thin iron plates, and a fine slip of boxwood, split, inserted between the second plate, and a third metal plate or clamp. This sensitive arrangement is connected in circuit with a battery, and a galvanometer. When heat-rays are allowed to fall on the slip of horn, it expands lengthwise and presses on the charcoal, reducing the electric resistance of the latter proportionately to the pressure. There is thus a corresponding rush of electricity through the circuit, causing a deflection on the galvanometer. The arrangement is exceedingly sensitive, the heat emanating from the hand being sufficient to give a deflection of 10°, with a single cell, through a galvanometer of about 100 ohms resistance. It is said that Mr. Edison hopes to measure the heat from the fixed stars with it.

THE UNSEEN UNIVERSE AND THE TASIMETER.—The extreme delicacy of Edison's tasimeter has been proved during the recent solar eclipse, and we now hear that the latest pioneering project of Mr. Edison is to employ it in exploring those blue fields of the night sky, which to the eye are void of stars, in order to discover the unseen orbs which tenant them. His plan is to adjust the tasimeter to its utmost sensitiveness, then attach it to the reflecting telescope, when, if in any particular direction of space the latter there is a marked and workable deflection of the tasimeter, it may safely be inferred that there is an unknown world in that "Seeing," says the *Scientific American*, "that the undulations than the eye can take cognisance of, and are that it will open up infinite successive regions of space, and possibly extend the range of our real knowledge so far beyond the limit attained by the telescope as that is beyond the range each of unaided vision. Possibly too, it may bring within human ken a vast multitude of nearer bodies—dark and non-self-luminous.

EDISON'S TASIMETER.

A long description of Edison's tasimeter having appeared in the *Times*, and conveyed the impression that the instrument was in use prior to its invention were not sufficient to indicate to detect the heat of the heavenly bodies, Dr. Huggins wrote to say that he had measured the heat of the stars with a thermo-pile, and Mr. A. C. Ranyard points out that more than ago as 1812 Magrini, of Milan, found that the needle of a galvanometer in circuit with an old-fashioned thermopile was thrown at right angles to its zero position, though the heat of the moon was insufficient to affect it. So far as practical experience has yet gone, it would appear that the tasimeter is really too sensitive, the heat from the observer's body, from current of air and from other sources, have as great an effect upon it that it is difficult to distinguish the amount of deflection really caused by the celestial object, the best of which it is desired to measure.

EDISON'S TASIMETER.

Dec 5 1879

MR. PROCTOR ON THE SAME—THE STATEMENTS OF PROF. YOUNG.

To the Editor of the New-York Times:

I do not doubt that, in justice to myself, Mr. Edison, and Prof. Young, you will allow me to correct a misleading statement (unintentionally misleading, of course) in THE TIMES of Dec. 4. It is there said that, whereas Prof. Young very plainly stated that the tasimeter did not disturb the eclipse of the sun in 1878 answer the purpose for which it was constructed, I am as well satisfied with it that I have suggested its application to detect the presence of meteors, "not being aware, apparently, that in order to be effective it must be adjusted to every slight alteration in the position of a vessel." And, at the close of the paragraph, the writer remarks that it is a consolation to get correct information at last, though "the manner in which it is conveyed is calculated to mark the difference between field and platform astronomer in a way not complimentary to the latter"—a remark which (I would note by the way) appears to me to be in rather bad taste, especially as both the statements commented upon came from the platform. However, the only point I care to touch upon is simply that there was no contradiction whatever. My suggestion about the use of the tasimeter originally appeared in an article in the *Times* newspaper of Nov. 15, 1878, in which I carefully set forth the opportunity of testing the limit to which this photometer could be made sensitive, but we have spoken to and found pointed (a metre (135 yards) apart, and there seeing no reason to doubt that the results will be obtained at whatever distance a beam of light can be flashed from one observatory to another.

The photophone is operated with a Siemens spiral circuit, a telephone and battery. The light is passed through an orifice in an opaque screen consisting of a circular disk pierced with holes near the circumference. Upon rapidly rotating the disk an intermittent beam of light falls upon the selenium, and a musical note of persistent character is heard, the pitch of which depends upon the rapidity of the rotation of the disk. It was necessary, in order to reduce the tone to be practical, to devise an apparatus to be operated by the voice of a speaker, by which variations could be produced in a parallel beam of light corresponding to the variations in the air produced by the voice. A large beam is therefore concentrated by means of a lens upon the diaphragm mirror, and after reflection is again rendered parallel by means of another lens. The beam is received at a distant station upon a parabolic reflector in the focus of which is placed a sensitive selenium cell connected in a local circuit with a battery and telephone. A large number of successful trials have been made with the instrument so far apart that sounds could not be heard directly through the air.

After giving a detailed account of his many experiments, Professor Bell said that it is not only pleasant to remember these things and to speak of them, but it is a duty to record them, as they give a practical refutation to the often repeated stories of the blindness of scientific men to unsuccessful novelties, and of their jealousy of unknown inventors who dared to enter the charmed circle of science.

The photophone, Professor Bell said privately, is the invention he was known some time since to be perfecting, and the existence of which gave rise to the discussion in England and America of a supposed invention for seeing by telegraph.

THE PHOTOPHONE. Sept 15, 1880

At the session of the American Science Association, held at Huntington Hall, Boston, Mass., Friday evening, August 27th, Professor A. Graham Bell lectured upon his new invention, the photophone. The lecture was illustrated with diagrams, and the photophone was shown. Mr. Bell began by declaring that discoveries made by Sumner Tainter and himself had resulted in apparatus for the production and reproduction of sound by light. They began to experiment with selenium, a remarkable substance that has always been regarded as one of the curiosities of the arts; but the final result of their researches widened the class of substances sensitive to light vibrations until they are able to propound the fact that each sensitiveness is a general property of all matter; the only objects which yielded no results were carbon and thin microscope glass. Professor Bell said:

We find that when a vibratory beam of light falls upon these substances they emit sounds the pitch of which depends upon the frequency of the vibratory change in the light, and that when we connect the form or character of the light vibrations on selenium and probably on other substances we control the quality of the sound and obtain all varieties of articulate speech. We can thus, without a connecting wire as in the electric telephone, speak from station to station by means of a ray of light. In practice no three men have had better opportunity of testing the limit to which this photophone could be carried than I have had, we have spoken to and found pointed (a metre (135 yards) apart, and there seeing no reason to doubt that the results will be obtained at whatever distance a beam of light can be flashed from one observatory to another.

The photophone is operated with a Siemens spiral circuit, a telephone and battery. The light is passed through an orifice in an opaque screen consisting of a circular disk pierced with holes near the circumference. Upon rapidly rotating the disk an intermittent beam of light falls upon the selenium, and a musical note of persistent character is heard, the pitch of which depends upon the rapidity of the rotation of the disk. It was necessary, in order to reduce the tone to be practical, to devise an apparatus to be operated by the voice of a speaker, by which variations could be produced in a parallel beam of light corresponding to the variations in the air produced by the voice. A large beam is therefore concentrated by means of a lens upon the diaphragm mirror, and after reflection is again rendered parallel by means of another lens. The beam is received at a distant station upon a parabolic reflector in the focus of which is placed a sensitive selenium cell connected in a local circuit with a battery and telephone. A large number of successful trials have been made with the instrument so far apart that sounds could not be heard directly through the air.

After giving a detailed account of his many experiments, Professor Bell said that it is not only pleasant to remember these things and to speak of them, but it is a duty to record them, as they give a practical refutation to the often repeated stories of the blindness of scientific men to unsuccessful novelties, and of their jealousy of unknown inventors who dared to enter the charmed circle of science.

The photophone, Professor Bell said privately, is the invention he was known some time since to be perfecting, and the existence of which gave rise to the discussion in England and America of a supposed invention for seeing by telegraph.

Sept 1880

Manufacturer and Builder

DIAGNOSIS BY THE MICROPHONE.—The principle of the microphone in medical and surgical diagnosis has recently been lectured upon by Sir Henry Thompson, of London. He showed how a small acoustic wave is converted by it into a large electrical vibration, which is reconverted into sound at the diaphragm of the telephone, where it is rendered by the ear of the operator. Thus, in case of stone in the bladder, the minute wave transmitted through the sound on its impact with a very small stone, is so magnified that the operator is enabled to determine with certainty the presence of the smallest stone or particle of stone, or other foreign substance. These experiments, it appears, were conducted with a couple of steel sounds, each fitted with the microphone, and an artificial bladder, in which was enmeshed, in turbid fluid, a naturally formed uric acid stone, about as large as a pea.

IENTIFIC PRESS.

SCIENTIFIC PROGRESS.

A Delicate Instrument.

Prof. S. P. Langley, of the Allegheny observatory, read a very interesting paper at the recent meeting of the National Academy of Sciences, in New York, on the "Measurement of Stellar Energy," in which he described a novel and very delicate instrument, which he had found it necessary to devise to take the place of the thermopile, which he found was not sufficiently sensitive for his purposes. The apparatus is founded on the principle that a wire conveying an electric current be heated, if one electricity flows through it than before.

The application of this principle is thus made: Iron or steel is rolled into sheets of extreme thinness. Of these sheets 50 laid one on the other did not together equal the thickness of light tissue paper. Minute strips, 1-32 of an inch wide and 1 of an inch long, cut from this were rolled so as to form a prominent part of the battery, through which a current of a powerful battery passed to the galvanometer. Experiment proved that an almost inconceivably minute warming of a set of these strips would reduce the passage of the electricity so as to produce very large indications on the registering instrument. The instrument thus formed was from 10 to 20 times more sensitive than the most delicate thermopiles; but this was almost a secondary advantage compared with the great precision and the readiness with which it is tested. Thethermopile is very slow in its action. Thisnew instrument, which he calls a bolometer, almost takes up the heat and parts with it again in a single second. It is almost as prompt as the luminous rays itself.

Toshow its sensitiveness, the statement was made that it would register a change in temperature of the iron strips, just described, which did not exceed 1-50,000 part of a Fahrenheit degree. When mounted in a reflecting telescope it would record the heat of a man or other animal in a distant field. It would do this equally well in the night, and might be said, in a certain sense, to give the power of seeing in the dark. A more valuable proof of its efficiency was shown in a series of measurements of the heat of the moon, made under varied circumstances, to guard against error, but each made in a few minutes. All agreed in showing that the almost inconceivably minute amount of heat from the moon could be certainly measured by it, even with a common refracting telescope.

SCIENCE:

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

JOHN MICHELS, Editor.

PUBLISHED AT

229 BROADWAY, NEW YORK.

P. O. Box 2898.

SATURDAY, OCTOBER 9, 1880.

Two or three weeks ago we complained of the coldness of British writers in neglecting to recognize and acknowledge the full scientific value of Bell's and Edison's discoveries, and we condemned, more particularly, their omission from Gordon's illustrated catalogue of recent advances in electrical science, which had then just appeared in London. To day, after having read a four column pean of eulogy and encomium on Prof. Bell and his Photophone, in the last number of *Engineering* we make a candid confession, that, in order to arrive at the real estimate of an American discovery in the average English mind, it is indispensable that the 'meat' of English criticism should first be drawn.

The concluding paragraph of this article reads as follows: "Who can say to what great fields of science this one discovery of Prof. Bell may not lead, fields of research not limited in locality to this earth, but reaching to the planets, and to the farthest limits of visible stellar space. It is by a beam of light that the modern astronomer is able to analyse the chemical constitution of the farthest stars and nebulæ, and is enabled to detect and to deal with metallic vapors through distances of thousands of millions of miles as surely as in his own laboratory, who, after Prof. Bell's experiments will have the hardihood to affirm that sounds taking place in the far off regions of the universe may not one day be heard on the earth, and new fields of acoustical astronomy may not be opened to the intelligence of man. When such a time arrives, the thought of the poet will be clothed with the truth of the fact, that "Light is the voice of the stars."

In the same strain which excites *Engineering* to this transcendental flight of fancy, may we not also hope, in the future, to catch the whisperings of Venus as she waltzes among her heavenly companions, and if we dare to reach so far in our aspirations for the perfection of the Photophone, may we not yet be able to hear the reflections of light, mixed with heat, which Mars, an ardent admirer of old, throws to that splendid luminary as they near each other? It is also true that Mr. Edison has helped to begin that sort of business; for did he not, long since, catch the warmth of the coronal beams, when the sun withdrew behind fair Luna's screen, and didn't Mr. Lockyer (who was there) tell us all that happened? Let us not, however, go too far and admit that the era has arrived which Gulliver predicted, when he described the process of the philosopher of Laputa who extracted sunbeams out of cucumbers.

Engineering should know that the Photophone is but a simple machine for registering heat waves that have impinged upon a piece of hard rubber, and that these waves, originally set in motion by the voice, when made to act on any material expansible by heat, will reproduce, more or less effectually, the original motion which gave them birth. Such an instrument is the Tasimeter, which Professor Bell has stripped of its swaddling clothes and made to talk.

Herald Apr 29, 1881

Measuring the Sun's Heat.

A recent English invention of great simplicity and sensitiveness promises to open up to scientists a new field of meteorological research. The invention is by Mr. David Winstanley, and is designed as a meter, self-recording, both of the duration and intensity of each day's sunshine. This instrument consists of a curved tube fixed on the rim of a brass wheel and free to revolving in two hollow bushes, one of which is blackened and exposed to the sun, the lower half of the tube being filled with mercury. The wheel carries a fine steel needle resting against a metal drum covered with ginned paper and revolving at regular speed by clockwork, and the sun's rays falling upon the black bulb the enclosed air expands, driving the mercurial column toward the protected bulb, thus causing the wheel to move and its attached needle to mark the movement on the paper. The slightest cloud passing over the sun reverses this movement and thus a continuous record of the intensity of solar radiation every hour is secured.

The value of this simple contrivance, says the London *Journal of Science*, lies in the fact that it will enable meteorologists to decide whether a noted degree of temperature is due to the action of clear sunshine or to a transient air current. The two kinds of heat differ in their effect on animal and vegetable life, bright sunshine being needed to ripen grain, while warm air unaccompanied by direct sunlight is desired for the germination of seeds. Hence, if we are to learn where certain crops will succeed, it must be ascertained which of these two sources of heat plays the

most prominent part. Bunsen long ago pointed out that "the more refrangible solar rays exert the most marked influence on the chemical changes upon which the vegetable world depends," and observations with sensitive-recording instruments have been regularly taken at Kew, England, and Para, in Brazil, to determine the sun's chemical forces. Para sensitive, it has been found, is chemically six times stronger than English, even in summer; that of Cairo, Egypt, is five times as intense as German sensitive, and the latter twice as strong as what has been observed at Melville Island in the Arctic Ocean.

These highly interesting observations, if continued over the United States with such an instrument as Mr. Winslow's melinograph, would greatly enrich the Signal Service investigations, and would assist agriculturists to define the limits in which the cotton and sugar belts might be wisely and profitably expanded. But the province of the melinograph is also to facilitate the solution of the grand problem of the varying amount of heat received by the earth from the sun from year to year, partly with a view to the provision and forecast of the phenomenal characteristics of coming seasons. As the lower strata of the atmosphere are so replete with aqueous vapor, which obstructs the sun's rays, observations to this end must be made at high stations and preferably in the tropics. But, inconvenient as these geographical conditions may be, the scientific and practical value of such solar observations is so commanding that they cannot be longer postponed. The British journal, *Nature*, of April 14, publishes a letter from the Spanish government to Professor Piazzi Smyth, making him a liberal offer to occupy the majestic dome of Teneriffe, in the Canary Islands, for solar investigations. Degrees, in the Colombian Andes, nearly nine thousand feet above the ocean, presents another exceedingly eligible point for such studies, which our own Signal Service might convey with great advantage to solar physics.

Die Einlage wird gebildet aus ineinandergeschobenen, mit Schlitzen und Löchern versehenen trichterförmigen Blechen, welche den Dämpfen und Gasen eine möglichst grosse Berührungsfläche bieten sollen. (D. R. P. 14474 vom W. Menzel in Meerane.)

Practisches—Electrische Lichte.
Erzeugung von electrischem Lichte.

Die Neuerungen (D. R. P. 14058 von Th. A. Edison in Menlo-Park, Amerika) beziehen sich auf Verbesserungen an den unter No. 9165 patentirten Vorrichtungen und bestehen in der Construction des Brenners, der automatischen Regelirung des Stromes, in dem Systeme der Leitung, in den Mitteln zur Erzeugung und zur Messung der Electricität, sowie in andern mit der electrischen Beleuchtung zusammenhängenden Einrichtungen.

Fig. 1.

Fig 2.

Den Brenner a stellt Erfinder aus einer Spirale, einem Draht oder dgl. aus Platin her, das er mit Magnesiumoxyd überzieht und in eine völlig evacuirte Glasglocke b einschliesst. Zur Regulirung benutzt Erfinder die vom Brenner entwickelte Hitze, indem er die Luft, welche in dem die eigentliche Lampe b umgebenden Gefässe c enthalten ist, wenn sie durch die Hitze ausgedehnt wird, auf eine elastische Klammer l wirken lässt, die dann durch Oeffnen eines Federcontactes e den Strom nach dem Brenner so lange unterbricht, bis die Temperatur desselben wieder entsprechend gesunken ist.

Zur Leitung von den Stromerzeugern M dienen zwei Haupt-Conductoren A und B (Fig. 2). Ersterer ist ein in die Erde gelegtes Rohr, letzterer ein in dieses Rohr gelegtes isolirtes Kabel, von dem durch Zweigrohre A^1 einzelne Drähte nach den Verbrauchsstellen $a\,a\,a$ abgezweigt werden.

Zur Messung des verbrauchten Electricitätsquantums benutzt Erfinder eine electrolytische Zelle, in der eine dicke und eine dünne Kupferelectrode in isolirter Kupfervitriollösung sich befinden. Nach der Ablagerung von Kupfer auf der dünnen Electrode soll diese das Quantum verbrauchter Electricität bestimmt werden.

Alle diese Einrichtungen hat Erfinder in zahlreichen Modificationen ausgeführt und beschrieben.

It is gratifying to note how promptly the dangers of fire that might arise from the introduction of electric lighting are being dealt with. We have before us two documents bearing on the same subject, both covering the same ground approximately, and both making substantially the same recommendations. The one is the report of a committee of the Franklin Institute of Philadelphia, the other is a paper read by Mr. William A. Anderson, of New York, at the first annual meeting of the United Fire Underwriters. As the latter document is by far more authoritative and reaches further, being a report to the New York Board of Fire Underwriters, we need deal with it alone. The requirements of the Board have been precisely formulated, and are now being complied with by the leading illuminating companies as rapidly as circumstances will admit, remodelling old plant and making arrangements to alter the construction of new apparatus turned out. In order to prevent the possibility of heating a wire if it has not conductivity enough, and the dangers of conflagration arising therefrom, it is recommended that "wires have fifty per cent excess of conductivity above the amount calculated as necessary for the number of lights to be supplied by the wire." Experienced electricians state that if the conducting wire is two and one half times greater in weight per foot than the wire wound around the dynamo-electric machine, it will be amply safe. A very important point, insisted upon by all who have given the subject careful study, is to thoroughly insulate the wires. To this Mr. Anderson adds that the wire must be doubly coated. He expresses it as his conviction that the wire of the future must be different from any now in use. With the same object in view, thorough insulation, he recommends that all wires be secured to walls, etc., by some approved non-conducting fastening. There appears to have been much negligence in this respect hitherto. Now, however, porcelain fastenings are being rapidly substituted in lieu of metal staples. For the distance between wires, a minimum of two and one half inches for incandescent light wires and eight inches for arc light wires is prescribed. All arc lights must be protected by glass globes inclosed at the bottom, so as to effectually prevent sparks or particles of the carbon from falling from the lamps; and when necessary, chimneys with spark-arresters must be placed at the top of the globe. The conducting frame-work of chandeliers and lamps must be insulated and covered the same as wires, and an absolute cut-off must be placed at the point of entrance of the electricity into buildings. So far as present experience has shown and can suggest, all beyond number of the practical and economical application possibilities of fires by the introduction of electric lighting have been of this mode of illumination can now be pointed to, such as effectually guarded against by these requirements, and, according to all were scarcely thought possible by most persons within a indications, the light-giving agent is destined to be the fire underwriters' short a time, when the fire underwriters' report was drawn up. friend. Factious opposition will not stand long against a light which proves that they fully appreciate the importance of the subject.

The Crystal Palace International Electric Exhibition.—In connection with the forthcoming electrical exhibition at the Crystal Palace, we are informed that allotments of space are already nearly made to about one exhibitors. Included in the list of intending exhibitors we notice the following:—Her Majesty's Post Office (Right Hon. H. Fawcett, M.P.), the Anglo-American Brush Light Corporation, the Electric Light and Power Generating Company, the Edison Electric Light Company, M. Gaulard, for the Compagnie Générale d'Electricité, Messrs. Siemens Brothers and Co., Mr. Edison, Messrs. Rowan and Tyer (the Pilsen and Joel Light), Mr. Graham, M. Werdermann, Messrs. R. E. Crompton and Co., Messrs. Siemi and Co., M. Gaulard, M. Gerard, Messrs. Hammond and Co., Messrs. Hawkes and Co., Mr. Edmundson, the Lighting Supply Company, Messrs. Legrand and Sautin, Messrs. Gould and Co., Messrs. Zonin and Co., and Messrs. Latimer Clark, Muirhead, and Co. The list of exhibitors, a copy of the rough draft of which has been forwarded to us, serves to convey some idea of the magnitude and variety of the forthcoming exhibition; but it is still, we are told, far from complete, as many letters of protest allotments are still being made, and many applications for space are still under consideration.

THE METROPOLITAN.

DECEMBER 3, 1881.

The Edison Electric Light.—As we were able to announce last week, the City Commissioners of Sewers have given their consent to the lighting of the Holborn Viaduct by means of the Edison system of electric lighting. We have since been informed that the parties by whom the experiment is to be carried out have also arranged to light the City Temple, Messrs. Spicer and Pond's Imperial Hotel, and several shops on the Viaduct. The plans of the promoters of the Edison system in this country, as described in previous issues of the *Metropolitan*, are thus, it will be seen, being gradually developed, and we hear it rumoured that the proprietors of another incandescent system contemplate adopting a similar mode of bringing their light more prominently under the notice of the public.

Electric Lighting Bills for Next Session.—The subject of electric lighting bids fair to occupy a very considerable share of the attention of Parliamentary committees during the ensuing Session, and even of the House of Commons itself. The notices which have been published in the course of the past month show that numerous Bills are to be promoted in respect of cities and towns in all parts of the country, seeking powers to supply the public with this means of illuminations. Municipal authorities are particularly appear to be on the fore, and in several instances we notice that Corporations who are not the owners of the gasworks in their respective towns ask permission to set up electric lighting establishments, and thus enter into competition with the gas companies. There are, also, six notices on the part of independent companies (one gas companies) of their intention to seek the necessary powers to open roads and distribute electricity for lighting, and for the various other purposes to which it may be rendered applicable. As might have been expected, as a result of the publication of these notices, attention has been directed to the report of Mr. Lyon Playfair's Committee on the subject. That committee, which, it will be remembered, sat for many days in 1879, took a vast amount of evidence and issued a very valuable report, but we never certainly are within sight of those who anticipate that anything contained therein will in any way rule the decision of Parliament on the Bills to be brought forward next year. The condition of things existing now is altogether different from that which prevailed over two years ago. Indeed, the progress of the light during this period, readers of the *Metropolitan* hardly need reminding, has been most marked, and instances of this mode of illumination can now be pointed to, such as were scarcely thought possible by most persons within a short a time, when the fire underwriters' report was drawn up. Factious opposition will not stand long against a light which proves that they fully appreciate the importance of the subject. Other parties, by the present legislation to any extent, and they will best consult their own interests by adopting a course which shall, at any rate, show some regard for the requirements and convenience of the public at large. The question has only been raised as to the desirability of a monopoly of the power to supply the electric light in a given district being in the hands of a company or Corporation. This is a point which will require very careful consideration at the hands of the committee or committees to which these Bills may be referred. We are aware that there are many, even among those who think with us on the main question, who hold that combined, or, indeed, competition at all, in anything involving the disturbance of the public ways has, so far as London is concerned, had its day; but, on the other hand, it has been only too plainly demonstrated that in the case of private undertakings, such as gas and water companies, for instance, it has hitherto been exceedingly difficult, if not practically impossible, to impose conditions which shall adequately protect the consumers. Possibly such an arrangement may be come to as will remove the necessity for any decision on this point until a future occasion. In any event, it will be seen that the public generally, and local authorities in particular, have every reason to watch with very considerable interest the proceedings of Parliament in relation to the subject.

A GRAND WEST OF ENGLAND ELECTRIC LIGHTING SCHEME.

THE interesting process of forming an electric lighting company may now be observed in action in Bristol, and dispassionate spectators may extract a considerable amount of amusement from the performance. The people of Bristol have for many years been cogitating as to what use they can make of the River Avon, besides the obvious purposes of navigation. Lately there has been considerable talk about the wasted power of the tides, and the Bristol folk have apparently fully persuaded themselves that the tides in the Avon, which are popularly credited with a rise and fall of about 40 feet, should be set to work in some useful way. There is this further inducement to such an enterprise, that the water of the Avon, from its usual extraordinary load of mud, is manifestly heavier, and therefore more powerful, than a cleaner fluid. Whether this idea has worked on the minds of the local public or not, it has occurred to a few smart individuals that the time is favourable for starting an electric lighting company, with the admitted collateral possibility of lighting the city by means of a conversion of the power of mud and water which is such a conspicuous natural advantage of the locality. The agent of the Brush Electric Light Company and Mr. St. George Lane Fox have opened the campaign with a course of public meetings on the approved pattern; and the services of a portion of the staff of the University College have been impressed to give a public lecture, with experiments, on electric storage and lighting. Professor S. P. Thompson was the lecturer, and in the course of his remarks he is reported to have said that Faure accumulators wasted ten per cent. of power in charging and discharging; while further on he also said that incandescent lamps could be lighted from the generator with greater economy than when fed directly from the generator. After this it is scarcely necessary to add that the lecturer was enthusiastically applauded, especially when he referred to the probability of the Edison lamps being successfully tried in New York. Indeed, for a supporter of the local lighting scheme, which was to favour Messrs. Brush and Lane Fox, the lecturer talked most unmercifully of Edison and his doings. The upshot of all this ingenious advertising is the proposed registration of a Company with a nominal capital of £500,000, to acquire the right of using Brush and Lane Fox lamps in the West of England. The Bristol public will display little of the meekness with which they are popularly credited if they allow themselves to be inveigled into parting with any sum of money, to say nothing of half-a-million sterling, for the supposed privilege of using two systems of lighting, the best that can be said of which is that they are certainly not superior to my of half-a-dozen others which will always be free to cut up the electric lighting business in the West of England, as elsewhere, as soon as it can be shown to pay. Bristol gas is 2s. 10d. per thousand cubic feet, and the Gas Company pay full dividends. They should be interested to learn, from my of the promoters of the Bristol Electric Lighting Company, where there exists a single instance of a similar Company to theirs making profit from lighting, in competition with gas at any figure. We observe that this particular Company contemplate earning at least fifteen per cent. Can they cite a precedent for this expectation? While the statements relating to electric lighting companies which appeared in three columns last week remain as indisputable facts, we are justified in regarding with the gravest possible suspicion such schemes as this Bristol enterprise, with its flaunted fifteen per cent dividends.

ELECTRIC LIGHTING AT GOSFORTH.

We have received from Mr. A. Thomas, Manager of the Basingstoke Gas Works, a letter on the subject of the electric light as at present in use at Gosforth, in the course of which he says:—

Having heard much, and reading as much favourable accounts of the success of the electric light, also reading Mr. Dawson's remarks in the JOURNAL of Nov. 15th, I felt determined to see for myself. I arrived at Gosforth along with a friend about 5.30 p.m. on Tuesday, the 1st inst. The first electric light we saw was the one on the Tramway Office, which is a very good one. We then went straight for the place; but before entering there, and near the light, and a rush of men, boys, and women came against us, being driven away from the column by a policeman. The boys appeared to have been hanging the pillar, as though they were trying to shake the light out, and laughing at the policeman as if they had actually done so. On the light being shut out by, for the column appeared to be very loose in the ground. about 100 yards from the first light, another light was next noticed. When I went round to see if it was re-lighted. The light began to come up, and we stood for two minutes watching it, and in that time it went out seven times, and I went on, leaving it out, for it appeared to be like a drunken man who was trying his utmost to rise, and finding he could not do so, gives it up in disgust, and lies down. We went on and looked at the other three lights, which appeared to give a very good light, excepting for the constant flickering. While looking at the last one of the three, which is opposite to Wharf Street, a dray went near it, and the light went nearly out. (Was this the cause of its doing so?)

Afterwards we went on to view the 100-candle Brsp lamp erected by the Gas Company on the River Bridge, and I think any unbiassed mind will say that this is the best light in the town. As we could not find anyone who would give us any information upon the subject, we determined to find out the distance between the lamps, and then to look to see over the ground again. I asked him (Mr. Park) when the town lights, or rather the bits of "polished copper wire" were; and was informed they were replaced with oil lamps, which I saw were put in ordinary street lamps. Mr. Park informed me that they had been taken out a fortnight; also that last Saturday, Sunday, and part of Monday night the arc lights would not light; and seeing to the wind and rain the oil lamps would not light; and seeing to the wind and rain the oil lamps would not light; and seeing to the wind and rain the oil lamps

...erican Gas Light Journal. Sept. 16, 1881.

Electric Lighting at Cardiff

The correspondent, whose account of the trial of the electric light at Cardiff was published in our issue of the 2d inst., sends the following account of "further escapades"—

The exhibition is now in at the large drill-hall in Cardiff during the Exhibition of Fine Arts are giving the committee considerable exercise and trouble, not unmixed with anxiety. The committee are responsible for drawing a large concourse of persons together to witness the many valuable objects collected within the largest building in the town. Previously, gas has admirably answered every requirement as an illuminant within its walls; but, of course, something modern and more pretentious than gas was needed for the exhibition.

The electric light was the consequence of such an idea gaining ground, and to the movement we are indebted for a novel proceeding on the part of the present method of attempting to light up a great space by its aid. A large building and large open spaces are the *forte* claimed as special vantage-ground for the electric light. The exhibition is accompanied each day with performances, chiefly vocal and instrumental, of a high order. One evening last week circumstances of a somewhat grim character seemed to coincide, with a view to give a life-like, or rather a death-like reality to this particular occasion. An *artiste* was announced to sing the "Death of Nelson," and a crowded audience was present. The electric light had apparently its part, or *rôle*, allotted to it, for when the singer commenced the song the electric light suddenly disappeared. Of course the gas was immediately called upon to do duty in the emergency.

From previous experience of the electric light this was a contingency quite looked for; the committee having very thoughtfully ordered that the gas should be *lit up but turned down so as to have it ready if unexpectedly required.* The man in charge of the hall was quickly on the alert, and the gas-tap was manipulated, but to the intense disappointment of the committee in particular, and the disgust of the public in general, the tap was turned the wrong way! Thus the small glimmer of gas kept in waiting for the electric lights to perform one of their "fantastic tricks," was put out, and all was darkness.

Is not this a burlesque on lighting? The meeting thus had an unpleasant, but withal a somewhat grotesque ending. Strange things within and yet stranger things without. The large hall thus lighted is by one electric system which shall be nameless; the approach to the hall, in Dumfries Place, is also lighted by electricity, but by a separate and entirely different system. As the audience left the large but dismal hall, and emerged into Dumfries Place with its brilliant lights, the effect upon the visual organs was most marked and indeed painful.

This sensation was of short duration, and had instantaneously to give way to another cut to be had. The electric lights were by some means unexpectedly extinguished, and where a few moments before everything seemed to be flooded in an effulgence of light nothing but universal blackness prevailed. This is called electric lighting; but some people are beginning to think a few more substitute term might be found with which to describe such a nondescript method of extending zones of misery from those who seem to expect something better than gas for their pains.—*Journal of Gas Lighting.*

Sept. 3, 1881.

ENGINEERING NEWS.

THE ELECTRIC LIGHT IN A SCOTCH COLLIERY.

On Tuesday afternoon, Aug. 2, Earnock Colliery, near Hamilton, belonging to Mr. John Watson, of Earnock, was the scene of an interesting ceremonial which may well be said to mark a new era in mining annals. In proceeding to win the rich mineral wealth of his estate Mr. Watson determined that, in respect of fittings, machinery and general appointments, it should be a model, and he has been highly successful in giving practical effect to his aims. Among other things he early resolved to, if at all practicable, substitute the electric light for the ordinary modes of illuminating the workings, and after investigating the various systems he decided on giving that of Mr. Swan a trial. Accordingly, since April last, Messrs. D. & E. Graham, electrical engineers, Glasgow, have been engaged fitting up the Swan incandescent lamp with modifications, to adapt it for safe use in the mine, and on Tuesday the inauguration of the new light took place in presence of a large company of leading gentlemen from Glasgow, Hamilton and the West. Arrived at the colliery about half past one o'clock, the visitors were received by Mr. Watson, and after a brief pause spent in inspecting the three magnificent winding and fan engines, the Guibal fan, and framework for screening the coal, they were conducted by Mr. James Gilchrist, manager, down one of the workings in the William at a depth of 138 fathoms. Here at the pit bottom, in the roads and at the face, twenty-one Swan lamps were burning, giving forth a brilliant, steady flame, the luminosity of which, while sufficient to supply the desired light, had none of the disagreeable intensity associated with most systems of electric lighting. Besides the pear-shaped Swan lamps, in which the glowing or incandescence is carried on in vacuo, there is an outer lantern, the invention of Mr. David Graham, consisting of a strong glass globe, air-tight, protected with steel guards. Each lamp was also connected with two different forms of Graham's patent safety cut-outs and switches for cutting off and letting on the current. The effect of which, it is believed, would be to render the lamps quite safe, even in the presence of explosive gas. At first the intention was to employ the fan engine to drive the dynamo-electric machine or generator, but this was departed from, and an engine of 25-horse power was erected in the workings on the surface for the purpose. From the generator the electric cables, five in number, are conducted along the road of the workings over ordinary miners' pulley to the pit-head at No. 2 shaft, and thence down into the workings. From the pit-bottom of workshops to the pit-head, a distance of several hundred yards, the cables consist of ordinary copper wire, 7-16 in. diameter, inside the workings and below ground, to allow of their safe handling, they are composed of insulated wires, while on the way down the shaft they are inclosed in a galvanized tube. Near the bottom of the shaft, branches are taken off for supply light to the principal roads and for the haulage engine-room, the main cables being carried into one of the sections of the mine, a distance of half-a-mile. After careful inspection of the lamps at the pit bottom, the party were shown, grouped in three groups, with the aid of the electric light, Mr. Arnan, of Glasgow, who may well be credited with the distinction of being the first to exercise his skill in the bowels of the earth. They were led to the haulage engine-room and into the workings, where they witnessed the effects of the light. At the latter point, while, of course, the visitors were at a safe distance, a shot was fired, bringing down a large mass of coal. Having spent fully an hour below ground, the party returned to the surface, where carriages were in waiting to convey them to Earnock Mansion House, where luncheon was served.—*Colliery Guardian.*

GAS AND ELECTRICITY IN LIVERPOOL.

The annual meeting of the Shareholders of the Liverpool United Gaslight Company was held on Tuesday last, when full statutory dividends were declared. The report stated that the gross profit on the past year's working amounted to £99,624. Payment of the second half-dividends will leave a balance of £26,629 on the net profits of the year; consequently the Directors announce a reduction of twopence per thousand cubic feet in the price of gas, and the Chairman, Mr. Edward Lawrence, stated that the reduction would have been at least a penny more, had it not been that quite half of the extraordinary net profit was secured in consequence of the exceptional demand for coke during the past severe winter. This fact was reasonably held to affect the disposal of the surplus, it being, of course, quite uncertain whether the operations of the current year will be equally successful. One penny per thousand cubic feet of gas means in Liverpool about £7500, so that a reduction of threepence would have shown an apparent loss of £22,500. It would thus be rash to say that the Company could positively afford a greater reduction than that which they have given. At the same time, they do not seem to reckon sufficiently on the increased consumption which the cheapened price will probably bring. They have also a balance carried over from previous years, so that a further reduction cannot be very far off. We do not mean to imply that the present determination of the Directors is an evidence of excessive caution on their part, especially as their action appears to have given considerable satisfaction in the city. The utmost that can be said is that while they have not seen their way to take off threepence this year, next Midsummer may find the undertaking well able to bear another remission equal to that now announced.

An interesting episode marked the Chairman's opening speech, in connection with the electric lighting experiments in Water Street. It appears that the British Electric Light Company were employed to light this thoroughfare with a tramway was being laid. After some nights' experience, in the course of which much trouble was occasioned by the lamps going out, &c., the Corporation were compelled to return to the use of gas, and this has been the method of lighting since preferred. The Chairman naturally mentioned this incident with unfeasible satisfaction; but it has since transpired that the affair is not so pleasing to the other side. Consequently, the Engineer to the Electric Light Company has written to the local newspapers, stating that the fault chiefly complained of arose from the carelessness of a workman, and, of course, "in no respect affects the principles or the ultimate success of street lighting by electricity." This is the usual way of accounting for a failure. As with the City of London experiments, when all the lights on a circuit have gone out—which has happened on several occasions—it is never the fault of the "system." There is always some workman, or defective wire, or some other irresponsible thing upon which the blame may be cast—that mysterious entity called the "system" is always held sacred. The only way to meet these excuses is by the plain, straightforward remark that the light on such an occasion *went out*—how, or why, is of no interest whatever to the public. They are not supposed to know or care how gas may sometimes fall below the prescribed standards of purity and illuminating power; the gas manufacturer has to look to this part of the business as well as to others, and he is heavily fined in case of default. We wonder if it has ever struck the authorities of towns where electric lighting has been tried, that if there were penalties to be incurred by the contractors, just as in the parallel instance of a Gas Company, there would either be no offers to supply from the electricians, or the cost of the lighting would vary directly with the amount of the fines. The Liverpool Gas Company have certainly scored heavily at the expense of their rivals in the matter of the Water Street lighting; and as we have had occasion to remark in these columns, we believe that much instruction would be derived from a record of every instance where electricity has been superseded by gas.

THE DAILY NEWS, OCTOBER 5, 1886.

CRYSTAL PALACE INTERNATIONAL ELECTRIC EXHIBITION.—The period of the series of international exhibitions at the Crystal Palace inaugurated thirteen years ago by the late Prince Consort, the Duke of Connaught will be an Electric Exhibition. It is intended that this exhibition should be opened in the autumn of 1887, and continue seven months. Nearly all the systems of electric lighting will be represented at the Crystal Palace, so that manufacturers, theatrical managers, and others who are thinking of applying electric lighting to their premises will have opportunities, &c., will for the first time in England have an opportunity of comparing the various electric lights, and judging for themselves which will suit their local circumstances best. The water is the best time for an electric exhibition, as the season will allow of the lights being seen from about 4 p.m. or even earlier. In addition to the many and various systems of electric lighting, the Crystal Palace will have a complete exhibit of its numerous inventions. Subscription to these various forms will be already represented—Faure's, Sellon's, De Mantier's secondary batteries, Trouvé's boats, and many other scientific exhibits will render the exhibition the most interesting to the public and the most important to a scientific view that has ever taken place in England. Influential committees have been formed to advise and aid the directors in the undertaking.

THE COST OF INCANDESCENT ELECTRIC LIGHTING.

Some correspondence has been going on during the past week in *The Times* and other newspapers, respecting the cost of domestic lighting by incandescent electric lamps, with the result usual in similar disputed questions, of the subject remaining as vague as ever. The matter is mentioned in another column in connection with statements published in the *Quarterly Review*, and it is therefore unnecessary to argue here the case of gas *versus* incandescent lamps, although a few observations on the correspondence above mentioned may not be out of place. One of *The Times* correspondents complained of the great cost of setting up the necessary apparatus for electric lighting; and also drew attention to the excessive prices charged for some of the fittings, such as lamps, which are sold at 25s. each, while intrinsically worth about 2s. 6d.; and Faure batteries sold at £4 per cell, which cost less than 10s. Another correspondent, in reply to this indictment, contended that the inventors of electrical apparatus have a right to charge as much for their goods as the public can be induced to give; and also claimed that the cost of electricity is not to be reckoned at the rate at which private and separate users can now generate it, but that taken in a manufactured and distributed wholesale, electricity will be much cheaper than gas. This argument is so often used that it cannot be too frequently reported, on the part of the partisans of gas lighting, that there cannot possibly be such economy in the wholesale production and distribution of electro-motive force as in the apparently parallel but really very different case of gas manufacture and distribution. The cost of steam power is well ascertained to be little less per horse power per hour for a large than for the smallest engine which fully occupies the attendant's time. This being the case, taking the example of a large consumption requiring about 60-horse power for from 300 to 400 lights, the question of expense resolves itself into this—whether it would be cheaper to purchase this power from a Company having a station, say, half a mile away, or to produce it by steam or gas engines on the premises. In the former case it is clear that the possibly smaller proportionate expense of obtaining the power from a large engine will be more than counterbalanced by the separate establishment expenses and separate profit of the generating Company, besides the cost of the conductor, meter, and other obvious charges. We are now assuming the expense of the power, supposing it to be always fully utilized. But in the case of a Company supplying electromotive force generally, so far from their difficulties and expenses diminishing with the amount of their business, the reverse will be found to be true; and in support of this statement we are content to cite the undoubted authority of Mr. William Crookes, F.R.S., who is Electrician of the Electric Light and Power Generator Company, into whose possession the Maxim patents for the United Kingdom have just passed. Professor Crookes corroborates the observing, to the effect that if there are twenty lamps in a room three must still be maintained as at first. We can easily imagine what would be thought of the economy of gas lighting by consumers, and how unsaleable it would be deemed by philosophers, if the cost of supplying one burner were the same as for twenty. In the interest of gas lighting we much desire to see the supply of a Metropolitan district undertaken on business terms by an electric generator Company, and to learn the exact result of competition of incandescent electric lamps with gas at 2s. per thousand cubic feet. We shall be greatly surprised, when such a clear of business is attempted, if electricians do not accomplish that they still want something to make them quite happy.

theories should be confined to their proper place. Prophesy in another column, also, is not altogether objectionable in its season, and especially when it suggests or contains the germs of its own fulfilment; consequently it should be indulged in sparingly, if considered by any means a legitimate exercise for a commentator on passing events. When, therefore, it is found that a communication on a technical subject appearing as a review, and obviously intended to impart trustworthy impartial evidence on the subject of which it treats, is chiefly occupied with the writer's own largely in theorizing and prophesy—and more particularly the latter—we are justified in considering that the reviewer has overshot his duty both to his subject and to his readers.

The *Scientific Review* contains in the current number a long article on the "Development of Electric Lighting," an attentive perusal of which has suggested the foregoing reflections. It is seemingly based on the Parliamentary Blue Book of Aug. 13, 1879, which contains the report of the Select Committee on Lighting by Electricity, and on the Official Catalogue of the Paris Electrical Exhibition. The tenor of the article may be inferred at starting from the opening paragraphs, which state in as many words that the opinions of the witnesses examined before the Electric Lighting Committee of 1879 have been proved to be altogether erroneous by the proceedings of the electricians in Paris during the present year. It is interesting in this connection to find that the report of the Committee is really as applicable to the present day as it was to the conditions of 1870. The Reviewer states that the commercial establishment of electric lights, which was "the dream of the visionary and enthusiast" two years ago, and was condemned as impossible by the "universal consensus of opinion among all the scientific witnesses," is now realised, and what was impossible then may be now done in daily action at the exhibition. We cannot find any reference to impossibilities in the report of the Committee, and must therefore conclude that the Reviewer has attempted to throw unjustifiable discredit on the result of their labours; for if the "dream" is now a reality, it is important, it is remarkable that no mention of such a determination appears in the report. The Reviewer has apparently forgotten that the Committee was appointed for a definite purpose, and this purpose was fulfilled as perfectly as the results then to be had, notwithstanding the assumed difference between the state of electric lighting now and in 1879.

The Reviewer gives a very readable account of the principles governing the development and application of the magneto-electric currents for the purpose of lighting by means of the arc and by incandescence. His descriptions of the various dynamo machines, and their differences, are very clear, and are worth perusing by any one who may require a succinct guidance in the distinctions between "alternating" and "direct current" machines, and similar elementary matters in reference to electric engineering. The information given in respect of dynamo machines is indeed much more ample than with regard to the lamps or regulators, which are dismissed with a very insufficient amount of attention. There is no reference of the Reviewer to the difficulties with the management of the somewhat amusing. He says that the "alternation" between the positive and negative carbons "takes place sixty times a minute, and the sudden increase and diminution of the length of the arc produces those flickerings which were so much complained of in the early days of electric lighting, two years since." Is it intended to be understood that are lights have given up flickering since this epoch? It would appear so, for the Reviewer informs us that in the best modern regulators "the light is practically steady"—for how long?

The Reviewer's sympathies and hopes are, however, most strongly enlisted on the part of the incandescent lamp, between the various descriptions of which he does not attempt to pass judgement by specific reference, and any one will find, by methods of executing a number of incandescent lamps for domestic lighting are well described, as also is the system of electric measurement, the units of the latter being very clearly explained. It is not mentioned, however, that the production of electric energy required for an incandescent lamp is the same whether the light is turned up or down. This circumstance is too frequently ignored when, in lecture-rooms and elsewhere, the sensitivity of the incandescent lamp to control in the matter of illuminating power is demonstrated. How many observers of this operation know that the power of the lamp is only modified by the friction of internal resistance coils, which absorb and practically waste the force that is not employed in affording light?

With reference to the glare of the electric light in houses, the Reviewer is somewhat remiss in his statements. He contends that only those people need complain of glare who, having been accustomed to 10 or 20 candle power gaslight in their drawing-rooms, are not satisfied unless they replace the gas-burners with lamps of equivalent power in the form of electric lamps. Assuming the incandescent lamps to be of equal brilliancy with the discarded gas-lights, and further reckoning these at only 10 candles each, it is difficult to believe in the existence of individuals who would submit to rate for 1 or 2 gas-burners no less than 70 or 80 incandescent lamps. The Reviewer, however, goes on to remark that if "people will be content to substitute for their 50-candle power gas light, 80 to 90 candle power electric light, they will find that they have a beautiful soft light, which, if the shape of the lamps is hidden by a shade, *is impossible to distinguish from pure, except that it is steady* and does not vitiate the air." The italics are ours, and while it is new to find superior steadiness claimed for electric as compared with gas light, we will pardon this slight mistake for the sake of the compliment expressed in regard to the beauty and softness of gas.

On the question of expense the Reviewer is sanguine. He starts, however, with a grand blunder respecting the annual cost of the electric lighting of the City of London streets, which he states to be about the same annually as the previous cost of gas, whereas the "electric light companies are all paying good dividends." As a matter of fact, the yearly charge for the 640 gas lamps extinguished was under £1700, at the rates then prevailing, which have since been reduced. The actual cost of the electric lighting experiment is not known, but the amount of the accepted tenders for lighting only, besides establishment charges, was £5000 for the current year. Consequently the cost of the experimental lighting in 1882 per cent. higher than that of the gas formerly used—without reckoning the cost to the electric lighting contractors of the gas occasionally used when their lamps have been accidentally extinguished. This error on the part of the Reviewer is so gross, and from the misuse which he makes of his wrongful assumption so unpardonable, that his authority in the further question of expense is worthless. Moreover, as to the quantity of light afforded, there can be no available basis of comparison between the two systems of lighting while the electricians are busily permitted to obtain temporary powers for their lamps; and the matter of the "good dividends" said to be made by electric light companies is also one on which outsiders are scarcely competent to form an opinion while authentic returns and statements of accounts are less common than statistical quotations.

Fortunately the Reviewer does not commit himself to a statement of the probable cost of incandescent lighting, but deals only in the usual generalities. One specious argument is to say notice, in which it is stated that "to estimate what will shortly be the relative cost of lighting a house by gas and by electricity, we might, if we maintain the cost of electricity at its present price, to be under the mark, and it will place more coals, but at what gas-works in his own back yard." The above comparison is obviously not fair. The reason why gas cannot generally be made in a small undertaking are already known, as can be bought of a large public undertaking are already economical, and easily enumerated by any one who cares to take the trouble to do so. Where there is a point, however, when private consumption becomes independent of the public undertaking, and it would pay the consumer to manufacture his own gas. We do not know how much cheaper a house power of energy will be in the near future, when the cost of copper conductors is taken into electric energy can be obtained as cheaply as it could be purchased from a central generating station with the cost of the main conductors superadded, as they must be in the latter case. It is therefore impossible to believe, as suggested by the Reviewer, that the mere production of electro-motive force in a central station, and its distribution through the streets by means of costly conductors, can operate materially in the direction of lessening the estimated present cost of electric lighting. The error that Mr. Edison is engaged in laying down nearly 200 miles of electric light mains in New York City, and has contracted to light certain districts by means of his incandescent lamps, and to charge to the consumers exactly the same as they now pay for gas, "plus the cost of the coal company," may or may not be true; but it is sufficient to remark, by way of rejoinder, that London gas is not sold at 2s. per 1000 cubic feet, and that the Edison Electric Lighting Company do not publish their accounts.

The Reviewer concludes his effusion with the prophecy that we may "even now confidently look forward to the time in the immediate future when gas-lamps for lighting purposes will be as much as wooden torches," and so on, in the usual vein. The prophet is welcome to his opinions in this matter, as the expression of them will do us harm, nor even need the most timid holder of gas shares a moment's uneasiness. To the readers of the *Quarterly Review* it is, however, a trifle hard that the scientific writer who has invaded the calm repose of their literary circle with profound information on one of the most absorbing subjects of the day, should, when brought face to face with the financial aspect of the matter, find cause for a shocking blunder, and then hurriedly proceed to cover up his poverty of correct statistics with the well-worn mantle of prophesy. Notwithstanding all his show of deep convenience with his subject, his acknowledged visit to Paris, and conversation with Mr. Edison, the Reviewer cannot tell what his favoured method of lighting costs now, or is likely to cost in the immediate future. Moreover, he has utterly forgotten the critic in the partisan, and has said nothing about the real reason—the common instrumentalness—why it is that all electric lighting continues in the experimental stage. He has sought to convey the impression that all difficulties in the way of the daily and nightly application of electric lighting are overcome, and in so doing has overstepped the bounds even of fair advocacy, to say nothing of the limits of impartial criticism. In his haste to consign gas lighting to oblivion, he has omitted to notice and study the imperfections of electric lighting, but also the improvements in gas-lamps which are revolutionizing the aspect of the streets of London by night, in a way even more striking than the City electric experiment. In the demand for "more light," which is now heard from all sides in our thickly-populated towns, where busy streets and bustling interiors have to be illuminated, the *despised* gas of the writer in the *Quarterly Review* will not be overlooked, so long as it retains in a pre-eminent degree the properties of cheapness in use, and remaining alight as long as required.

THE Directors of Messrs. Newton, Chambers, and Co., Limited, have given notice that no further application for shares in the Company will be received after Thursday next, the 10th inst.

The Fire Risk of Electric Lighting

The Boston *Globe* says: The dangers incident to the employment of electricity for illuminating purposes are being illustrated daily in all sections of the country. Only a few evenings since a man who was making a connection of the wires at the Mechanics' Fair Building was knocked almost senseless by the fluid, and another man in an establishment on Washington street was badly "shook up" by the same imperial agency. But the saddest effect of the new invention yet recorded was at the burning of a mill in Philadelphia last week, when half a dozen were killed and more than twice as many made cripples for life. Quite a serious fire occurred in Chicago the other day from one of the electric light wires in the city getting "crossed" with a telephone line. It seem that Mr. Orcutt, manager of the Telephone Exchange, noticed some smoke coming from the annexing board, which is composed of brass strips one-eighth of an inch apart, ten of them being connected with a key or a peg for the purpose of putting subscribers in communication with each other. In a minute or two little blue and white flames began jumping from one strip to another across the space between them. The telephone manager at once suspected a cross with an electric light wire, and the wires were immediately disconnected. Returning to the board, he saw that the transmitter was burning, the current having jumped two feet to reach it. After cutting off another wire the loss was cooled by throwing water upon it. Nothing more was observed until the lapse of one-quarter of an hour, when another section of the board, eight feet from the first one which was on fire, began to smoke. The blue and white flames was seen here too. Disconnecting the ground wire ended the display, some water being used. Half an hour later the switch-board, through which connections were made with the trunk lines, commenced to smoke, the current having jumped ten feet this time. The flames ran along for two feet, and the board smoked for five minutes before the fire was put out.

This cross was a very expensive one, the damage resulting from it being the loss of a microphone and a head instrument in the office, and about 25 feet of the Owl Club's line on the roof. The wire melted like lead. An instrument in the store of the Chicago Music Company, situated on State street was also destroyed, the induction coils on the inside melting. About $200 will restore everything as it was. Investigation showed that a wire had been run from Willoughby, Hill & Co.'s store to McVicker's Theater for the purpose of furnishing the electric light used there a part of last week. Its use was discontinued Thursday, but the dead wire in some way dropped down on the telephone wire, the tremendous current passing through the former thus finding its way to the central office.

The Chicago *Tribune*, in commenting on the affair, says that the effect of this "cross" shows how dangerous electric light lines are. A current that will burn carbon will set wood on fire, if it is within two feet of the wire and damp, and, finding a better current than carbon, the current will take to it. If great care is not taken in stringing the lines, fires will be frequent when the electric light comes into general use.—*Iron Age.*

SOME NOTES FROM AMERICA.

[FROM OUR OWN CORRESPONDENT.]

August 24.

A sort of endless controversy has been going on of late in the New York papers, between the representatives of the Edison and the Maxim Electric Companies, in reference to a decision of the Commissioner of Patents, by which he recently adjudged in favour of the latter Company in the matter of a claim in regard to the question of invention of the thermostatic regulator. It seems that this interesting device claimed both for Edison and for Maxim; and the question was referred to the Commissioner of Interferences, who decided in favour of Maxim. Mr. Edison appealed to the Examiners-in-Chief, and they also declared in favour of Maxim. Mr. Edison then appealed to the Commissioner of Patents, and he has affirmed the decision of his subordinates. Now, however, as the matter has been decided in this manner, the Edison Company claim that the invention is valueless, upon which the Maxim Company retorts asks the pertinent question, why did the Edison Company expend time and money in fighting for the title to a worthless patent? So the matter stands, and will probably remain until the fierce cones when lighting by incandescence have proved a commercial success. Then we may hear of it in the Courts.

I have frequently alluded in my letters, during the last year, to the Edison central station which was "just going to be established" in a section of the business part of New York city; according to the statement of the Vice-President of that Company, which has appeared in the daily papers, the Company hopes to last proclaim a building wherein to establish the station. However, it does not yet appear when they are going to commence supplying light.

Anticipating difficulty in procuring competent workmen to run their engines, the Edison Company have established a sort of school for the training of the employés. So far, the instruction consists of lectures by a Mr. E. H. Johnson, the Company's principal assistant—on electric lighting, and the Edison light in particular; to which was recently added instruction in the way of running the wires, particular reference being made to the fitting up of houses.

It will be remembered that in a former letter—published in your issue of June 7—I stated that a contract had been entered into between the City of New York and the Brush Electric Company for the lighting of several of the principal squares of the city. At the time it was expected that the lights would be in operation by the 1st of June; but, as a matter of fact, the Company have not yet commenced to carry out their contract. Part of the delay has been caused by some of the property owners—in front of whose houses the poles for carrying the wires are to be erected—obtaining a temporary injunction against the Company erecting them pending action thereon with the view of putting up the poles. Lately a motion was made to dissolve the injunction permanent; but this was denied, and the case, said, "The embarrassment of the Judge in giving his decision on the question of erecting poles in certain parts of the city, with cross-bars of 7 or 8 feet in extension, for the purpose of carrying the wires over them in the city where these poles are erected. . . . I feel constrained to say that I cannot decide the question without creating a nuisance, to the actually lessening the value of residences. This question, however, cannot be properly examined and determined on this motion, but should be left for the trial. . . . The question of irreparable injury raised as to the diminution or continuance of the preliminary injunction restraining the defendants from erecting the well-settled rule, in equity, of preventing irreparable injury to the interposition of the Court. The contract is completed with the execution of the erection of one pole, and it therefore is a year. Under the circumstances, with considerable hesitation, I think the temporary injunction should be continued.

The Brush lights on Broadway, between Fourteenth and Thirty-fourth streets, were again out part of last evening. The officials of the Company assign various explanations to account for these repeated failures of the lamps; that time it is the wet weather; then the slipping of a driving band at the station. The night when the party in charge of the central station was aggrieved, he did succeed in getting the dynamo at work, but the explanation of this, the last failure, the reporter was unwilling, that there were several causes; but that he was too busy to explain them.

extent they are right. It seems only natural that the *deposits* of man and beast—containing, as they so undoubtedly do, highly manurial properties—should be employed in restoring fecundity to the soil, whilst the *fertilising power* which is thrown away at present from another so far applied earlier, that the sewage would be utilised to the full without causing nuisance to the dwellers in the midst of our towns to applied to the soil almost in its natural state, or only after a process or two of other treatment? This is a matter which must be left for experts to determine.

The question of sewage disposal is one which must necessarily be of importance to all those bodies in whose hands are placed the sanitary requirements of towns. To these the Native Guano Company, Limited, are prepared to give advice and assistance. They are willing, for a moderate annual payment, to undertake the whole trouble and responsibility of dealing with the sewage of any town, and guarantee an efficient water of sufficient purity to flow into any stream, and a valuable manure of high commercial value, and that over which the Company's operations have been carried out without creating any nuisance in the neighbourhood. Experiments on a large scale with the Company's process of rendering innocuous and fit for streams polluted by sewage and chemical manures, were awarded by them the prize of £20, given by the Mayor, and a special silver medal.

The multiplication of works for the treatment of sewage by some such system as the one above described would augment the value of land in every country gone-sultry; and it is therefore to be wished that it may soon be adopted by the Native Guano Company may find the area of their operations widely extended.

NOTES FROM SCOTLAND.
(From our OCCASIONAL CORRESPONDENT.)

Since last week the municipal touch has been lightened, and on Saturday, September cities as well as the measure of electricity, it has been dealt with more or less satisfactorily according to its composition. Looking over the metropolitan and provincial contracts which have been entered into during the past year, it will be found that the electric light is being extensively adopted by municipal authorities for the purpose of illuminating streets, and for other similar purposes. Thus, in Edinburgh, the Gas Commissioners have appointed a Committee to report to them during this autumn as to the extent to which the electric light can be introduced in Aberdeen, and the extent to which it may with advantage be employed. The Committee have accordingly met, and have agreed to recommend that the electric light be introduced in the Castle Street area, and in the Union Street area, and that the Gas Commissioners be empowered to enter into contracts with the Electric Light Company for the supply of electric lighting in the streets and public buildings, the contracts to be for a period of ten years, and to be terminable at any time by either party on twelve months' notice. The Committee have also recommended

considered the electric lighting of mines would be so easy to accomplish, he could not give a satisfactory answer, for he saw many difficulties in the way. These difficulties had been carefully dealt with by the gentlemen who had spoken, and from what he had heard there seemed to be every prospect of success having been fully anticipated. The incidence of the candle there to keep the Swan lamp, which would be ignited by the fire-damp in the atmosphere of the mine. He Swan had shown that they could produce a lamp of 4-candle power, such as miners would require at the face, for 10 hours with a battery weighing 30 lbs. Mr. Swan's little lamp commanded the power for taking away of lamps one that could be carried easy entirely by him (the Chairman), for it was easy to get and fill it with a chemical charge, which occupied only a few minutes each week necessarily, the same as he now filled it with oil. He could enable him to be could not see how a mine could be lit without lamps. The question which would be a new one for a whole shift without any more action, being exceedingly rough, and the brackage of the mines. The area, too, of coal-fields which had heretofore been thought to be of little value had been shown that the electric lighting had been overcome, and he saw in the lighting

THE METROPOLITAN.

THE ELECTRIC LIGHT.

On Thursday, in the Mathematical and Physical Science Section, Dr. C. W. Siemens read a paper detailing a series of experiments he had made with the view of showing the influence of the electric light on vegetation, and the application of electric energy to farming operations. The most recent of these experiments were made between October of last and May of present year, the electric light being in operation from 5 and 6 p.m. until the dawn of the following morning. The general results of these experiments went to show that the electric light was capable of producing on plants effects comparable to those of solar radiation and favourable to healthy growth. As to the theory of plants not being necessary to plant life, Dr. Siemens gave as his opinion that the result of his experiments, that, although parasitic plants evidently favoured growth, the continual stimulus of light appeared to promote healthy development and to reconcentre the plant through its different stages of flower and fruit. The questions, however, of temperature and the intensity of the electric light still remained to be dealt with experimentally with the view of determining the best conditions. Dr. Siemens also gave the results of experiments which he had made in applying electric energy to farming operations, including the pumping of water, ploughing, &c. He had been so strongly impressed with the results obtained that he thought the electric transmission of power might eventually be applied to the thrashing, reaping, and ploughing—in fact, that all the work of a farm might be directed from a central station of electric power, instead of being carried out, as at present, through the agency of steam. So far as he had gone, the electric apparatus had been under the sole charge of his head gardener, with the assistance of under-gardeners and field labourers, who had probably never before heard of electricity.

The Journal of Gas Lighting, Water Supply & Sanitary Improvement. Sept. 6. 1881.

THE PROGRESS OF ELECTRIC LIGHTING.

From different parts of the country we continue to receive conflicting accounts of the fortunes of electric lighting. At Edinburgh, as described in our own correspondent's letters last week and in the present issue, the experiments with the Brush light, which were to have lent additional brilliancy, to a masterly manner, to the occasion of Her Majesty's visit to the Scottish capital, ended in a complete *fiasco*. The commercial men of the local newspapers on this affair are amusing. Although on the first occasion when the light was tried, it went out altogether after a flickering existence of only about twenty minutes, the Scotsman described in a lively print as "eminently successful." On the following night the collapse was even more signal, for the gas lamps, which on the former occasion were still available, had been turned off to allow the electric light full swing. When, therefore, the sudden extinction experienced on the previous evening was repeated, the crowds of people thronging the streets were left without guidance to find their way home as best they might. In Glasgow, the Committee of the Corporation, to whom a proposal to introduce the electric lighting into the city was recently referred, have reported adversely thereto, on the ground that they had not sufficient confidence in any of the electric light systems now before the public; and this when it is consequently to be used indefinitely. In Dublin the electric lighting contractors have had to explain why the district confided to them was recently plunged in darkness. "This mishap we trust," they "will not discourage again." As against this concensus of complaint, the Crompton light at Norwich must be recorded as having given great satisfaction, notably to the self-appointed test members of the British Gaslight Company in the Corporation. As even a child's nightlight would, by those gentlemen, be considered superior to the finest Argand burning the Company's gas, their judgment in the matter of the Crompton light may not be deemed quite impartial. We do not consider it necessary to devote space to congratulate Mr. Crompton, or to condole with the British Company, on either of the one sinecure light to be called in question; but our readers may be allowed to form their own opinion on these brief records of interesting facts.

ANSWERS TO CORRESPONDENTS.

L. C. G.—The publication of your letter would be an useful process, the Board of Trade having declined to sanction the proposition of Mr. Preece.

L. London.—Apply to the Secretary of the Metropolitan Gas Company's stock will take place early in November next.

The Cost of Electric Lighting.—The annual report of Lieut.-Colonel Donnelly, the Assistant-Director of the South Kensington Museum, which has recently been issued, contains some interesting particulars in regard to the cost of electric lighting as compared with that of gas. We find on reference that some of the figures included in this report have already been published in these columns; but as they are now given in a more complete form, and on the authority of the official specially entrusted with the charge of the building, we offer no apology for returning to the subject. Colonel Festing stated that the consumption of gas at South Kensington during the past twelve months shows a diminution as compared with the previous year of 2,230,000 feet, and of 5,647,000 feet. This diminution he attributes to the fact that since March, 1880, one-half, and since June the whole of Lord President's Court has been lighted by the electric light. The circumstances under which the rest of this new mode of illumination was suggested may be briefly stated. Sir Frederick Leighton having expressed his fears that the mural painting recently executed by him in the Lord President's Court might be injured by the gas, it was decided to try to light this court by the electric light. The "Brush" system, which had quite lately been introduced into this country from America, appeared to the authorities in many respects to be that best suited for the purpose, and a dynamo-electric machine and eight lamps on this system were therefore purchased to light up the eastern half of the court. The machine was driven by the gas engine, and the result was so far satisfactory that it was determined to extend the lighting to the other half of the court; but as the gas engine is not sufficiently powerful to work the sixteen lamps a more powerful steam engine was purchased for the purpose, and placed in a temporary shed outside the building. Towards the end of June the lighting of the whole court was commenced, and has been uninterruptedly continued ever since. Between the 22nd of June and the 31st of December the sixteen lamps were at work on eighty-seven nights for a total of 370 hours, and the working expenses for this period amounted to £69 2s. or 3s. 10d. per hour of lighting. The consumption of gas which used to be at the rate of 2ft. an hour for the same period has been at the rate of 1,230 ft. The annual working expenses, Col. Festing says, has therefore been £218 2s., or at the rate of about £420 per annum. The outlay for dynamo-electric machine, lamps, steam engine, shafting, &c., including the cost of fixing the machinery, amounted to £1,041. "As, however," adds Colonel Festing, "the steam engine is capable of driving two such machines, the cost of the machinery and apparatus for lighting the court may be set down in round figures to have been £2,000, while to outlay the saving on working expenses, as compared with gas, amounts to 17 per cent. per annum."

Electrical Exhibition at the Crystal Palace.—The second series of international exhibitions at the Crystal Palace inaugurated this summer by his Royal Highness the Duke of Connaught will be an electric exhibition. It is intended that this exhibition shall be opened in December, and that it shall continue during several months. Nearly all the systems of electric lighting will be represented at the Crystal Palace, so that manufacturers, theatrical managers, and others, who are thinking of applying electric lighting to their factories, warehouses, theatres, &c., will, for the first time in England, have an opportunity of comparing the various electric lights, and judging for themselves which will suit their local circumstances best. In addition to the many and various systems of electric lights, Mr. Edison will have a complete exhibit of his numerous inventions. The Edison-Gower-Bell Company will be strongly represented. Faure's and De Meritens's secondary batteries, Trouvé's boats, and many other scientific exhibits will be seen; and the managers hope to make this exhibition the most interesting to the public and the most important in a scientific point of view, that has ever taken place in England. As hon. secretary to the exhibition and industrial gentlemen is now being formed to advise and assist the directors in their undertaking. The Lord Mayor has convened a meeting at the Mansion House for Monday, Oct. 24, at 3 p.m., to consider the question of holding the exhibition at the Crystal Palace.

FORMS AND FUNCTIONS OF THE ELECTRIC DISCHARGE.

ON the Monday evening devoted to the meeting of the British Association, 1877, Professor Tyndall, F.R.S., delivered a lecture on "Electrical Discharges: its Forms and Functions," in the course of which he remarked:—"We have only to observe the phenomena which we have been studying here to perceive that they are in the highest degree significant, not merely as regards science, but whether the conclusions of science be true or false, as regards any explanation of natural facts. Many natural phenomena doubtless fundamentally connected with electricity have many years been left lying before us. But there are two in particular—namely, lightning and the aurora—which have attracted the attention of mankind, and which are undoubtedly electric in their origin, and with the characters of which the most distinguished men have occupied themselves. We have no aggregation of aqueous vapour, which is enough to show that electricity is suspended in the air. All of these phenomena are, I think, strongly suggestive of electrical action, and are certainly not excluded from further conclusions. By these considerations I was led to the experiments which I have described in the opposite scenes, and as soon as the electric light was sufficiently within reach, I endeavoured to see if its discharges assume sufficient resemblance to the lightning discharge to throw any light on the origin of lightning. A similar action may naturally take place in the case of the aurora borealis. The quantity of light required for a flash of lightning is of course enormous. The light of a candle is less than 3,500,000 cells would be required. There is, however, no reason why the light of a flash of lightning should not be produced by electricity. It is, on the contrary, extremely probable, to say no more than that the electricity of the cloud which produces the flash of lightning is discharged in the form of a luminous arc. The most striking general characteristic of the discharge is its zigzag course or its sinuosity, and disappearing in the air, and the manner in which it breaks up into branches. Then the question arises, what is the function of which it is the mechanical expression? Is it merely a necessity, a thing which must be, but which has no function? Or has it a function? Is it, for example, the means by which the electricity of the cloud is distributed over the earth? Is it the means by which the electricity of the earth is distributed over the cloud? Is it the means by which the electricity of the earth is distributed over the cloud? Is it the means by which the electricity of the earth is distributed over the cloud

Chamber's Journal, Dec 1887.

OCTOBER 15, 1881.

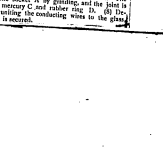
THE METROPOLITAN.

Board of Works announce that they are prepared to receive proposals and estimates from electric lighting companies and others for lighting certain parts of the Strand district with the electric light.

Electric Lighting at the Mansion House.—The General Purposes Committee of the Corporation having invited tenders for the lighting of the state rooms in Egyptian Hall of the Mansion House with the electric light, seven companies responded. After due consideration the committee have resolved to submit to the Court of Common Council for approval the tender of Mr. Crompton, of Mansion House-street. The system is the same as that used at Sandringham during the visit of H.R.H. the Prince. The contract is to light the saloon and Egyptian Hall for 100 nights at £415, £300 being for the lights, and £115 for working expenses. If, at the expiration of twelve months, the Court decide to purchase all the necessary fittings, the expense will be £1,200, less the £300 paid for the year's lighting.

Electric Lighting at the British Museum.—Since the use of the electric light in the Reading-room of the British Museum was last discontinued for the summer season slight improvements have been introduced with a view to get rid of the glare, which caused readers some annoyance. Each ground glass globe has been divided laterally, and the upper half removed, leaving the light in a sort of glare cup, and open in the direction of shade immediately above, which reflects the rays down into the room. The change answers its purpose, though the glare has become somewhat stronger. The electric lighting was resumed for the winter on the 1st inst., and the average attendance of late readers—the number who, between 6 o'clock and 9, and at 10 o'clock, 121. At 9—is only about 1,000 books except the books of reference in the room, for which no tickets have to be filled out, must be given in to the attendant—there were 88 persons present, most of whom remained till seven o'clock, the time of closing. Each reader's place has been allowed for library books, which may now be retained for a quarter to seven. Saturday, as our readers are no doubt aware, is the busiest of all days at the reading room, the number of readers in the earlier hours of the afternoon on that day being generally between 500 and 600. On Saturday last no fewer than 1,000 were counted at the time of lighting up; at six there were 780, and shortly before closing time 130. The system of extended hour rendered possible by the use of the electric light first came into operation on October, 1879. The proportion of readers who avail themselves of this valuable concession shows, on comparison of month with month, a slight tendency to increase.

Electric Lamps.—We illustrate below the main features of an invention of T. A. Edison, of Menlo-park, New Jersey, U.S., in respect of which letters patent have been granted to Mr. J. G. Stewart, of 33, Chancery-lane. The invention relates (1) to the conductors by means of which the current is brought, and is led away or out, as the case may be, from the lamps, and is not a new upwards by a vertical platinum carrying a conductor. (2) In order to prevent heat from the incandescent material being carried down to the point where the conducting wires are fused into the glass, a long interval is interposed between the clamps of the carbon and globe, and the conducting wires are supported by a glass pillar. (3) Lamps to be used in mines may be cheaply constructed of a globe, a sealed glass sphere, and protecting conductors. (4) Figs. 1 and 2 show an arrangement whereby the intensity of a lamp may be modulated at will. The case B contains in its clearance ring of heavy carbon, shown in Fig. 2. One main conductor is attached to the stud in the centre, and the current flows through the metal arm F to any one of the contact pieces a, to which the arm may be applied, by means of its external knob. In the illustration the arm rests on the contact of the second leading wire and the carbon resistance is out of circuit, but any number of its wings may be included in the path of the current. (5) Several forms of glass supports to prevent the heated air from over the fuse are illustrated. (6) The form of the glass stem through which the wires pass is modified so as to obtain an air-tight joint. (7) Fig. 3 illustrates a modified method of sealing the lamps; W is a wooden base A a glass socket fitted thereto, of a form resembling a W in cross section. The globe B is fitted into the socket A by grinding, and the joint is further secured by the cement C and rubber ring D. (8) Describes a new way of uniting the conducting wires to the glass, whereby a long contact is secured.



Journal of Gas Lighting &c. Oct 11th 1881.

Electric Light at the Rolling Stock.

Mr. J. H. Vail, representing the Edison Electric Light Company of New York city, has completed his contract for placing one hundred and twenty-five eight-candle power incandescent electric lights in the works of the United States Rolling Stock Company, in this city, and which, we learn, is the first of the Edison system introduced in Ohio. These lights were on exhibition to the public on Tuesday evening, and great satisfaction was expressed by all spectators at the exceeding steadiness and pleasantness of the light.

The dynamo electric machine is placed in one corner of the wood working room, and is driven at a speed of thirteen hundred revolutions per minute. The power is taken from the line shaft to a countershaft, having a tight and loose pulley, and thence belted direct to the dynamo. One hundred and twenty-five of these lights are placed in various portions of the extensive building, including the office, and at various machines as occasion may require. Each light is of full eight-candle power, or about equal to a five-foot gas light. Any one light can be turned on or off independently of all others. The lights in the above works are arranged to be turned off in sections or rooms.

The Edison system of lighting is particularly safe from all danger of fire, and the beauty, brilliancy and steadiness of the lights render them particularly valuable for lighting houses, stores, mills, factories, etc.

Since the excellent lighting qualities and cheapness of this light was satisfactorily displayed at the rolling stock, several of our merchants are negotiating with Mr. Vail, and we may, ere long, have the Edison electric light in several stores, factories, etc., in this city.

Messrs. J. H. Vail and C. E. Terbune, who have been placing the electric light in rolling stock works, are accomodating gentlemen, and their attention given the visitors on Tuesday evening, was highly appreciated by all.

ELECTRICITY *VERSUS* GAS.

The past week was to have seen recorded two new and striking illustrations of the advance of electric lighting, and of its success as a rival to gas. One of these was the lighting of the new Savoy Theatre; the other, that of the great temporary hall erected by the Lebanis of Leeds in which to give Mr. Gladstone. The Savoy Theatre is still unopened as we go to press, but we have been told, in the words of the proprietor, "the very complicated works and experiments" seem to be with the applications of the electric light to the "stage." We can readily imagine that the complication has increased as the works have progressed, as the inability of the contractors to meet the difficulties which have arisen has already necessitated two postponements of the opening night. A rehearsal of the lighting arrangements last Saturday evening resulted in a breakdown, and there is every probability that when the public are at last admitted, "Patience" will be recommended for yet a little while, and in the meantime the familiar gas will be employed till these difficulties are finally overcome. The system here adopted is that of Swan's incandescent lamps; and, as an address to the public, issued by the Manager, states that "the enterprise of Messrs. Siemens Brothers and Company has enabled us to try the experiment of exhibiting "this light in my theatre," we assume that this firm have undertaken the responsibility, and in some measure the expense of the work—looking to it, in the event of its success, as a great advertisement. Consequently we shall again find an impossible to ascertain the cost at which the work has been executed and the lighting carried on. We shall probably have occasion to return to this experiment next week, and in the meantime it is satisfactory to know that the Company has held on, "in case of accident the theatre can be flooded with gaslight in a few seconds."

The lighting of the "Gladstone Hall" at Leeds, as described in our news columns, furnished a rare opportunity for comparing the two illuminants; and it is matter for congratulation that Mr. Henry Woodall, on behalf of the Gas Committee, made such excellent use of it. Called in to serve a very humble secondary part, gas appears to have taken the chief place, and to have carried off all the honours. This is in no respect surprising. Whatever may be the effect produced by a multitude of incandescent electric lamps, there can be no doubt that none are powerful are lights are not suited to the purpose of a holiday gathering, where bright colours in dress or decorations need to be reckoned with. On the night in question rain was falling, and the air was damp and chill; and if one had wished ill to the prospects of the electric light in Leeds, a worse fate could hardly have been desired for it than to be left alone, with its cold and cheerless radiance, to receive the unmerited disgraced guests under such conditions.

Turning from the question of beauty of appearance and of comfort, what can be said to that of cost? Time it is not the good fortune of other towns to have a gas supply at quite so cheap a rate as Leeds; but at any ordinary rates the comparison will be sufficiently striking. To light a hall such as described *elsewhere*—having, we believe, a superficial area of about 20,000 square feet—as it was lighted with an expenditure of 1800 cubic feet of gas per hour, even though it cost considerably more than the Leeds price of 2s3d per thousand, is to give any competitor a difficult task to equal. The arrangements attended that effort to show the capabilities of gas in the position to which it has become rather a fashion to say that the electric light is peculiarly adapted, should encourage other contests at a similar nature whenever opportunity is afforded. The great improvements which have recently been made in burners, and by which Leeds gas was greatly aided on the occasion in question, help decorative point of view; and in this direction—the further improvement of burners, and still more in the wise use and arrangement of them so as to produce the best effect from the gas used—there lies a field as large (we wish to put this strongly) as there does before electricians in their efforts to compete with gas as it is commonly employed at the present time.

DANGERS OF ELECTRIC CURRENTS.

It at least one respect the result of the Paris Electrical Exhibition is not to the advantage of the electricians. To say nothing of lighting, it has been attempted to be shown at the Palais de l'Industrie that currents of electricity at high potentials are competent to serve unmolested purposes in dwelling-houses, warerooms, &c. Unfortunately, several minor outbreaks of fire from overheated wires, and not a few serious accidents to incautious visitors, have left an impression that electricity is not always the docile, harmless agent it has been claimed to be. We have all heard how edifices and other fires were to become unknown when electric lighting should be general; and how the danger of explosion—always present when coal gas is carelessly handled—would not be represented by any drawback of like potency when the reign of Edison and Swan should commence. It is well known now that while the risk of fire is at least equal in the cases of gas and electric lighting, the careless individual, in exchanging one for the other, merely avoids the danger of explosion for that of a lightning-stroke. The *Times* correspondent has lastened to reassure the public that when electric wires are laid and lamps constructed under the supervision of competent electricians, there is no danger of either fire or shock; and that the frequency of both at the exhibition was due to the fact that too much responsibility for such details had been left with ignorant workmen. We are not accustomed to hear the attendants at show places accused of ignorance of their business; and we may be considered that if the Palais de l'Industrie, under all the various Syndicates, Boards, and Commissions there in session, was badly fitted, it is a poor outlook for the security of smaller installations. And, on the other hand, if competent electricians, with commensurate salaries, are required to be as common as gas-fitters, the cost of retail electric force is likely to remain high; or a new and superlatively intelligent race of workmen, content to work for humble rates of wages, will have to be developed.

M. Y. Jones
Observer Sep 4, 1881.

THE EDISON ELECTRIC LIGHT.

WHY THE MASTS IN THE DOWN-TOWN DISTRICTS HAVE NOT YET BEEN LAID.

No little excitement exists among those who blieved their hopes upon the success of the Edison Electric Light Company in the matter of the down-town end of the system, and who had base their investments upon the understanding of October last. The company have sufficient capital, and the work of laying the mains is being pushed forward as rapidly as can be consistent, that are as far away from that end of the system as ever. Some months ago a number of poles were erected in the down-town districts, and these are beginning to require wires. Accordingly the company have applied to the Board of Aldermen for permission to string the wires on these poles, but the Aldermen positively refuse to grant the permission. We Aldermen positively refuse to grant the permission. We are heavy to make connection. We Aldermen positively refuse to grant the permission. We are heavy to make connection. We Aldermen positively refuse to grant the permission. We are heavy to make connection

THE EVENING POST: DECEMBER 1, 1881.

THE ELECTRIC LIGHT.

Its General Introduction Down Town Postponed until Spring—The Troubles of the Edison Company's Engineers.

The electric-light companies of this city are all more or less embarrassed by the difficulty of obtaining machinery and material for their mains and wires. The Edison Company especially has been delayed by the want of boilers and the need of large quantities of iron pipe for their street mains, of which nearly five miles have been laid in the down-town district since summer. About one-third of the district has been finished, and the work is now going on at the rate of one thousand feet a night; but work being done during the day to avoid interruption to traffic. Since the contracts for material were made last spring the prices have gone up, and many of the contractors delay carrying out their agreements. Suits have been begun against some of them. In the matter of copper wire, the large consumption by electric-lighting companies in the last two years has resulted in raising the price to unreasonable figures. Major Edison, of the Edison Company, estimated to-day that the company had used two hundred tons of finest copper since spring, and would continue to use about two million pounds a year until the work in this city was done. The contracts for mains being signalized that it should all be delivered by the 15th of August, whereas no one knows now when the work will be done.

The difficulty in getting boilers has also been one of the chief troubles of the Edison Company, the boilers furnished last month proving to be defective, owing to errors in construction resulting, as alleged, from hurried work. It is therefore now probable that the work of putting the mains will have to be extended this winter from end to end and the lighting of the down-town district postponed until spring. During the winter months can be stored up and the machinery made ready to begin lighting again with the opening in April. Several buildings which want the Edison lamps sooner than this will have steam power at hand have contracted for the use of the proper machinery and will not wait for the street mains. Mr. Bennett signed a contract to-day to be wired for lamps in the *Herald* building. The boilers and machinery will be placed in the Bennett building in Ann Street, the mains now running under Fulton Street. Provision is also to be made for the use of twenty-three pounds of electricity for the running of small presses, waiting-machines, etc. Wallack's Theatre will not be lighted by electricity before Mr. Wallack considered the price demanded for the use of the patent, but he has now concluded, the right to use their light. While the life of the Edison patents would be injuring the regular business of supplying steam-power from a central station. He was sure that eventually Mr. Wallack would use the Edison light when it was brought to his door just as gas is now, and the company's price for the use of the patent will have to be sufficiently high to equal the profits of many years' consumption of steel-pens. Especially in theatres would the small incandescent lamp of Edison be indispensable, because any number of lights can be placed in all sorts of positions, up in the flies or under the stage, or in the middle of frocables, without the necessity of running cumbrous gas-pipes or the slightest danger from fire.

The Edison Company have just received news through Mr. Henry Villard, who has recently returned from the Pacific coast, of the perfect success of one of the first of the company's experiments in practical lighting. In May, 1880, the company put a number of their lamps in the *Columbia*, one of the Oregon Navigation Company's steamships plying on the Pacific coast, and the lamps are still in use and give perfect satisfaction.

Mr. Edison has been for several weeks at Menlo Park, working, at the lamp with a view to making it last longer than at present. He is also finishing his machine for the electric railway two miles long which has been built across country near his factory to demonstrate to railroad men the practicability of electricity as a motive power. The Western road has invited Edison to make electric engines for a branch road fifteen miles long, and Edison has accepted. This will be many times the length of the Hoosac road near Berlin.

Mr. A. A. Hayes, Jr., the secretary of the Brush Electric Light Company in this city, said this morning that his company was suffering like all others from the impossibility of getting machinery. "Their new building in Elizabeth Street, near Prince, is one hundred feet square, and will be the first "station" yet built; but the machine men are all behind, and the Brush company cannot furnish any more lights until they can get more machinery. At present they are running 550 lamps, their wires covering an area of several square miles. An important feature of the business is getting to be the lighting of dark stores and basements where a light for distinguishing colors is required. Stocky lamps are now in use downtown, and the whole force of 500 lamps could be used if the current for the up-town lights was not needed long before business hours were over down-town. Since the excitement about fire from electric wires the Brush Company have had all their wires taken from house tops and placed on poles of their own.

DELAY IN ELECTRIC MID LAYING.

A Scarcity of Materials Caused by the Sudden Demand—Edison's Other Enterprises.

There has been some delay lately in buying the conductors of the Edison Electric Light Company, but now soon are again at work in Gold and William streets, near Fulton. The delay was caused in large part by the insufficient supply of iron pipe and copper conductors. Since the contracts for pipes and conductors were made, the middle have given out, and the demand caused by them made in the market raised the many contractors have failed to supply their contracts. Even the Edison Company admit that the Edison Company alone would use about two million pounds of copper wire a year, and it is not probable that the dealers will for the present supply the market. When the ground is dug up for the pipes and wires there cannot be found enough help and material without danger of the gas escaping to the surface and then not affording light.

Nearly one-half of the district has been laid with pipes and wires. The city, which was to have been finished by last April and then by July, is now promised by the contractors to be finished by the 15th of August, but this is considered doubtful. The following buildings have been contracted for: Bennett building, Fulton street; Mail and Express building, Park row; Tribune building, Printing House square; Times building, Park row; Sun building, Nassau street; Herald building, Herald square; Mercantile Library building, Astor place; Mutual Life building, Nassau street; Mutual Reserve building, Nassau

Elektrisk belysningsanläggning.

Elektriska belysningsanläggningen å Stadsteatern kommer att utföras på följande sätt: Ångmaskinen, hvilken kommer att användas härstädes, är af 80 hästkrafters storlek och naturligtvis mobil, så att den kan flyttas från ställe till ställe. Den kommer att stå på Gustaf Adolfs torg och Norrbro samt förses med elektriska lampor, hvarjemte de medelst kablar, gående under jorden, förbinda med det nedanför rådhuset uppförda elektriska strömmen skall passera, förelöpande, i hvilket elektricitetsmaskinen finnes uppställd. Vi lämna nu Dagens Nyheters följande beskrifning öfver det nya belysningssystemet:

I skjulet finner man en lokomobil af 15 nominella hästkrafter, en stäfvo elektricitetsmaskin, en mindre sådan färdig att lysa, 24 st elektricitetsmätare samt en mängd lampor af olika storlekar. Så vill elektricitetsmätare som lampor tillhöra amerikanen Brush's patent, och det den mätare som med så stor framgång blifvit försökt i London City. Att beskrifva denna, hvarpå strömmen genereras, är för tillfället af tekniska vara föregifvit möjlig. Vare det nog sagdt, att Brush's maskiner äga förmågan intensse med bäkeye till den ovanligt höga tonsiffran lika väl som styrkan hos den strömmen de genererar. Kablarne äro af bredvid hvarandra lagda kopparstänger af omkring ¼ millimeters tjocklek och äro omgifna af en ledarmassa, tjocad hampväf. Lamporna äro groom-en mycket slarmik apparat, som fästats, att de dela lemna obehindrad passage åt strömmen, fall de icke äro tända, dels att regleras med hänsyn till lampornas inverkan, den afsäkrar. Skall en lampa tändas, löker strömmen passera genom spiralformigt virdan kopparstråd, som omgifva öfre delen af ett stålfjäd likaväl strömmen sakna och upphäfva uppstår mellan kolspetsarna. Två par kolstift ger lampa i hvarje lampa. Endast den öfre tändningen förbrukas. Då den ena, efter omkring 40 timmars förlopp, är uppbränd, omkastas strömmen af sig själf, så att den andra tändgen samma. 10 timmar utan att vårdnen af monnlarband. At Brush's lampor äro uppsatta 6 på Gustaf Adolfs torg, 6 på Norrbro och 4 framför nord västra slottsflygeln, tillsammans 16 lampor, som motsvara från samma maskin. Lysstyrkan hos hvarje lampa är, beräknad till 2,000 normaljus, d. v. s. öfver 120 vanliga gaslågor. Dessutom finnas mindre lampor, bestående af små hattformiga glödgkroppar, i hvilka är gupnen strömmen införaren. Skulle lampor derstad lära förut lemna ett stadigt ljus. Förslyftning.

Samtlig maskiner och ändtrådar för den elektriska belysningen förskaffas af fyra dugtiga engelsk-amerikanska ångbåtsbolaget, som redan tagit hufvudstaden.

Brush's electric light, which will commence in Gustave Adolf's square, that the electric which the lamp cables strong from a shed (shed) the ele are placed (of Stockholm) for shed is a Brush large electric several lamp Electric engine

authorized by the police court of Lambeth to demolish certain houses belonging to a Mr. Munn, which projected beyond the authorized building line unless the terms of the Building Act were complied with. As Mr. Munn did not conform, the surveyor freed him from the necessity of doing so by pulling down the houses.

ELECTRIC LIGHTING—ITS FIRE RISKS AND THEIR REMEDIES.

BY HENRY MORTON, PH.D.,

President of the Stevens Institute of Technology.

Some very lamentable accidents have strongly directed public attention to the question of danger possibly accruing to life and property through the rapidly increasing employment of electricity as a source of light, and as the actual conditions of this danger, like the true properties of the agency from which it may arise, are but little known, a brief explanation of some simple facts related to this subject will be at this time acceptable and perhaps useful.

I would propose, then, to treat this subject under two general heads, namely: 1st, The sources of danger; 2d, The conditions of their prevention, or of security.

The sources of danger in the use of the electric light are essentially two; from the conducting wires and from the electric lamps.

As long as the electric fluid or electric energy, is conveyed by a sufficiently good conductor it is perfectly harmless, resembling a river flowing in its natural channel, and powerless to rise above its banks; it is only when some easier channel into surrounding objects is offered or some partial obstruction of a certain character impedes its regular flow that trouble may arise.

The conditions of these difficulties are, moreover, very peculiar.

Thus, for example, if two electric conducting wires, forming the outgoing and returning paths of a powerful current are placed near each other, but are separated by a bad conductor, as, for example, when both are tacked on to a board partition, the current will follow the wire from end to end, with no development of heat in the same, or tendency to leave the conductor or pass into any adjacent object. If, however, between the two conducting wires we introduce some imperfect conductor, such as a small wire, some metallic dust, or a film of water containing mineral matter in solution; then a portion of the current will be diverted into this "short-cut" from wire to wire and may heat the fine wire or the metallic dust or the wood wetted with the aqueous solution, so as to cause the ignition of inflammable matter.

Accidents of this nature have already occurred. Thus a telegraph or telephone wire having fallen across one or more of the conductors used for street lighting purposes has been fused, or, itself escaping, has caused the fusion of finer wires connected with it.

Again, two wires being the outgoing and return circuits of a powerful current, have been nailed side by side, without other insulation, on the same board of a floor, partition, or ceiling; and though used safely for a long time, while the wood was in its normal state, have developed a very dangerous activity when the wood between them was wet with dirty or impure water. In that case the water offers a circuit through which a cross current is established which first heats the damp wood, then chars it, and finally establishes a series of minute arcs or electric sparks along this charred surface, which would soon develop a conflagration if left uncorrected.

Again, two such wires as above, insecurely attached near each other, may be brought into momentary contact and then separated, in which case an electric arc with its intense light and heat, will be established between them. In like manner a conducting wire itself may be inaccurely connected at some point, and if the abutting ends are separated slightly during use, a similar "arc" with its intense heat may be there developed.

These examples will give a fair idea of the dangers arising from the conducting wires, as they are manifestly to be guarded against by proper separation and insulation of the wires themselves. Of this, however, more anon. At present, I would only further point out that there is no risk whatever of any heating or other injurious action arising in or from the conductor itself when an adequate one is used, as must be the case from motives of economy; since an inadequate conductor would involve ruinous expense in the use of the electric current.

Electricity is not to be regarded as a set of fluid fire passing along the conductor; and the popular notions on this head are as absurd as were similar ones which prevailed in referen to illuminating gas, at the time of its first introduction, and which caused rules to be made in places that no gas pipe should be allowed come in contact with any wood-work.

Turning next to the dangers which might be expected from the electric lamp, it is to be remarked in the first place, that these in the case of the arc lights depend much upon the number of lamps operated on the same circuit. Thus if thirty or forty lamps are operated in series, the electro-motive force of the currents must be sufficient to maintain a correspondi number of arcs; and, therefore, if by any mea many of these arcs are closed out the elec motive force of the current available for t maining ones would be so excessive that the arcs might become excessively long, and ev the metallic carbon holders and other parts the lamps constitute poles between which arc would spring, melting the metal work establishing a very dangerous course of ex bustion.

To avoid this class of dangers two provisio should be made.

In the first place some arrangement in t lamp itself by which, whenever the arc exce certain safe limits, the current will be aut matically diverted from it and through a strong a good and sufficient conductor; and, in t second place, some simple apparatus in connectio with the electric generating machine by which the electro-motive force of its current should be varied automatically in correspondence with the resistance of the circuit, so that any diminutio of such resistance, as by the closing out several arcs, should cause a correspondin diminution in the force of the current generated

Numerous contrivances for both of these purposes have been already carried to greater or less perfection and efficiency, and it is manifestly possible by such means to secure immunity from risks of this sort.

The securing of adequate insulation for the conducting wires in view of the endless ramifications of telegraphic and telephonic systems, to say nothing of the other conductors found in all buildings is a problem of no small difficulty.

One important general principle would seem to be the equal insulation of the return as well as of the outgoing wires, as also of the machines, and the avoidance of all ground connection for any part of the circuit. Another general rule would be the separation of outgoing and return wires as far as possible from each other; and yet another, the continuous insulation of conductors leaving no vulnerable places even where danger would not directly result from accidental contact.

Fully to discuss all the details of this subject would be impossible within the proper limits of such a note as the present, and I will therefore only say in conclusion that, with well matured plans and skillful and intelligent provision, these dangers may be provided against and electric lighting may be made as safe as that obtained by gas or by candles; but without such care and judgment the use of electricity on the grand scale either for lighting or for transmission of power, would involve serious additions to the risks which accompany so many of the conveniences which constitute a large factor of our modern civilization.

Elektriska belysningen.

Det ena af förra tvenne stallarna, som blifvit ombyggda till elektrisk belysning, hvilka komma att användas i närvarande skola, derest ej naturhinder möta, tagas början i afton. Såsom bekant är, det på Gustaf Adolfs torg och Norrbro samt Bron emellan, kommo att användas. De stolpar, som för några 16l sedan på dessa platser upprestes, hafva nu blifvit försedda med elektriska lampor, hvarjemte de medelst kablar, genom hvilka den elektriska strömmen skall passera, förenats med det nedanför rådhuset uppförda trånskjul, i hvilket elektricitetsmaskinen finnes uppställd. Ytterligare upplysningar beträffande följande beskrifning öfver det nya belysningssystemet:

I aftonen äger man en lokomobil af 15 nominella hästkrafter, en större elektricitetsmaskin fullt monterad, en mindre eldad ångpanna, uppställdes samt en mängd lampor af olika storlekar. Så väl elektricitetsmaskiner som lamper tillhöra amerikanen Brush's system, hvilken det samma som med så stor framgång blifvit vid förra London City. Att beskrifva dessa sätt, hvarpå strömmen genereras, skulle utan tillhjälp af teckning vara försöket värdt. Vare det nog sagdt, att Brush's maskiner äga till synnerliga interesse med hänsyn till den ovanligt höga tensionen lika väl som styrkan hos den stadin de genereras. Kablarne bestå af 7 hvarandra lagda koppartrådar af omkring ½ millimeters tjocklek och äro omgifna af en isolerande, tjocklagd, lampen förenas genom en nyckel stenrik sprängning så inrättade, att de dela lemna obehindrad passage åt strömmen, ifall de icke äro tända, dels af sig själfva, d. v. s. genom strömmens inverkan, reglerne med hänsyn till kolstavarnes tändlängd. Skall en lampa tändas, låter man strömmen passera genom spiralformigt vickad koppartråder, som omgifva öfre delen af ett ankare, vid hvilket öfre kolspetsen är fäst. I följd häraf uträtbaras ankaret och upplyftes öfre kolstången, så att en elektrisk fjunkbåge uppstår mellan kolpetsarne. Två per bolaltiga äro lampor i hvarje lampa. Bestå den öfre ättogen förbrända. Då den ena, förbrukad, tänna lampan förloppa, är upptänd, enkastas strömmen af sig själf, så att den andra lampan antändes. En Brush's lampa kan således brinna 10 timmar utan att vårdnas af maskinskund.

Af Brush's lampor äro uppsatta 9 på Gustaf Adolfs torg, 8 på Norrbro och 4 framför nuvarande slottsflygeln, tillsammans alltså 16 lampor. Alla metalla äga samma maskin. Ljusstyrkan hos hvarje lampa skiftar vara lika med 2000 normalljus, d. v. s. öfver 100 vanliga gas-lågor. Ljuset är dagsljus. Dagarna finnas tanken kommande att små luftstorma glasglober, i hvilka en konst elektrokemisk metallrid bringas till glödgning i egenom strömmens inverkan. Sådana lampor inuti de fästa för belysning hos hus. Förut-nämnda dermed lära först komma att anställas å Norrmalm och Ryssbacken.

Samtliga maskiner och materialier för den elektriska belysningen förskrifva sig från den engelsk-amerikanske Brush-bolaget, som redan beskrif öfvan nämda belysningsföretag i den engelska huvudstaden.—

The Edison Electric Illuminating
Company of New York.
65 Fifth Avenue.

New York. 188

succeeded so well in London. To describe how the current is generated, would be impossible except by aid of a drawing — It will be enough to state, that the Brush system is particularly noticeable on account of the high tension of strong current generated. The cables consist of seven copper wires of ¾ Millimeter thickness, which are carefully isolated by tared hemp. The lamps are very well made so that the current passes through them when not lighted and also automatically regulating the distance between the points of the carbon candles of a lamp is to be lighted the current is allowed to pass through spiral shaped wire which surround the upper parts of an anchor by which the upper electric candle is fastened — In consequence there of the anchor is attracted and the upper candle lighted. Two kinds of carbon candles are used in every lamp, only the upper is burnt. The current is automatically conducted to the other candle part of

The Edison Electric Illuminating Company of New York.
65 Fifth Avenue.

New York. 1883

the lamps a Brush Lamp can therefore burn 10 hours without any help from Man. Of Brush's Lamps, 6 are on Fürstrans Adolphus Square, 6 on the North Bridge, and 4 in front of the N. W. Wing of the Royal Castle, together 16 lamps fed from one engine. The power of the candle is said to be equal to 2000 normal candles or 150 common Gas flames. There are besides smaller lamps, consisting of glass globes that are free from oil, in which a horse shoe formed metal thread is brought to white heat by action of the current. Such lamps are meant to be used indoors. Trials with them is expected to be made in Hotel Rydberg. All the engines are worked by the English Brush Company which have already made trials with the electric light in London.

$2 Sunday Engineer Oct. 1881.

Under the title "Real Workers in Electric Lighting," the *Tribune* quotes from the *London Electrician* the following statement, which well expresses the exaggerated degree to which, in some quarters, the public has been led to expect impossibilities in electric lighting:

The non-technical papers, totally ignorant of the scientific aspects of the case, have introduced into the popular mind ideas altogether erroneous, yet so abiding that they still exist. The divisibility of the electric light is what the misery and slow say the inventors are endeavoring to find, and think that, to a certain extent, success has been achieved. It is impossible to drive away the illusion and to enforce the doctrine that on this direction nothing new has been or is likely to be done. Mathematicians know years ago as much about resistance, lamps in "series," or in "multiple arc," as they know now. It was not in this direction that science was working at all. The men who have developed the properties of electric lighting are those who have worked at the perfecting of the steam-engine as a motor for the dynamo-machine, who have improved the dynamo and magneto machines, so that the current is more economically generated, who have experimented in every direction, and added minor improvement after improvement to the arc and incandescent lamps—these are the men who have made electric lighting not only practicable, but the light of the immediate future.

ACCORDING to *La Lumière Electrique*, M. de Pezzer has made some important modifications in the Planté pile. Instead of the thick lead plates usually employed he uses very thin plates, the negative electrode being ½ millimetre in thickness, and the positive 2½ of a millimetre. Moreover, he makes the positive plate but one-half the size of the negative. M. Pezzer claims that with these modifications he can store the same quantity of electricity as with plates of greater thickness constructed in the ordinary way.

Record

Journal Oct. 1881

ELECTRIC LIGHT NOTES.

It is reported that Mr. Brush, of Cleveland, has invented a storage battery which he claims is far superior to that of M. Faure. The details of its construction will not be made public until patents have been issued.

A portion of the Junior Carlton Club, London, is lighted temporarily by incandescent lamps, the electricity for which is furnished by Faure's secondary batteries. There are 40 of them sufficiently charged to maintain 15 lamps for six hours.

The Brush Electric Light Co. have commenced the lighting of the towers in Union and Madison Squares, but the results are by no means encouraging to the company, or agreeable to the people. The difficulties, however, will doubtless be remedied entirely or in part after further trial.

There are sixteen electric lamps in the Laboratory Department of the Woolwich arsenal. The workmen while appreciating the purer atmosphere resulting from this method of illumination, complain of the shadows cast upon their work, and also that the intensity of the light impairs their eyesight.

Mr. Edison has constructed a dynamo machine of sufficient power to operate 1,000 incandescent lamps. It contains twelve magnets, each weighing about 685 pounds, and cost $6,000. It is intended for a station at Charing Cross, London. It is stated that Mr. Edison is constructing some dynamo machines of very large size for use in lighting the district in the lower part of this city.

A correspondent of the London *Times*, writing of the Paris Exhibition of Electricity, mentions several novel applications of the electric current as a motive power. The plowgliding machine of M. Menier, the circular saw three feet in diameter, a stone cutter and electrical hammer of M. Pint attract considerable attention. There are machines for pumping water, and rock-drilling, besides a number for sewing and embroidering.

At the meeting of the British Association at York, Mr. J. H. Wigham, of Dublin, read a paper on the use of gas for lighthouses, in which he claimed that gas could furnish the great volume as well as the great intensity of light which would be desirable. Of late years the system of lighting by naked gas flames in connection with the ordinary dioptric apparatus, has come to be fully recognized as of great importance. The advantages possessed by longer gas flames over flames of the ordinary focal size were pointed out as being equality to be found in revolving and flashing lights as in fixed lights." The penetrating effect of the gas flame in foggy weather is far greater than that of the electric light of even greater power, for the simple reason that the former contains a greater proportion of the red rays than the latter, and it is the red rays which are least obscured by fog.

In our last issue we referred to the opinion of Prof. W. Thomson on the possibility of utilizing the water-power of Niagara Falls in the production of electricity to be conducted to a distance and there converted into light and heat. It seems there is a plan being discussed for making the experiment, but on a small scale as compared with the suggestions of Prof. Thomson. It is proposed to form a company, place dynamo-electric machines at the Falls, to be operated by the very large water-wheel recently constructed there, and to convey the electric current to Buffalo, there to be used for the purpose of light or motive power as may be desired. The experiment will certainly be a most interesting one, and it well managed will help to settle the question as to how far it can be put to the immense power of the Falls can be economically utilized at a distance. Prominent electrical engineers consider that the thing can be done, but the real question to be settled is—will it pay?

and payment of the dividends, the same was carried unanimously"; as also the re-election of Messrs. Henry Wood and Henry Willis as Directors, and Mr. George Willis as Auditor.

Mr. Cuthbert Quilter, in seconding a vote of thanks to the Directors for their past services, expressed a hope that they would see their way to reducing the price to furnish the Shareholders with copies of the accounts and report.

After a vote of thanks to the Secretary and Officers of the Company the meeting separated.

LEICESTER CORPORATION GAS AND WATER SUPPLY.

A Quarterly Meeting of the Leicester Town Council was held last Thursday—Mr. MARTIN (Alderman) J. Bennett presiding—when the following report of the Gas Committee was submitted and read:—

The Gas Committee have to report that the accounts of this undertaking for the half year ending the 30th of June last have been audited by the Borough Auditor, and that the results are by no means encouraging to the company, or agreeable to the people. The difficulties, however, will doubtless be remedied entirely or in part after further trial.

There are sixteen electric lamps in the Laboratory Department of the Woolwich arsenal. The workmen while appreciating the purer atmosphere resulting from this method of illumination, complain of the shadows cast upon their work, and also that the intensity of the light impairs their eyesight.

Mr. Edison has constructed a dynamo machine of sufficient power to operate 1,000 incandescent lamps. It contains twelve magnets, each weighing about 685 pounds, and cost $6,000. It is intended for a station at Charing Cross, London. It is stated that Mr. Edison is constructing some dynamo machines of very large size for use in lighting the district in the lower part of this city.

A correspondent of the London *Times*, writing of the Paris Exhibition of Electricity, mentions several novel applications of the electric current as a motive power. The plow-gliding machine of M. Menier, the circular saw three feet in diameter, a stone cutter and electrical hammer of M. Pint attract considerable attention. There are machines for pumping water, and rock-drilling, besides a number for sewing and embroidering.

At the meeting of the British Association at York, Mr. J. H. Wigham, of Dublin, read a paper on the use of gas for lighthouses, in which he claimed that gas could furnish the great volume as well as the great intensity of light which would be desirable. Of late years the system of lighting by naked gas flames in connection with the ordinary dioptric apparatus, has come to be fully recognized as of great importance. "The advantages possessed by longer gas flames over flames of the ordinary focal size were pointed out as being equality to be found in revolving and flashing lights as in fixed lights." The penetrating effect of the gas flame in foggy weather is far greater than that of the electric light of even greater power, for the simple reason that the former contains a greater proportion of the red rays than the latter, and it is the red rays which are least obscured by fog.

In our last issue we referred to the opinion of Prof. W. Thomson on the possibility of utilizing the water-power of Niagara Falls in the production of electricity to be conducted to a distance and there converted into light and heat. It seems there is a plan being discussed for making the experiment, but on a small scale as compared with the suggestions of Prof. Thomson. It is proposed to form a company, place dynamo-electric machines at the Falls, to be operated by the very large water-wheel recently constructed there, and to convey the electric current to Buffalo, there to be used for the purpose of light or motive power as may be desired. The experiment will certainly be a most interesting one, and it well managed will help to settle the question as to how far it can be put to the immense power of the Falls can be economically utilized at a distance. Prominent electrical engineers consider that the thing can be done, but the real question to be settled is—will it pay?

The Committee have further to report that about the middle of last year they received a communication from the Corporation Surveyor, Mr. Paget, calling their attention to the fact that the Corporation Surveyor had been instructed by the Council to prepare plans for the purpose of erecting the abutments to the Freer Law Estate; and subsequently Mr. Joseph Firth, the Borough Engineer, had been instructed to prepare plans for the widening of the bridge. The latter work was first carried out. The Committee subsequently superintended the various portions, and £21,311 19s. 7d. in February last was paid to the contractor, Mr. Thomas Firth, of Sheffield, on account of the widening of the bridge, and which completed the contract price to £24,200, exclusive of £1035 1s. 6d. duties of superintendence, engineer, and subsequently interest, and £1,888 19s. 5d. duties of engineer, surveyor, auditor's fees, and incidentals, which will be paid in the present half year's accounts, making the total cost of the bridge £27,124 0s. 11d., which will be payable to the general account fund at the close of the present half year.

The reduction in the price of gas, as approved by the Council in March last, has not yet been carried into effect, the necessary alterations, as they took effect from the 1st of July last, having been delayed.

Your Committee have further to report that about the middle of last year they received a communication from the Corporation Surveyor, Mr. Paget, calling their attention to the fact that the Corporation Surveyor had been instructed by the Council to prepare plans for the purpose of erecting the abutments to the Freer Law Estate; and subsequently Mr. Joseph Firth, the Borough Engineer, had been instructed to prepare plans for the widening of the bridge. The latter work was first carried out. The Committee subsequently superintended the various portions, and £21,311 19s. 7d. in February last was paid to the contractor, Mr. Thomas Firth, of Sheffield, on account of the widening of the bridge, and which completed the contract price to £24,200, exclusive of £1035 1s. 6d. duties of superintendence, engineer, and subsequently interest, and £1,888 19s. 5d. duties of engineer, surveyor, auditor's fees, and incidentals, which will be paid in the present half year's accounts, making the total cost of the bridge £27,124 0s. 11d., which will be payable to the general account fund at the close of the present half year.

The reduction in the price of gas, as approved by the Council in March last, has not yet been carried into effect, the necessary alterations, as they took effect from the 1st of July last, having been delayed.

Your Committee have further to report that they have had under consideration the question of the electric lighting of the Town Hall, and have had several interviews with Mr. Swan, and they have also had the advice of Mr. Preece, the engineer to the Post Office, as to the best mode of lighting the Town Hall by the electric light

Journal of Gas Lighting &c. Oct. 1887.

The Expenditure of Energy in Incandescent Electric Lighting.

At the York meeting of the British Association, Sir W. Thomson and Mr. Hottenley gave the results of some experiments carried out by them in order to determine the illuminating power of incandescent vacuum electric lamps with various strengths of current. Every lamp was tried with higher and higher potentials until the carbon broke. The electricity was obtained from a number of Faure's cells, of which 20 were first put in circuit, developing 0·003-horse power, and others were added until the lamp was destroyed. Three lamps only were tried, the first of which broke down after fourteen experiments; the second lasted through fifteen tests; and the third broke before the third reading could be completed. With 20 cells the first lamp gave the illuminating power of 11·6 candles; four more cells then brought it up to 25 candles; with 32 cells it showed 42-candle power; and successive additions of cells forced the light up through a very irregular scale until, when giving the maximum of 114-candle power, the carbon gave way. The next lamp was first tried with 40 cells, affording 0·27-horse power, and giving the light of 19 candles; and the lamp broke when connected with 70 cells, when the light would have been over 200 candles. The irregularity of all the records is very striking, the power of the batteries and the light given by the lamps being very uncertain and by no means increasing in any common ratio. For example, the first lamp gave the light of 81 candles, with the expenditure of 0·217-horse power from 56 cells. The next lamp, with the same number of cells, gave only 49-candle power in one instance, and 32 candles in another, although the energy of 0·27-horse power was recorded, or nearly the same as before. Again, the second lamp gave 186-candle power with 66 cells, while the addition of 6 more cells, instead of increasing the light, brought it down to 180 candles. Much of this variation is said to be caused by the blackening of the interior surface of the globes by the deposition of volatilized carbon, when high powers were applied. The photometric method employed by the authors consisted of directly comparing the depth of shadows thrown by a pencil on a piece of white paper, and the candle employed was the usual standard sperm article, assumed to burn at the normal rate, but not weighed, as the object of the experiments was simply comparative.

Art and the Electric Light.

It may be remembered that when the announcement was made in the spring of last year, that the electric light was about to be adopted for illuminating the Paris *Salon*, a good deal was said, both in the English and the French Press, as to the superiority of the intensely over gas for the lighting of picture galleries. After a few preliminary difficulties had been overcome, the light was brought into use, and the public—influenced, probably, by what they had read in the newspapers—were loud in their praises; and, judging from the public prints, there appeared to be for once a general and mutual feeling of gratitude to the authorities for the adoption of the new system of lighting. This happy state of affairs, however, did not last. After the electric light had been for a short time in operation, a protest against its use was raised by some of the artists whose pictures were being exhibited. They complained that the light was not a good one for showing off their productions, and urged its discontinuance. But the remonstrance came too late. The contract with the electric light company had been signed, the necessary appliances were all fixed, and the light was allowed to illuminate the *Salon* for the remainder of the season.

It would have been thought that the action taken by the artists last year would have led to a repetition of their remonstrances when the determination of the authorities to again employ the electric light this year in the *Salon* became known; but we are not aware that any steps were taken. At any rate the light was once more brought into use, and was heralded with much the same flourish as on the previous occasion. It may be presumed, however, that the artists, though silent, were not altogether enraptured with the new illuminant; and so far as may be gathered by the remarks contained in a characteristically French article, emanating from the pen of M. Charles Kurner (which appears in the current number of *La Cour*, gentlemen of the brush will not be inclined to regard its introduction as an unmixed blessing. The writer of the article in question is of opinion that the light will in time entirely supersede the employment of gas for the lighting of picture galleries, but he believes that it will cause some trouble to artists in the mixing and employment of their pigments. "This superb invention, the electric light," he writes, "will upset our ideas, depreciate our *chefs-d'œuvre*, and convert our masterpieces into patterns for paper-hangings." All this is, he says, owing to the colour of the light, which, according to the statements of the electricians, should be pure white, but is in reality—at least, so M. Kurner says, speaking of that used for lighting the pictures in the Electricity Exhibition—"pale and wan, bluish, violet, and lilac;" and consequently when it is employed certain colours produce effects which are not exactly in accordance with artistic notions. He then makes special reference to several pictures which were exhibited in the *Salon* this year, and are now on view in the eastern gallery of the Palais de l'Industrie—of course, illuminated by the electric light; and with very few exceptions his remarks are altogether condemnatory of the light. One exception is in the case of the painting representing the meeting of Dante and Matilda—

> A lady all alone, who, singing, went,
> And culling flower from flower, wherewith her way
> Was all o'er painted.

The picture is composed of figures, phantoms, and flowers, over which the electric light throws a strange, unearthly pallor, which rather heightens the effect of the artist's work.

It is needless to follow M. Kurner in his remarks on the various paintings exhibited, as viewed by him under the electric light; or to indicate those points where he considers the effects intended to be produced by the artists have been perverted, if not entirely marred, by the medium employed for the illumination of the gallery. He confesses to being somewhat hard in his remarks; but he assures his readers that they are made in all sincerity. He is one of those who approve of innovations in the arts; but in the present case he says he is in a dual between the arts and the electric light, and the question is, which is to give way? The electric light will not; therefore it will remain for artists to arrange their subjects and prepare their colours to suit the new illuminant—in other words, to abandon the old order of things and adapt themselves to the new. Are they prepared to do this? M. Kurner answers emphatically, "*Jamais!*"

Journal of Gas Lighting &c. Oct. 1887.

The Utilization of Water Power—A New Discovery.

In the dull season, which is now at its nadir, a very small item of news only is required to form the motive for a column of commonplace in the daily newspapers. The broad sheets must be filled somehow, and since sea serpents and gigantic gooseberries have become suspected by the general public, other curiosities have to be sought for. The wonders of electricity have for some weeks been largely drawn upon by hard-pushed leader writers, whose sublime ignorance of scientific truths is balanced by the possession of imaginations untrammelled by considerations of fact. The Paris Electrical Exhibition having been worked out as a theme for similar amateur utterance is available. The *Daily Telegraph* had a long leading article, on Friday last, on the apparently insignificant circumstance that an fledgling an electric lighting experiment is being carried out, the motive power for the generators being a water-wheel, instead of the usual steam or gas engine. A reader of our somewhat sensational daily contemporary, unless previously instructed to the contrary, would be induced to believe that the institution of water-wheels is a novel and startling innovation, for which the Godalming millwrights deserve infinite credit. We are told in the scholarly article in question, how the stoker and collier are to be in a great measure dispensed with if the Godalming example be followed. The contagion is said to be already spreading, and that Guildford also "is to be illuminated by the brilliant ray of the electric vibration." The same well-informed writer also reminds us that "Sir William Thompson (*sic*) has long ago lighted his mansion in Scotland by a stream of the burn which wimples near it." The mis-spelling of the Glasgow professor's name is a trifle to the *Daily Telegraph*, but this error might be still less important if the story were otherwise correct. As a matter of fact, most people interested in the subject are aware that to Sir William Armstrong, in Northumberland, is due the credit for the idea of lighting his house by the power of a brook. To proceed, however, engineers and others do not require to be told that water power is liable to the three elements—a flood, drought, and frost, all which cause total stoppage of the machinery. These things are conveniently ignored by the *Daily Telegraph*; but those who saw us remember last January, and the annoyance caused even to Gas Companies and their customers by the fearful frost, we cannot regard the coming winter as being devoid of the possibility of troubles to the wise men near Guildford. We may be tolerably certain that if the water-power scheme of electric lighting breaks down there, the *Daily Telegraph* will have its columns too full of other matter to report the fact. For the present, our reflections on the "all talk" of our contemporary may be thus expressed: Whereas it was once the remark of a keen observer, "With some spirit exclaim, "Soo what little knowledge is required to compose a quasi-technical article for a newspaper which boasts of the largest circulation in the world!"

Electric Lighting in America.—In the matter of electric lighting, America would certainly appear to be far in advance of this country. Englishmen are oftentimes disposed to, view with doubt and suspicion accounts of what is done on the other side of the Atlantic, and there can be no question that in regard to this subject of electrical illumination doubt and suspicion have been freely expressed, when the doings of the Americans are referred to. We are bound to confess, however, that if the reports which reach us from time to time are at all to be relied upon, and in most instances they emanate from sources which we are prepared to accept as thoroughly reliable, the old country has in this matter a long way to go, so far as the use of electricity for ordinary interior lighting is concerned, by no means taken the lead. We have always regarded with undigested satisfaction the steps that have been taken, chiefly at the risk of Frenchmen, partly of English speculators, towards lighting parts of London and some other towns by electricity, and also the adoption of this mode of lighting in numerous private business establishments, &c.; but neither in England nor on the Continent have there yet been established general lighting stations, to supply the electric light after the fashion of gas-works. We are of course aware that some enterprising firms are now seeking to establish central stations of this character, but nothing at all practical in this direction has yet been accomplished here. In the United States, however, we are told that "no considerable city is without such an institution." At Salt Lake city an arc-lighting system has for some months supplied electric light to subscribers' customers. In Denver, Colorado, a city of 35,000 inhabitants, above 200 arc-lights are supplied to shops, hotels, &c., by a company; the light in each case being furnished at from 20 per cent. to 30 per cent. below the price of gas, as well as being much greater in quantity. The Salt Lake company is said to have been the first in the world to supply electric light in direct competition with gas. The returns to the proprietors are stated to be lucrative in the extreme. The system referred to has been attacked in America precisely as, thirty or forty years ago, the manufacture of gas was introduced into our smaller towns. A local company having been formed, a concession from the patentees of the system chosen is arranged for; ground is bought, buildings are erected, and engines, boilers, dynamo-machines, and the whole light-producing apparatus are purchased and erected. Powerful engines are employed with fly-wheels weighing from 8 to 10 tons, in order to have steadiness and uniformity of motion, the absence of which (so one informant writes) is evinced by that flitting, fleshy-like pulsation of light with which we have become familiar on the banks of the Thames. Wires are conducted either under or over the streets, to be supported where required, in the same manner as gas-mains. Automatic contrivances, for the purpose of turning light on and off at pleasure, are supplied with the lamps, which are visited and kept in order by the servants of the company. The result appears to be the advance of electric lighting all along the line. The use of masts or towers of the height of 250 ft. for the lighting of squares and streets is also becoming general. The city of Denver is lighted from lofty towers, and for the price formerly paid for gas four times the area is now lighted by electricity. In the city of Albany gas-electric lights, placed on alternate blocks, have replaced some 2,000 gas and oil lamps. Akron, in Ohio, is lighted from towers; and Wabash, Ohio, by four lights on the steeple of the Court House. In New York there are competing companies, one of which is now supplying 1,000 lights to shops, and is prepared for 4,000 more. Most original of all is the application of this source of illumination at New Orleans, where the companionship of the night is now selected for running the races of the Jockey Club by the light of electricity. We could add instances innumerable of the adoption of electricity as a practical and commercial means of lighting not only the public streets and large buildings, but ordinary interiors. This probably we have already alluded sufficiently to what is being done by the Americans to show that, beyond doubt, they are in advance of us in the matter; and to show, further, that the steps that are now about being taken in this country for the purpose of rendering the electric light available for every-day use in hotels, theatres, business premises, and even in ordinary dwelling-houses, are not, as some persons so persistently assert, a part of any impossible or impracticable scheme, but are, on the contrary, measures shown by experience to be capable of yielding a fair return to the parties adopting them, and calculated to prove of the greatest advantage to the community.

THE METROPOLITAN.

NOVEMBER 26, 1881.

Gas, Water, and Electricity.

The Paris Electrical Exhibition, which finally closed its doors on Monday, would appear to have proved as great a success financially as in every other respect. It is now stated to have realised a net profit of over £20,000. An immense crowd besieged the Palais de l'Industrie on Sunday, admission being free. In the evening, when the exhibition was illuminated for the last time, there was scarcely standing room either in the main hall or the galleries, most of the visitors being of the artisan class. The total number of closing exhibitions by a general letting loose of all the noisy elements contained in the show was observed on this occasion with an almost deafening effect. Shortly before eleven the whistles of all the steam-engines and every electric bell in the building were set going, making such an inharmonious din as was certainly never heard before. Fortunately for the hearing powers of the audience, the scene lasted but a few minutes, and had the desired effect of clearing the palace of its thousands of visitors.

Edinson's System of Electric Lighting in the City.—Londoners will shortly be afforded an admirable opportunity of judging for themselves of the practical value of the Edison system of electric lighting as a general and economical means of illumination for both exteriors and interiors. The Edison Electric Light Company recently applied to the City Commissioners of Sewers for permission to light at own cost, for a period of two months, "all the existing gas lamps on the Holborn viaduct as far as the subway extends, and also the bridge and the four towers," they undertaking that the light shall be as good as and not to interfere with the gas. The Commission have decided to allow the company to make the experiment, and the necessary preparations are to be proceeded with forthwith. We believe, however, that the Edison Company do not intend confining themselves to the lighting of the roadway of the Viaduct, but will be prepared to supply and maintain any number of lamps in houses or business premises in the immediate vicinity. In a future issue we hope to be able to furnish our readers with further particulars of this interesting installation; but, as an illustration of what is aimed at, we may, perhaps, state that the Edison System, according to its promoters, contemplates universal lighting of exteriors and interiors. Every detail of a comprehensive system, it is asserted, has been worked out, and is ready to be put into practical operation for the purpose of demonstrating its efficiency. All questions affecting the substitution of electric for gas light have received due consideration, and a degree of economy of production, distribution, and consumption is said to have been attained which will prove of successful commercial competition with gas.

Corporations and Gas Profits.—The question of the disposal of profits realised by Corporations and Local Boards in respect of their gas-works is one which very frequently arises in those cities and towns where the gas supply is in the hands of the public authorities, and varied in the extreme are the opinions expressed as to how gas profits should be appropriated, directly or indirectly, in relief of rates, or indeed to any outside purposes. There seems every probability that in the ensuing session this question will be brought specifically before Parliament. The Paddiham and Haydon Local Board have announced their intention to apply for an act for the following among other objects:—"To authorise the Board to supply any artificial light within their district, and to apply profits from the gas-works for redemption of water annuities." We hear that steps are being taken in order that in connection with this Bill the general question of principle shall be considered in all its bearings, regard being also had to the position of one or two other towns of a typical character, and an authoritative decision obtained.

The Storage of Electricity.—This was the subject of the lecture on Wednesday at the Society of Arts, the lecturer being Professor Sylvanus Thompson, of Bristol. Professor Adams presided, and the room, which was crowded, was lighted during the lecture by two groups of suspended Edison lamps connected with 40 Faure cells brought to the building ready charged. Professor Thompson said the electric storage of energy must not be mistaken for the storage of electricity itself. Electricity, like heat, was a kind of work done was as much chemical as electrical.

J. P. Thomson, Bristol.

AN ELECTRICIAN'S VIEWS ON ELECTRIC LIGHTING.

Mr. Ellershausen Hodges' practical knowledge of electric lighting should peculiarly fit him for writing a small book on the subject, intended for general readers; although his well-known personal and professional interest in a part of the matter as which he treats would naturally lead us to refuse him the position of an unbiased arbiter of science. Hodges' book has now arrived at the dignity of a third edition, the first having been published in 1878. In his preface to the third edition the author refers to the period of four years which has elapsed since his work first appeared, and states his conviction that electric lighting having in this time "passed out of the hands of the experimentalists, has taken a recognised position as the illuminant of the nineteenth century." In the first edition Mr. Hodges apologised for saying little as to the cost of different systems of electric lighting; and in the present edition this branch of the subject will be found to occupy a chapter to itself. In regard to incandescent lighting, which the author elsewhere acknowledges to be the system in which public opposition is principally directed, he candidly states that it "is because the success in practice believe it will, it is still doubtful whether it will ever be sufficiently economical to warrant its superseding gas in all cases;" and that, "although Mr. Edison says to the contrary, it is a question whether heat for cooking purposes could be practically produced at all; and even if it were, the cost would be enormous." Mr. Hodges says, however, that arc lighting should be one-third cheaper than gas; but as he appears to rate gas at about one-third of its actual luminous value, when employed in the most powerful flames necessary in comparison with arc light, the comparison is not so advantageous to electricity after all. The author gives tables of the cost of some of the best installations of arc lighting, by which he seeks to prove that when used in large centres, electricity is cheaper than gas. He confesses again that the case is reversed with incandescent lighting; and, as usual with gentlemen of his way of thinking, he begs the whole question of distribution by asserting, without a shadow of evidence, that this will be altered when "the current is generated at a central works, and supplied like its either fluid." With regard to street lighting, Mr. Hodges confesses that gas must still be employed for the narrow thoroughfares, but asserts that the electric lighting of the City is a success "except in the material one of cost." In respect of lighting-power, the author quotes Professor Morton, of Hoboken, New York, who states that the power of an electric arc lamp is equal by day to that of an oil lamp, which is ordinarily rated in the proportion of 10 to 1. Mr. Hodges kindly devotes a few paragraphs to the purpose of reassuring fluid gas-shareholders as to the continued value of their property. He acknowledges that the present position of the gas industry in this country is due to the continued exercise for 70 years of the most praiseworthy enterprise, and believes that the results of this enterprise will remain valuable. This little work is, on the whole, a well-compiled account of facts, accompanied by a fair and interesting commentary, and is calculated to impart much valuable information to unprofessional readers.

LA PERSEVERANZA DI MERCOLEDI'

Mercoledì, 27 Febbraio 1882

La luce Edison a Milano. — Il distinto prof. cav. G. Colombo terrà fra breve una conferenza sopra l'illuminazione elettrica, sistema Edison, introdotta in Milano, con tanto prove di esperimenti riusciti a meraviglia, dall'egregio ed infaticabile James Shepherd, il quale volle in questi giorni fare un dono all'istituto tecnico di S. Maria e all'istituto tecnico superiore di quattro lampade Edison a incandescenza.

La conferenza sarà tenuta nelle sale del Ridotto al Teatro della Scala, le quali verranno come le sere precedenti, illuminate da lampade Edison di un sistema semplicissimo e proiettanti una luce tanto limpida e chiara da confondere qualsiasi altra luce.

La lampada Edison infatti da una luce calda, vivida, fissa, che non altera i colori del viso, nè delle vesti; il blu, il rosa, per esempio, restano blu e rosa, e non paiono, come col gas, verde e vermiglio.

La prova del Ridotto della Scala persuaderà della superiorità di questa luce non solo una sala, ma tutto un teatro, compreso il palcoscenico; poichè, data la facilità, come è il caso di questa luce, di moderarla a piacimento e di darle anche le tinte che meglio converranno; parrebbe risoluto il problema delle esigenze degli spettacoli, e tutto il fatore e il toglierlo dal lumi della ribalta sarebbe un notevole vantaggio per gli attori e i cantanti), vien tolta la causa principale d'incendio.

L'impressione che è esperimento ha prodotto in me e tutti i presenti è che il sistema dell'Edison, introdotto fra noi dall'egregiare Shepherd, fa entrare nel campo pratico l'applicazione della illuminazione elettrica negli ambienti chiusi e negli usi comuni della vita.

Anzi il signor Shepherd, che si è assunto con ferrea volontà il difficile compito di diffondere la luce Edison in Italia, colla perizia nacia del suo volere riuscirà senza dubbio a rimuovere alle nostre difficoltà che gli si oppongono, e l'Edison non poteva trovare un più intraprendente, operoso e tenace rappresentante.

James Shepherd ha già iniziato la via Stella una Stabilimento in cui farà l'applicazione del nuovo sistema di luce elettrica e l'Edison visitando l'Italia e Milano, farà senza dubbio stasio al suo carattere fermo e perseverante.

Attualmente si trova a Londra una esposizione d'elettricità ed in tutte le Compagnie sono rappresentate, e, quantunque l'installamento sia incompleto, vi funzionano 2000 fiamme. Ebbene l'Edison vi alimenta 2 4 giobi con una macchina a vapore d'una forza di 25 cavalli ed il suo sistema porta la palma su tutti gli altri e siamo certi che anche a Milano l'illuminazione elettrica con questo sistema farà, stante la sua eccellenza, continui progressi e verrà giorno in cui tanti privati, pubblici stabilimenti, istituti, negozi, caffè e case private vorranno illuminati con la luce elettrica di Edison.

L'Edison, il genio di Menlo-Park, può dirsi il Promoteo moderno, ed ha trovato in Italia un apostolo fervente, e piano d'abnegazione nello Shepherd, che non risparmia nè cure, nè fatiche, perchè la luce elettrica trionfi.

LA PERSEVERANZA Dio. par.
DOMENICA, 12 FEBBRAIO

La luce elettrica Edison alla Scala.

L'infaticabile signor James Shepherd, rappresentante in Italia della Società Edison, per far apprezzare degnamente il sistema, ha con questi illuminato il salone del ridotto della Scala, venerdì sera, in prima delle esperimento, che durerà quindici sere, la Commissione municipale incaricata di studiare l'applicazione della luce elettrica ai teatri, in questo vedere e giudicare come piccolo lampade del celebre inventore americano.

Il successo non poteva essere più bello e completo, tanto più che risaltava il confronto colla luce dei lampadari a gas delle sale attigue.

Come si sa, il salone del ridotto ha tre lampadari con 50 becchi a gas, complessivamente. Ebbene, precisamente su questi 50 becchi che il Shepherd ha infisso 52 lampade Edison, della forza di 8 candele ciascuna, oltre ad una trentina comuni a gas.

La lampada Edison di una luce calda, vivida, fissa, che non altera i colori del viso, nè delle vesti: il blue, il rosa, per esempio, restano blen e rosa, e non paiono, come col gas, verde e vermiglio.

La lampada Edison sono di tre categorie, della forza cioè di 16, di 8 e di 4 candele, il secondo per tutti gli usi, anche per i più modesti di servizio domestico, se ne può regolare, moderare, attenuare, come e quanto, la forza, e sono indipendenti l'una dalla altra. Quelle applicate ai lampadari del ridotto sono, come abbiamo detto, della forza di 8 candele.

Un altro vantaggio del sistema sta nella facilità della sua colazione, in quanto che alle lampade Edison possono servire di sostegno gli stessi apparecchi dei gas.

La prova dell'altra sera persuase alla opportunità di illuminare non solo una sala, ma tutto un teatro, compreso il palco scenico, poichè, data la facilità di moderare a piacimento la luce e di darle anche le tinte che meglio convengano, parrebbe risoluto il problema delle esigenze degli spettacoli, e tutto il fatore e il toglierlo dai lumi della ribalta sarebbe un notevole vantaggio per gli attori e i cantanti, e tolta la causa principale d'incendio.

In questo esperimento l'egregio J. Shepherd fu assistito dal sig. Cabenon, perito elettricista, allievo di Edison.

I lili sono riusciti di una maestria inconcepibile, che ora si possono vedere, perchè trattasi di un esperimento, e che diversamente sarebbero mascherati.

Nel sistema Edison si completano a vicenda la lampada, la macchina dinamo-elettrica e la canalizzazione co' suoi commutatori, regolatori, contatori.

La lampada — frutto di perdinet studi e di molteplici prove — è un globo chiuso, di vetro, grande come una grossa pera, contenente un filo di carbone in fibra di un diavvocalato, ottenuto da una lima di carbone a della grossezza di un crine. Agli estremi è collegato a due fili di platino, che vi conducono la corrente.

Il globo, vuoto d'aria, è chiuso da un disco di materia isolante, attorno a cui sono calati due anelli in rame, per mezzo dei quali la corrente passa dal filo esterno agli interno. Questo filo di carbone, sottile le lampade, durano da 300 a 1200 ore.

L'impressione che l'esperimento ha prodotto in me e in tutti i presenti è che il sistema dell'Edison fa entrare nel campo pratico l'applicazione della illuminazione elettrica negli ambienti chiusi e negli usi comuni della vita.

Ieri sera, il pubblico che assisteva allo spettacolo della Scala, ha veduto questa nuova illuminazione nel ridotto, e tutti, ammirandola, constatavano la bellezza della luce e la mirabile semplicità del sistema Edison. Fu un vero successo.

ELECTRIC LIGHT VS. GAS.—Judge Wilson, Jan. 7.—Judge Gibson, in the Circuit Court to-day, announced his decision in the Gas Light Company of Paul du Lac against the City of Fond du Lac, the United States Electric Light Company and the Eagle Tubular Iron Works Company, granting a perpetual injunction restraining the defendants from erecting towers and purchasing machines for lighting the city with electricity. The court continued the injunction against the Electric Company, on the ground that the contract with the city in question were illegally made, that the city has no right to enter into such contracts, and that the city has no power under its charter to manufacture its own light.

La luce elettrica Edison. — Si pretende che l'anni celebre e popolarissimo romito di Monte Pork abbia avuto un dì ad una dei suoi fanciulli chierici: « Ogni volta che la teorie l'analogia ed il calcolo mi dimostrano l'impossibilità di trovare quel che cercavo, io era sulla via di una nuova scoperta. » (*L'Electricien, 15 février 1882*).

Conviene dire che ciò sia vero e che quella frase sia proprio di Edison, altrimenti come si potrebbe spiegare i successi ottenuti? Due anni fa, quando si parlò per la prima volta della luce elettrica prodotta dall'incandescenza di un pezzo di carbone carbonizzato, il mondo scientifico non dissimulò il suo scetticismo ed il suddivisamente nel tempo che la prova era fatta, e nell'apprendere che anche l'invenzione era spacciata, il grande Edison poteva andare una distanza.

Due grandi elettricisti, Price in Taghttrem, Du Moncel in Francia, dimostrarono con gran pompa di scienza, che così doveva essere, e che forse la preziosa scoperta si sarebbe concretata fra un centinaio d'anni e più di lì, e ci augurarono di comparo quanto basiasse per assistere al trionfo delle idee della scoperta americana. Così e loro se quel voto fosse stato esaudito! Ma Price e Du Moncel non sono due monumenti viventi che temono degradarsi, confessando il loro errore, sono due onesti ingegni, due uomini coscienziosi che per i primi ridono del giudizio che emisero, ed oggidì schierano fra i più caldi fautori del sistema Edison.

E questo sistema infanti presenta la soluzione completa del grande problema dell'illuminazione elettrica.

Diatrico, generatore dell'elettricità, sistemi di distribuzione per la via e per l'interno degli edifici, apparecchi regolatori e moderatori, apparecchi di sicurezza, contatori dell'elettricità consumata, tutto sorti dalla mente di quell'uomo straordinario, o tutto è mirabilmente ideato dal punto di vista della pratica, della semplicità e della solidità.

La luce ora emana dalla lampada, prodotta dall'incandescenza di un filetto di carbone di lampion, che brilla nel vuoto entro un vaso di vetro, o sinibio, dolce, inoffensiva e sopratutto gradita alla vista perchè non ha quel colore bianco-lunare che rende antipatico questo genere di luce.

L'esperimento, che per opera del valente ingegnere signor James Shepherd, rappresentante dell'Edison in Italia, si va facendo di più sera nella sala del Ridotto del nostro massimo teatro, ha convinto i più restioni della superiorità del sistema Edison.

Il pubblico milanese, che sino ad ora non si mostrò mai molto tenero in fatto di luce elettrica, questa volta dovette smettere la freddo. ammiratore che decidere di volerla prendere sinbilo dimora almeno nel massimo e nei minori teatri.

Electric Lights in Philadelphia Post Office.

A Philadelphia paper says that there are seventy-five small incandescent lamps at present in use in the City Post Office, supplied by the Maxim Electric Light Company. Each lamp is run to twenty-four candle power, though the power can be more than doubled. When the lamps were first placed some trouble arose in the machinery, in breaking globes, and in the carbons burning out; but the two latter difficulties have been overcome. The carbons are supposed to burn from six hundred to seven hundred hours. Theoretically there is no reason why they should ever burn out, but experience demonstrates, in the Post Office at least, that the carbons rarely last over three hundred or four hundred hours of actual service. The lamp of the Maxim lamp is of vulcanite rubber and metal, and the work of removing the exhausted carbon and substituting a new one requires but a few minutes. Postmaster Huhlekopf expresses himself very much pleased with the lamps. When they were first introduced some of the employes thought the light hurt their eyes and they wore shades, but, with two or three exceptions, these protectors have been discarded.

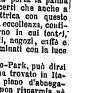
2020. INCANDESCENCE IN ELECTRIC LAMPS. *Gower, and H. Eyre, London.*—28th June, 1881.

This consists in maintaining the points at which an incandescent carbon rests in contact with the terminals supplying the current, by, e.g., wires, as shown in Fig. 1, twisted, say about half an inch. They are then inserted in a paper or other tube, Fig. 2, of thickness to bind with the insulating material. When this is



burnished, the end of tube secured, the contained carbon rubbed down to a point, and the whole then inserted in a socket with the rebellion wires if required round them. The wires are then connected by a plumbago line, the lamp placed in circuit with a galvanometer, and the resistance of the lamp determined. The carbon is then withdrawn, and the tube with the wires cut off as at A and B, Fig. 3. Finally the tube is inserted into a fine carbonizing the fine composition.

SOME NOTES FROM AMERICA.

[FROM OUR OWN CORRESPONDENT.]

Jan. 23, 1882.

The period that has elapsed since my last letter has had its usual quota of accidents chargeable to the electric light. In Denver, Col., an employé of an electric light company was adjusting a lamp over the entrance of a store, and happening to take hold of the wires, received a severe shock. The man fell to the pavement, and was picked up insensible. In Philadelphia, where the electric light is being experimented with for street lighting, a couple of architects have occurred owing to the wires coming in contact with telephone wires. In another case was there any serious damage done, although the fire alarm was rendered useless for a time.

It is reported that Mr. Edison has nearly completed, at Menlo Park, an electric railroad, three miles in length, which is to be used to demonstrate practically the economy of electric over steam railroads. If he perseveres in his attempt to light part of New York with his licensed-secret lamps, it will certainly be curious to watch how the current used by the several consumers will be measured to the satisfaction of the contractors. At present, the system in vogue is to measure the current by the use of what is, I presume, so called, the *voltameter* of which is that a certain part of the current supplied to any building is caused to pass through a couple of cells containing zinc plates, which are removed at stated times and their increase in weight noted.

The United States Illuminating Company claim to have produced a more agreeable light than any other in use. The advantage claimed, is that the absence of the unpleasant violet rays in the light produced, which is more provided by lessening the distance between the carbons, thus having a steadier light.

There is the usual amount of cheap talk going the rounds of the daily press throughout the country relative to the probable formation of companies to supply electricity for the lighting of dwellings, &c. A prominent Boston paper recently stated that electricity could be supplied for lighting, by the licensed-secret lamps, at a no competing gas company at the price of the latter were the former not per 1000 cubic feet. Of course such a low price is impossible, and would not pay the companies. The figures were it not for the fact that it is just such items that remache timid and uninformed holder of gas stock to sacrifice his investment. One of the most recent electric light schemes is the proposition to light one of the entrances of New York Harbour, popularly known as Hell Gate. Already a bill has been introduced in Congress appropriating 30,000 dols. for the erection of the necessary electric lighting plant. It is, however, hardly possible that the bill will be passed.

THE ENGINEER.

FEB. 17, 1882.

FILE-BARING BY ELECTRICITY.

SIR,—At the present time any successful application or transmission of power by means of electricity cannot fail to interest many engineers.

On Thursday last I visited Bartlett Park to inspect a sufficient trade across a portion of the river Lea, which is to be worked with electricity driven by the power of a water wheel situated at a distance, which power was transmitted by two dynamo machines to the couple of wires in passing connected to a pile-driver of ordinary construction. These were erected on a large floating in the river, and the work of driving rather rapidly constructed by the employés on the adjacent bank very well, lifting a daily weighing about 4 cwt. with ease and driving the piles to full depth. Should this system of transmission prove successful, the largest size could be driven by the same means successfully. Such an adaptation may prove of much value in certain situations.

Great merit is due to the energetic clerk of works, Mr. Skillin, Bartlett of skilfully arranging and carrying out the scheme. The Harrods of Salisbury, who takes a lively interest in electric lighting, as well as in the application of other mechanical improvements, has also been under the tuition of the foreman of Mr. Skillin, succeeded in lighting by means of the same dynamo both the principal rooms and corridors in the old mansion at Hatfield. The incandescent lamp is used, and the dynamo is about one horse-power, and superior from the house. I hope shortly to communicate details surthy the attention of those interested in electric lighting.

Gas, Water, and Electricity.

Electric Lighting at the Savoy Theatre.—On Wednesday afternoon last, for the first time in this country, the electric light was alone employed as the illuminating medium of a theatrical representation. For some time past the electric light has been in use in the new Savoy Theatre, but until the present week gas was retained upon the stage. On Wednesday, however, the building was entirely illuminated, both before and behind the curtain, by electricity, and we are glad to be able to record that the experiment proved completely successful. As the public are aware, the electrical lighting is carried out by means of Swan's "incandescent," which are supplied by Siemens' Brothers' generators. Of these lamps there are about 1,200 in front of the house. Behind them are 1,000 8cp lighting the stage and 30 the numerous dressing-rooms. Each lamp burns only in vacuum. On another occasion we hope to be able to furnish our readers with full particulars of this very important and interesting installation. The general effect is certainly very pleasing. The light is singularly soft and pure, and altogether free from the glare and shiftiness which used to be considered indispensable from its employment. But the great thing in connection with this mode of illumination is the absolute security from fire which, as its inventors claim, is afforded by its use. If a lamp glass is broken the air rushes in, with the effect of putting the light out instantaneously. It is asserted, further, that no sort of danger can by any possibility arise from the heating of surrounding wires, or in any other way. The importance to a public place of entertainment of this character of being able to dispense with gas, and all its dangers, discomforts, and inconveniences, cannot be over-estimated.

Gas, Water, and Electricity.

Electric Lighting.—This method of illumination is getting a former hold every day upon the public. It has never met with that degree of virulent opposition and ridicule that attended the early days of gas, and it is rapidly receding from the confidence of impossibility. While it is fast to be expected that gas will cease to be manufactured and sold, or even used, it might be almost safely asserted that for lighting on a large scale, electricity will, before another decade has passed, take the place of all other media. As a proof of this, we need only turn to the proceedings in many of the local Boards this week, examples of which we give below.

The Electric Light for Millwall.—On Wednesday, at the Vestry meeting, a letter was read from the Vestry of St. George's East, stating that the House having of opinion that the time has arrived when the question of the further introduction of the electric light into the public streets should be considered, have referred the subject to their Lighting Committee for a preliminary report. "It has been suggested that it might be thought desirable to select the City of London for the purpose of experimenting, and as the position of this vestry, it is suggested, should be used for the purpose, is partially within the borders of Mile-end, I (Mr. Harrison, the Clerk) have been requested to ask your Vestry whether they are also prepared to join and take part in the experiment, and if so, to suggest the advisability of their instructing Mr. Knight (Mile-end surveyor) to meet our surveyor and prepare a full report for the latter." [Some of our representatives, as Mr. Ward, have reported that this matter be referred to the Committee of Works, with power to act with the St. George's East Vestry.—Ed.] Having been duly seconded, Mr. J. Rush said the matter of gas was of serious importance, and not to be treated hastily. He (Mr. Rush) would certainly object to entering on a partnership with another local Board for the proposed purpose. (Hear, hear.) If the Vestry were to do anything, they should do it for themselves; and, as regards sites for an experiment, they possessed a finer road even than the Commercial-road. (Hear, hear.) Whitechapel had already considered the matter of electric light, and have given permission to one company to enter the district. But this case was not one to be followed lightly, for these were other companies whose claims for lighting should be impartially examined before giving away public rights. (Hear, hear.) St. George's Vestry was, no doubt, anxious to get everything to help with the expense of the experiment; but to this he objected, for several reasons, and especially because the electric light was treading down the Whitechapel-road, and it was difficult to get rid of. He wanted the Mile-end-road. (Hear, hear.)—Mr. Hall objected to anything being done in an important a matter until they had seen the economical and other results of the experiments in the City by the several rival electric light companies. To spend public money in Mile-end at present would be premature, and might prove very wasteful.—Mr. Giles, on the other hand, urged that Mile-end should not be lagging behind other public districts, and even the municipality of London, in this matter. Ample sufficient was known of the new light to justify the Vestry's immediate action, and this would be a splendid field. Mile-end-road practically required special lighting more adequate to its proportions than gas could afford. The Mile-end-road was the finest one in the world they should have the best of lights.—Mr. Jupp explained Mr. Giles's references to the matter by attributing it to a desire for his own shop should be illuminated as that he could reduce his personal expenses for gas, and do it at the public cost. A prospect so gratifying to Mr. Giles would not arouse similar feelings in the back streets, and the ratepayers would not assent to any such use of the experiment would have to be drawn.—Mr. Glass indignantly denied the justice of this analysis of his motives, and chimed—what in a person of Mr. Jupp's habit of mind must be difficult to him—a patriotic note in favour of the whole metropolitan area. He advised Mr. Rush to withdraw his objection that "from a building they could expect only a small or a barbarous light."—Tuckwell counselled a cautious movement in the matter of the electric light, for he felt assured the advance of discovery and invention would be so rapid that in a short time they would be able to see at all their lamp posts and plant for the desired purpose, without rushing into large expense.—Eventually the subject was referred to the Committee of Works.

Electric Light in Whitechapel.—On Monday, at the meeting of the Whitechapel District Board of Works, by the minutes of the Committee of Works it appeared that they had considered a letter from the agents of the Brush Electric Light, stating that they were contemplating laying down an electric light main along the Whitechapel and adjoining roads, with the object of letting out electric lights to private consumers, and asking permission to carry the wire underneath the roadway. "Many of the inhabitants of the immediate neighbourhood of the High-street are very anxious to have an

experimental trial of the lights by Christmas, and we have consented to meet them on Wednesday [that is, last week].—The time being very short, it was suggested that the Board would allow the agents to take the wire for this trial underground. It was added by the writers that the best insulated wire would be used, and carefully covered with gutta percha, so that there would not be the slightest risk of an accident of any kind.—A representative of the agents attended, and explained that it was proposed to light the premises of some of the inhabitants in the district in Whitechapel-road, Commercial-street, and also in Whitechapel-road.—The Committee of Works resolved to recommend that no objection be offered by the Board to an experiment being made by Messrs. Hammond and Co., agents for the Brush Electric Light, to light certain private establishments in the district, and for that purpose to carry their wires above ground from point to point as may be arranged by them with owners of private property, such arrangement on the part of the Board to be terminable at three months' notice, to be determinable at the absolute discretion of the Board at any time before the expiration of that period.—In moving this report, Mr. Lidyard, by the Board, Major Nimmo (Metropolitan Board of Works) said the Board would doubtless feel it their duty to give every reasonable facility to the progress of science in its application of light. (Hear, hear.) At the same time it must be clearly understood that the present resolution was only to permission only to cross public thoroughfares as an experiment, and temporarily, and that the Board exercised assented over the proposed individuals for the use of whose houses the agents would themselves have to negotiate. Neither did the Board accept any responsibility for any damage resulting from the breaking of wires.—Mr. Bass longer seconded the motion, and it was supported by Mr. Basham, both speakers urging that Whitechapel should not be behind the rest of the metropolis in this matter.—Mr. Harris strongly objected to cables being allowed to hang over public thoroughfares. The Board, of course, had no power to prevent owners of property making their own use of the electric light agencies, but he should be sorry to let any of his property for the purpose.—The Chairman said he expected that he could support the motion, and therefore some explanation of his sometimes resolved to deter a little the Board's consideration of the matter was necessary.—Mr. Harris moved to defer it for a week, because he felt that on a matter specially demanding prudent action. The impression of the Board's decision was a very good thing; but also was the question of the public rights and interests. Using the form of contract offered by the electric light agency, he showed that sometimes local boards themselves for three years, whilst the company puts itself in the position of voiding the contract if their application to the local authorities is refused. Further, what the company wanted as a permanency was to take a portion of the subsoil. Doubtless that was the better method, for the expedient of carrying cables overhead was both clumsy and dangerous; but it was nevertheless one to the public property for private profit. It might be said that this was a mere experiment; experiments were everything, and cases there were where the wires would have to be very difficult to get rid of. He wanted the Board to consider well the attempt to promote science, they might not be absolutely blocking the progress, because there was no question that they would have to deal with it in the course of a very short time, applications from three or four companies, and they would then require to be in a position to deal with the matter. He moved his previous amendment.—Mr. Lidyard, on the part of the Committee of Works, explained that the action of the Committee was carried by the addition of the clause, "as an experimental trial," and that the object was to secure the Board's power to withdraw its consent at the end of the term mentioned," and thus amended, it was adopted.—Mr. Ox, the Board's surveyor, explained that this term had the Board's consent would come too late for the purposes desired.

Reduction of Price.—At the meeting of the St. George-in-the-East Vestry on Thursday, the Clerk reminded the Vestry of their proceedings in 1878, when the Vestry resolved to go in for the operation of other Vestries, in seeking a reduction in the price of gas supplied by the Commercial Company to the public lamps, and he now read a letter from the secretary to the company, recommending a reduction of the price of gas from 3s 2d to 2s 11½ 6d. per 1000 per annum, making a reduction of 3s. 6d. per lamp per annum, or 350 cubic feet, making an aggregate reduction in the public lamps.—Mr. W. Walker said they here saw the effect of the Gas Referees' Act, which was a very good piece of legislation as it ought to be. Gas companies, and only amounting to £700 per annum in St. George's-in-the-East, whereas the lamps was not at all in proportion to that on private consumers.—The Chairman said he thought a considerable amount of credit was due to their Clerk for the consistent perseverance he had manifested in bringing the proposal to a successful issue.

Electric Lighting for Paddington.—On Tuesday, at the meeting of the Vestry, the following resolution, moved by Mr. Keeche, was carried:—"That it be referred to the General Purposes Committee to consider and report whether the time has now arrived to invite tenders for the purpose of lighting this parish with the electric light; or, if it be advisable and more economical for the Vestry, to make arrangement with one or more of the ratepayers to work it themselves."

THE JOURNAL OF GAS LIGHTING, WATER SUPPLY, & SANITARY IMPROVEMENT. [JAN. 5, 1892.

SOME NOTES FROM AMERICA.

By W. H. MAW and GEORGE T. BEILBY.

Dec. 15, 1891.

Accidents caused by electric light wires are now recorded so numerous that it is almost impossible to keep track of them, or to note them all, as it nearly always the same story over again—either an electric light wire coming in contact with a telephone or telegraph wire, or else one of the wires becoming heated and setting fire to adjacent woodwork, &c. Thus, in Chicago, on the 9th inst., a fire broke out in the basement of a house in that city, where, on the same floor, the instruments are fixed in the several places. In this instance, the employé at the central office of the Telephone Company were promptly treated to quite a grand pyrotechnic display, the resulting bounds shooting out flames from all sides, making necessary the disconnecting of several wires. Of course the explanation, in such case, was that an electric light wire had become crossed with a telephone wire, or had fallen across it, and that the heavy current of electricity was certain to do a great deal of damage; but certainly at present they are a serious obstacle to the use of this mode of lighting.

Mr. Edison is making some progress in his task of "piping" a section of New York City. The work does not go on so rapidly as it might, owing, it is said, to a difficulty in procuring the cover mains. However, it has probably advanced sufficiently to examine the Edison Company that a good deal of money is being profitably paid to the owner of the advantages that electric lighting has over gas. These advantages referred to this reference in my "Notes," that it is not necessary to have a meter on the premises. It is said that the section being piped is in the down-town business portion of the city, where the incandescent lamps would doubtless find more customers than in any other locality, because the absence of excessive heat, which is the one good point in this mode of illumination, would be appreciated most. As to the law, dark offices which abound in that part of the city, but the supply of light would be practically cut in the district under Mr. Edison's control, and the value of lighting the streets. It is further to be noted that the great bulk of those who are agitating for gas life lamps when his mains are laid, take the light on trial only, and it is to be sincerely hoped that nothing will occur to prevent the scheme going forward to completion, so that the question of supplying electricity for the lighting of private houses may be practically tested.

A couple of more actions against gas companies have been in progress recently in New York City. In the first the Court of Appeals decided that the Metropolitan Gas Company for allowing gas to escape into a sewer. The action was brought under a statute which provides that any person who suffers matter from a factory to escape into the public sewers, and it was contended that the accidental escape of gas into a sewer could not be punished under the statute, and the action was decided in favour of the Company. In the second case, a well-known New York citizen is trying to get a permanent injunction against the Manhattan Company to restrain them from replacing the meters. It seems that the gentleman went to Europe during the summer, and before he left ordered the gas to be supply shut off; but on his return he received a bill from the Company for a quarter's worth of gas. This bill the gentleman refused to pay, and in consequence was threatened with the removal of his meter. A temporary injunction to prevent this was obtained, and now it is sought that the Company may be permanently restrained from carrying out their threat. The way in which the Manhattan Company put their bills is double-faced at the bottom of the trouble. The notice caused all the trouble. The notice caused all the trouble. The notice caused all

THE JOURNAL OF GAS LIGHTING, WATER SUPPLY, & SANITARY IMPROVEMENT.

[Dec. 20, 1881.

A local paper, commenting upon the abandonment of the proposal for the electric lighting of Dudley, says: "The negotiations for introducing the electric light into the town have broken down, as was only to be looked for when such conditions were asked for by the promoters of the light." The idea of adding a monopoly of 20 years to that which the period was simply in its infancy. The electric light was then only just coming into use, and it was clearly to be followed by improvements, but they could give us an indication of what may yet be done, and what will very likely be done in the years that are to come. Is it reasonable, therefore, that we should bind ourselves to a system for three generations, or even for two, which very likely, before ten years are gone would be looked upon as a thing of the past? Certainly not. Mr. Shackleton, Messrs. Hanson & Co. wished the Corporation to take up the electric light, and were willing to grant you one for the purposes of the town, by holding out to the Corporation, if offering to light underground from Crown to St. Edmund's Church, for one year, for the sum of £700. As the saying is, it was but "a sprat to catch a mackerel;" but the bait did not take. In introducing a novelty some risk must be run by the person who is introducing it, and some inducement given to those whose interests he seeks to disturb. Mr. Shackleton's offer was that the electric light should be tried and work satisfactorily, before there was any agreement to be entered into. This was all that could be reasonably expected in regard to the introduction of a novelty which as yet had not been sufficiently tested to render its adoption a matter of certainty."

THE ELECTRIC LIGHT IN BERLIN.—At the meeting of the Dublin Corporation on Monday last week, the Paving and Lighting Committee presented a report, in which it was stated that the Dublin Electric Light Company had withdrawn their application for the necessary powers to light for the purposes of public lighting certain streets proposed to be lighted by the Company, viz., Parkville Street, O'Connell Bridge, and South Great George Street. The object of this was, the report stated, to give the Council and the public an opportunity of testing the efficacy of the electric light. The Company offered, at their own expense, to lay their wires in pipes beneath the pavement, and they asked the Corporation to pay for the electric light is to be supplied the price they now pay gas for the lighting of the same streets by gas. The report, further stated, that the Company had not yet commenced to lay down any part of the mains which the Company proposed to light, and that May had not yet been lighted, did not recommend the Council to entertain the present application. Mr. Mulligan said that, as Chairman of the Committee, it was his duty to move the adoption of the report, but he disconcurred in its recommendation. Mr. Beasley seconded the motion. Mr. Shackleton moved, as an amendment, that the report be referred back to the Committee for further consideration. The amendment was not seconded, and the motion was carried. Mr. Lyons seconded the amendment, and it was agreed to.

THE JOURNAL OF GAS LIGHTING, WATER SUPPLY, & SANITARY IMPROVEMENT.

[Dec. 20, 1881.

FATAL ACCIDENT WITH THE ELECTRIC LIGHT.—At Hatfield House, the residence of the Marquis of Salisbury, a labourer named William Dunmack, 28 years of age, was accidentally killed on Monday last week, by coming in contact with a live wire connected with the electric current which lights the mansion. Hatfield House is illuminated with 117 lights on the Brush system, worked by an engine of 16-horse power placed in a detached stable some distance from the house. From electric wires and a telephone wire connect the stewards with the mansion. For some distance they are carried on poles; but to avoid the unsightly appearance of the poles near the house, the wires are run along the garden wall, 3 feet from the ground, and are protected by a wooden casing. Deceased, with a fellow-workman, was in the garden assisting to lay a telephone wire, and was next to cross the wire at the corner of the kitchen-garden wall, on the left-hand side. While he was almost the linesman heard the wires shake, and on looking round saw the deceased lying on his back, and on going up found he was dead. The machine was at work at the time, some of the Royal Company's men being down from London repairing it, and it is supposed that the deceased, in crossing the wire, came in contact with it, and was thus immediately killed by the current. The linesman stated at the inquest that neither he nor the deceased knew anything about electricity, but the man in charge of the lighting arrangements said he told the deceased, if it, and had purposely sent him to work at the telephone wire 150 yards away from the electric wires. This witness said he did not think the shock would have been fatal if it had not been a wet day and the deceased's clothes saturated with wet. The medical evidence showed that death arose from shock to the system, causing paralysis of the heart. At the inquest the jury returned a verdict that the deceased died through touching the electric wire, and appended a recommendation that there should be a fence put round the wires, and that notice should be given of it to all persons engaged near the wires. It was stated that to avoid similar accidents in future the wires would all be conveyed either underground or on poles out of reach.

The Electric Light.

A large number of interested citizens took advantage of the invitation extended them in Saturday's paper to call and investigate the Edison electric light for themselves, and all last evening a steady stream of ladies and gentlemen poured through the STATE JOURNAL building to see and be convinced. The verdict was unanimously in favor of the beautiful light, and all were astonished at the difference between all other known illuminators and the clear, pure brilliance which poured from the tiny loops of glowing carbon, inclosed in fragile glass globes. And just here a slight correction of an inadvertent statement in yesterday's issue is in order. The statement of carbon is the shape of a horseshoe, but it is inclosed in a pear shaped glass globe, exhausted of air, and hermetically sealed.

Last night thirty-six of these lamps were in action till nearly midnight, of which twenty-five were in the scanning room, editorial rooms and press room of the STATE JOURNAL, and the remaining eleven in the hallway and office of Mr. T. B. A. David, agent for the Edison Light, No. 49 East State street, in the next manner in which the spark apparatus was put in position, so that it was a pronounced success from the moment of starting. Electric engineer Mr. David and electrician Sergeant Nelson, Messrs. Charles Barnard and Charles Merrill, assisted.

[Dec. 20, 1881.

THE BARNSLEY TOWN COUNCIL AND THE ELECTRIC LIGHT.

Last Tuesday a special meeting of the Barnsley Town Council was held at the Masons (Odgen Brady) to the consideration of the desirability or otherwise of extending the trial of the electric light.

The Town Clerk read the minutes of the Park and Lighting Committee, who met on the previous day, including a letter from the contractors for the electric light, stating they were willing to continue the trial for twelve nights more for 25s. This the Committee recommended the Council to accept. Mr. Hall moved the following minutes, which will be laid before the Council at their next meeting:—The Committee instruct the Town Clerk to apply to the Directors of the City of London Electric Lighting Company for providing and supplying the whole of the public lamps in the town for one, two, or three years from the 25th of June, 1882.—Mr. Hall, in moving the resolution, remarked the Council at once to give notice to the Gas Company to terminate the present contract with them.

Mr. Hall moved the adoption of the Committee, in moving that the trial of the electric light be extended, referred to the display which had already taken place, to the streets, and to the fact that the first night of the experiments owing to a defect in the machinery, and a few success which had since attended its working. He assured the Council and those interested in the Gas Company that all the Committee desired to do was to ascertain which was the best and cheapest light. Such being the case, he thought the trial should be extended to the dark nights, in order that they might be able to know what gaslights would be displaced, and what the cost of lighting the whole of the streets by the electric light would be. The Committee had had many opportunities of testing and proving the light, and therefore he could not see the use of throwing away £50 more. He moved—That as further money be expended on the electric light until better data and more facts are laid before the ground.

Alderman PRIEST, whilst agreeing with Mr. Taylor that ample time had been afforded for ascertaining the merits or otherwise of the electric light, said he could not second the amendment, and therefore it fell to the

Mr. WADE called the attention of the Council to the fact that a record of 250 had been offered for information as to who stepped to the chimney of the electric lighting station. He then, amidst great laughter and interruptions, explained that he visited the depôt where the electric light was stationed, and on the Friday afternoon, for which on the previous Friday afternoon, when he was taken out on the roof, being something to the chimney, after which he observed a man with a ladder, who ascended more plentifully. He was to the same boy, but he had no, and got a handful of what appeared to be dust. He took it to Sheffield and had it examined by a friend of his, who said it was soot and charcoal wood, which had blown off the fire, and nothing more. He thought the Council ought not to be taxed to further experiments in the electric light.

After other remarks, the motion was put and carried by a large majority.

THE JOURNAL OF GAS LIGHTING, WATER SUPPLY, & SANITARY IMPROVEMENT.

[Jan. 31, 1882.

THE BARNSLEY TOWN COUNCIL AND THE ELECTRIC LIGHT.

At the Meeting of the Barnsley Town Council on Tuesday last the MAYOR (Mr. Charles Wood) presided. The minutes of the Park and Lighting Committee in reference to the street lighting of the borough were under consideration. The Town Clerk read a letter, which had been received from the Barnsley Gas Company, stating their willingness to continue the present contract for lighting the whole of the lamps in the borough, and to erect 100 additional lamps during the ensuing year, on receiving a reduction on the 30th of June next of the present price of 3s. per lamp per week.

Alderman PRIEST asked whether the Committee meant to dispose of the question of street lighting by the resolution. The Council were premised that the Committee would bring up a report as soon as many be thought the Committee ought to say whether or not they intended presenting such report.

Mr. HAWKINS (Chairman of the Park and Lighting Committee) said he had to ask the Council to rest satisfied with what they had. The Committee preferred for the present to keep back the information alluded to. They were timed by the Gas Company for what they had done, and they asked for a reduction of some 12½ per cent. Another reduction. The Alderman for the public house had been reduced to 42 each, and through the aid of the Committee the public had the price of their gas reduced 2d to 2d per yard. Having obtained this reduction, the best way was to pause for a time, and watch further matters.

Mr. WADE thought the Council were entitled to the promised report. He moved that the minutes be referred back to the Committee for them to make a full report to the Council.

Mr. WILSON, a member of the Lighting Committee, said they had worked out the question satisfactorily to themselves, and they did not wish to throw any difficulties in the Council—their cards. The electric light was not a failure, but it was a thing was a question of cost. He knew of nothing that if the shopkeepers were asked which they would have, they would vote for the electric light; but they had to take into consideration the private householders.

Mr. BEARDSHAW said when they found that the Gas Company were anxious to fulfil contract, such was developed. By a judicious expenditure of £70 the price of gas for the public lamps had been reduced from 42 to 42 each.

Alderman MARSHALL said he could not give the Committee so much credit as they gave themselves. The Committee had been 12 months in office 12 was no concession. This was the price when he moved the Council, and during the coal famine the price was advanced 6d per lamp per week. He thought after a time, when the coal famine was over, the Gas Company would have got back the price to the old rates. The Council remembered with thankfulness the reduction from 3s forwards, and now that they had got the price back it was not to be forwards only, but now that they when the charge with respect to the public lamps. He wished to know Mr. MAWHOOD explained that the contract had been commenced.

Mr. WILSON seconded Mr. Wade's resolution, but on being put to the vote the consideration of the minutes was agreed by a large majority.

THE JOURNAL OF GAS LIGHTING, WATER SUPPLY, & SANITARY IMPROVEMENT.

[Feb. 28, 1882.

AN ELECTRICIAN'S VIEWS ON ELECTRIC LIGHTING.

Mr. KILGOURHORN HUNTER' practical knowledge of electric lighting should entitle his opinion to be taken in writing a small book on the subject, intended for general readers; although his well-known personal and professional interest in a part of the matter on which he treats would naturally lead us to refuse him the position of an unbiased man of science. Mr. Hedges' book has now arrived at the dignity of a third edition, the first having been published in 1878. In his preface to the third edition the author refers to the period of four years which has elapsed since his work was first published, and states his conviction that electric lighting having in this time "passed out of the hands of the scientific specialist, has taken a recognised position as the illuminant of the nineteenth century." In the first edition Mr. Hedges explained for saying little as to the rival of different systems of electric lighting; and in the present edition this breach of the subject will be found to occupy a chapter to itself. In regard to incandescent lighting, which the author chooses acknowledges to be the system to which great expectation is principally directed, he candidly states that if it "becomes the success its advocates believe it will, it is still doubtful whether it will ever be sufficiently economised to warrant its superseding gas in all cases;" and that, although Mr. Edison says in the contrary, it is a question whether heat for cooking purposes could be practically carried at all; and even if it were, the cost would be enormous. Mr. Hedges says, however, that arc lighting should be one-third cheaper than gas, and he appears to rate gas at about one-third of its actual luminous value, when employed in the powerful flames necessary to compete with an arc light, the comparison is not so advantageous to electricity after all. The author then takes up the question of the subdivision of arc lighting, by which he seeks to prove that when used in large centres, electricity is cheaper than gas. He confesses again that the case is reversed with incandescent lighting; and after a consideration of the cost of lighting, he says the whole question of distribution by accumulators, without a number of evidence, that this will be altered when "the current is generated at a central works, and supplied like the older methods." With regard to arc lighting, Mr. Hedges confesses that gas must still be employed for the interior thoroughfares, but asserts that the electric lighting of the City is a success "except in the material one of cost." In respect of Holborn too, the author says that the experience of Dr. Barnard, of New York, who states that the power of an electric arc lamp is reduced by the to that of an oil lamp, which it ordinarily exceeds in the proportion of 10 to 1. Mr. Hedges kindly devotes a few paragraphs to the purpose of reassuring timid gas shareholders as to the continued value of their property. He acknowledges that the present position of the gas industry in this country is due to the continued exercise for 50 years of the most praiseworthy enterprise, and believes that the results of this enterprise will remain valuable. This little work is, on the whole, a well-compiled account of facts, accompanied by a fair and interesting commentary, and is calculated to impart much valuable information to unprofessional readers.

THE JOURNAL OF GAS LIGHTING, WATER SUPPLY, & SANITARY IMPROVEMENT. [Dec. 13, 1881.

THE DANGERS OF ELECTRIC LIGHTING.

An esteemed correspondence has favoured us with the subjoined account of facts in connection with electric lighting and its dangers, which appeared in an American trade journal—*the Scientific and Mechanic Repository*. In reference to it he writes: "An extract from it in the Journal would, I venture to say, be read with much interest by your subscribers." The article is as follows:—

In a former number we pointed out the unreliable and unreliable character of electricity as applied to illuminating purposes, and showed that even when the electric current was found to exercise a direct control over the action which would make it, at all times, a safe and reliable agent, a rival is already available substitute for gas or oils. We cited cases where a fire had been kindled, without any reasonable cause, and in cases had been consumed to fall back upon the less brilliant but more trustworthy coal gas. It now seems that the drawbacks incident to the use of electricity as an illuminating medium are not confined merely to the temporary loss of light, and the consequent inconvenience to persons in such application; but that serious injury to property and even loss of life, not to speak of numerous minor accidents, are resulting from its use.

In Boston a few days ago, at the Bowditch' Fair building, a man who was making a connection of the wires was knocked senseless by the field. Another man on Tremont Street, in the same city, suffered severe burns from a similar agency. A serious fire occurred in Chicago lately from the fact that the electric light wires getting in contact with a telephone line; and on the same occasion the wires of the Chicago Music Company, on State Street, was damaged to the extent of $5,000 by the burning of the roof melting the lead, and the induction rush could also being heard. In New York, a week ago, a fire occurred through a wire for illuminating purposes crossing the telegraph wires. On Oct. 21 one of our chiefs of the New York fire department saw flames and smoke issuing from the roof of a building in the vicinity of Germania Theatre in Thirteenth Street. He found the fire was caused by the wire of the Electric Illuminating Company, which led to the electric light on the roof of the house. This wire had become partly burned off, and, coming over a sheet of tin which covered the top of the arch, made the latter red hot, thus setting fire to the woodwork.

Just by far the most melancholy result of the use of this new light has been a distressing accident which occurred lately in Philadelphia, where nearly a dozen people were killed outright, the existence of peculiar terror, and many more injured and disabled for life. The circumstances of this affair may be called, it will be seen, more than ordinarily distressing, and the lesson they are intended to teach is one which cannot be too carefully considered.

It appears that in a certain factory in the above named city, which is devoted to the manufacture of fireworks, and which is lighted by the electric light, a number of persons were engaged in filling cartridges with powder, when suddenly a terrific explosion occurred, which shook the whole building to its foundations, and was heard for a considerable distance around. Fortunately, the explosion was not followed by a fire, but the scene which presented itself to the eyes of the people who rushed to the spot was one of the most appalling character. Dead and dying were lying in all directions, and the floor was covered with the mangled remains of human beings. Of the number employed in the factory at the time, it is said that only a few escaped without injury, and the list of killed and wounded is a very large one. The cause of the explosion is supposed to have been the ignition of some of the powder by the electric light, which was suspended immediately over the table at which the workmen were engaged.

Now, this is a case which, we think, should be carefully considered by all those who are using the electric light, or who contemplate doing so. It is evident that the danger of fire is not the only one to be guarded against, and that the electric current is capable of producing results which are as much to be dreaded as those which are caused by the agency of fire. Of course, it is impossible to say whether the explosion in the above case was caused by the electric light or not, but the fact that it was suspended immediately over the table at which the workmen were engaged, and that the explosion occurred at the moment when the current was turned on, would seem to point to the conclusion that it was the cause of the disaster. Whether this be so or not, however, it is evident that the electric light is capable of producing results which are as much to be dreaded as those which are caused by the agency of fire. Of course, it is impossible to say whether the explosion in the above case was caused by the electric light or not, but the fact that it was suspended immediately over the table at which the workmen were engaged, and that the explosion occurred at the moment when the current was turned on, would seem to point to the conclusion that it was the cause of the disaster. Whether this be so or not, however, it is evident that the electric light is capable of producing results which are as much to be dreaded as those which are caused by the agency of fire.

THE SANITARY ENGINEER.

DECEMBER 22, 1881.

ELECTRIC LIGHT NOTES.

An electric light company has been organized in Louisville, Ky., with a capital of $150,000.

Dr. Siemens has succeeded in melting five pounds of steel in 25 minutes, by means of the electric current.

It is stated that the substitution of the electric light for gas in the Philadelphia post office has effected a saving during the past year of over $6,000.

The Patriote states that the fires which so frequently occurred at the electrical exhibition are all due to one of two causes—this wires or contact of wires.

The Inspector of Public Lighting of Bristol, Eng., after visiting the Paris exhibition, thinks that a liberal use of gas will give results as effective as those of electricity.

The Mutual Electric Light and Supply Company have applied to the Board of Aldermen for permission to put up electric lights on Eighth Avenue, from 14th to 34th streets.

It is reported that the experiments with the electric light at Scarborough Spa, near York, Eng., which have been continued for about one month, are to be discontinued and a return made to illumination by gas.

The lavatories, cloak-rooms and gas-ages of the British Museum are now lighted by Swan's incandescent lamps, and it is expected that eventually the system will be introduced into other parts of the Museum not now artificially lighted.

The Cincinnati *Gazette* says that the Brush electric Lights in Middletown are a complete success, and that every one who has seen the illeni nation "must acknowledge that for street lighting nothing yet accomplished by man approaches it."

A corresp-ndent of the *Metropolitan*, London, gives figures to show that the illumination by incandescent electric lamps is more economical than by gas. He puts the cost of lighting 20 houses for 2,000 hours per annum by the incandescent lamps at about $2,060, while the same done by gas would cost $4,160.

The resolution which was passed by the Board of Aldermen granting permission to the Metropolitan Telephone and Telegraph Co., to lay wires in the streets of the city, was objected to by the mayor and returned to the Board with his veto. The Board have passed the resolution over the veto, and doubtless others will ask for similar privileges since they are bad for the asking. Indeed, the United States Underground Telegraph Co. now comes forward and reopens the privilege "upon payment of two cents per foot of street opened." It is difficult to see why matters of this kind cannot be conducted as business transactions, and it is certainly the duty of any Board of Aldermen to consider first the interests of the city they are supposed to represent. At the present rate our streets in the future are likely to be in chronic state of eruption.

St. Joseph, Mo., has an electric light company employing the Brush system.

The Brush Electric Light and Power Company of Niagara has been incorporated with a capital of $250,000.

THE JOURNAL OF GAS LIGHTING, WATER SUPPLY, & SANITARY IMPROVEMENT. [Dec. 20, 1881.

THE TOWER SYSTEM OF ELECTRIC LIGHTING.

AS IT IS PRACTICALLY AND TECHNICALLY CONSIDERED.

At a recent meeting of the Sheffield Town Council, one of the members (Mr. W. T. Wiseman) moved that—"The Brush system of electric lighting, by fixing lamps on towers, is a nuisance as to cleanness and power, the Anglo-American (Brush) Electric Light Corporation, lighting them in consequence of the failure of the Yeaty of the said Corporation's own report and in the light of the experience of this parish for one year from the 1st of January, 1882, to June 30th, 1882, and that the contract dated Dec. 31, 1879, and also the agreement dated Dec. 31, 1881, be cancelled for a period to be fixed by the Corporation—such tenders to be accepted as approved by the Yeaty at the said Corporation's own cost and risk." He said he thought the time had come to improve the lighting of the parish, and he was glad to see that they had adopt the electric light. One years ago on account of the long evening September last came to £10,000, Lighting towers might be erected there at the rate of £1,000 per mile, or half a mile from each boundary, in all directions. The area of the town was 3653 acres, and eight of these towers would light the whole of it, at a cost of about one-sixtieth of the present rate. Each tower would have a two-power night to read at a distance of half a mile from the light. The cost of the Brush system would be about £3000.

Mr. Wiseman believed. The experience of those who have tried the electric light on the tower system gives, however, a direct negative to his belief. The correspondence to which reference was made in our editorial columns of the 26th ult., furnishes particulars as to the failure of the system in the only places where it has been tried.

The Sheffield Town Council resolved, as noted many says, "a well-built, well-found, substantial, and workmanlike manner, at about £1,000 per mile." The electric light was started on Sept. 3rd; and on the 5th the Council met in the local newspapers the following day. The four electric light towers situated at the four points of the compass, and hardening upon the northern district, were in full blaze with the light for the first time. The test was not very encouraging. But it surely must not be presumed that these four towers were to light the whole of the city." Our correspondent writes: "I can vouch for the accuracy of the above statement. Entering the city by rail, on the evening of the 5th inst., the absence of light, as seen from the plains adjacent, was a brilliant point, diffusing light in the upper air—suggestive of a lighthouse guiding the distant steamer to port, rather than of an approaching dwelling. It was a dark night for the benefit of its immediate surroundings.

The *Electrical Light Correspondent* of the 2nd ult., wrote: "The Sheffield Electric Light Company have put up four towers, 150 feet high. On three of these they placed six lights—and on the fourth seven lights. The apparent intention was to effectually light the city, but for the space of one month endeavoured to operate them. *They made a most magnificent failure!* Some were abandoned [as we have mentioned] as a total loss. A postscript to his letter, the correspondent says: "One tower, with six lamps, is now in full blaze, and is a most disagreeable object to the inhabitants of the circle of light it is said to illuminate at 150 to 200 feet distance."

The *Denver Tribune* was less complimentary in its notice of the other local paper—the *Denver Republican*—was not a whit better account of the matter. On Oct. 1 they said, "The electric lights from the four towers which are supposed to illuminate the whole city, are heard forth their sickly glares every alternate night for whenever the conditions are favorable for the most effective work they are an intolerable nuisance. Every similar locomotive will not light the city," And again, three days later, "The electric light is a failure as well as a humbug, and they are utterly useless."

From Akron a gentleman writes: "There has been an attempt made to light—not my city by electric light from tall towers or masts; but it has proved far from satisfactory. I might say that lighting by this system is completely a failure. The masts are standing, taken from out of the city and scattered as follows: [giving the names of 3 places.] How much did it cost? It is all gone, and the fund is largely overdrawn if the late contract to erect six more masts is not set aside. The money was squandered, and the city is worse off for light than it ever was. These are the 'cold' facts of the case. The people who are supposed to be benefited by this statement, that the people what the electric light found his cost per year, and when we were in darkness it cost us nothing. If the company has reaped a little glory to himself, the people's money has been squandered, and we have for it all the most transparent swindle and consummate humbug that was ever attempted to be used lighting any people anywhere."

A long and interesting letter from an inhabitant of Salt Lake City gives details of the above there and in the neighbouring town of Ogden. Some extracts from it we may publish at some future time; but we will now conclude the record of failures by giving the words of a resident in New Orleans, who writes as follows, in regard to the electric light: "In most large cities in the United States, electric light companies are established, and a system which requires a large number of lamps to be run, at a fixed price per lamp, is the economy or final success of the system is said not yet satisfactorily determined. No dividends have been declared; nor has the consumption of gas been materially affected by competition. An attempt was made here last spring to run one Jablochkoff more by the light; but it failed completely. The Judges could not distinguish the horses or riders at the half-mile post; and after the first race the experiment was abandoned."

THE JOURNAL OF GAS LIGHTING, WATER SUPPLY, & SANITARY IMPROVEMENT. [Jan. 3, 1882.

THE PUBLIC LIGHTING OF CHESTERFIELD.

(From the *Derbyshire Times.*)

The town of Chesterfield was plunged in darkness on the 31st of August last, owing to a dispute between the Gas Corporation and the Gas Company, since then the inhabitants have been conducted to all the lessened annoyances which are inseparable from deprivation of gas-light, but for a long time there was little sympathy suffering, for light is a necessary of life as at the like taken by the Gas Company, and were disposed to treat the matter as a joke, but in what they considered was a breach of contract, and by and others at the time, that the quarrel was an absurd one, and that the public would be the sufferers. Happily both sides have adhered to terms of peace. Then than this, the public were misled, by a local coach-company, into believing that they could get adequate public lighting by electricity at a saving of about *the cost of gas*; and, as a consequence, they have had no system of lighting at all. But we have now a better state of affairs, and a system of lighting, and we have a heavy bill.

Just now the electric lighters have made a great spurt as yet their large electric lights started on Saturday night, and the public are pleased, and brighter nights they have not seen for months. The number, after allowing the town to remain in darkness week after week, was considered somewhat over, however, they have only provided the lamps on lights in the open streets, and these are separated by long intervals of darkness. Not a single lamp appears to have been provided for the side streets, nor is there any apparent intention to erect them. The present state of public lighting in Chesterfield may fairly be described as follows:—There are now a few large electric lights in the main thoroughfares at long distances apart. These lights burn in a most disappointing manner. They never give out a steady light, but

ACTION OF THE ELECTRIC LIGHT ON VEGETATION.

M. Deherain, Director of the Paris Museum of Natural History, carried on a series of experiments at the recent Electrical Exhibition to ascertain the action of the electric light on vegetation. A small conservatory was built in the exhibition building, and in it the experiments were carried on, although the conditions were not the most favorable. M. Deherain's report has been published in the *Revue Scientifique*, and an abstract of it in *Engineering*. The author concludes "that the electric light produced by the voltaic arc has only a feeble and uncertain action on vegetation." In the experiments of Mr. Siemens, the useful effect of the light was much more marked, but the conditions were more favorable.

M. Deherain says the inability of the plant to mature under the electric light, is due entirely to its being so heavily charged with moisture. The heat radiated from the electric light is almost nothing as compared with that from the sun, and consequently the plants must be heated in other ways to supply the loss.

ELECTRIC LIGHT NOTES.

The Birmingham, Eng., Town Council have decided to ask Parliament for powers to supply the electric light in addition to gas.

According to the *Electrician*, M. Tellier proposes crossing the English Channel, from Boulogne to Folkestone, in an 18-foot boat propelled by an electric motor.

At a recent exhibition of the electric light at Barnsley, Eng., the lamps went out several times, and it was found that the engine had been tampered with by stepping up the chimney.

The electric light experiment in Liverpool, Eng., has been very unsatisfactory, principally because of the unfinished condition in which it was left. The city council seem very willing to drop the matter.

A correspondent of the *Journal of Gas Lighting* says that "while Mr. Swan is a resident of Newcastle, and daily exhibits his light to the public, there is not, he believes, a single other person in the town using it. The corporation, who did some time ago try the light for street purposes, have now given it up."

The Philadelphia Board of Fire Underwriters have notified owners and occupants of buildings desirous of introducing electric lights that application must be made to the companies for permission, stating the number and kind of lamps to be used, the work to be subject to the approval of the inspector of the board.

The Philadelphia *Ledger* is of the opinion that the experiment of electric lighting in that city, although gratifying to the eye, does not warrant the council in granting the privilege asked by the Electric Light Co., to carry their wires without the city generally. The most complete success would not justify the extension of a system which involved carrying the wires on posts.

The Board of Aldermen of Boston have decided to introduce the electric light in street illuminations. The number of lamps is not to exceed 250, however. The *Advertiser* does not anticipate that this step will diminish the use of gas. Permission has also been given to certain private parties to construct continuous lines of pipe in many of the streets for the reception of telegraph and telephone wires.

An Englishman, commenting upon the electric lights in Broadway, does not not consider them satisfactory. "The powerful glare of these lights make it somewhat difficult to walk the streets, the comparative darkness between them adding very much to the danger of colliding with those walking in the opposite direction."

Mr. W. N. Preece, in a paper on Electric Lighting, read before the Society of Arts, said that the Paris Exhibition sounded the knell of all forms of electric excite, as well as those of the Wenderman type. He thinks "the rising favorite is the incandescent lamp, pure and simple;" and that of these the Edison lamp is the most efficient.

PROVINCIAL PUBLIC LIGHTING AUTHORITIES AND THE ELECTRIC LIGHT.

THE question of electric lighting is treated very differently by various corporate bodies in the United Kingdom, and while some of them deal with the subject in a spirit of wise discretion, neither despising nor admiring it, others act as though in this matter the common considerations of everyday business were to be cast aside. The prudent way is undoubtedly that indicated in the report, given in another column, of the Gas Committee of the Birmingham Town Council, who have sought and obtained the consent of the Council to the preparation of a Bill to be submitted to Parliament in the session of 1883, if considered desirable, which will include provisions for the supply of electric lighting by the Committee. It is stated that this action on the part of a body which has hitherto looked askance at the electric light, has been decided upon in consequence of the intended application by various parties to Parliament, during the coming session, for very extensive powers to introduce electric lighting generally throughout the country, and consequently to interfere for this purpose with the roads and property of the Birmingham Corporation among others. It is intelligible and commendable that the Corporation should desire that these powers, if proved to be of any value, should be taken by themselves in preference to any speculative Company; and the Gas Committee, with the consent and opinion of the Council as their authority, will be quite justified in watching the proceedings of the general electric lighting legislation of next session, in order to protect their own interests, and to gain information for use in respect of their intended Bill for the following year.

The Manchester Corporation are going to Parliament for electric lighting powers next year; as a preliminary to which we are informed that a Sub-Committee, composed of a few active members of the Gas Committee, paid a visit to the Paris Electrical Exhibition, with a view to satisfying themselves of the present state of electrical science. It would be cruel to speculate as to the results of the task laid upon the persons thus selected by the energetic gentlemen who undertook this onerous duty. It is, however, open to remark that whatever may have been the mental impressions of the several members of this deputation, which we would naturally influence their after action in committee, the net result of their observations, as expressed in their printed report to their colleagues, is not of great apparent value. The report, indeed, consists in the main of a string of paragraphs intended to describe the peculiarities of the various exhibits to which the attention of the deputation was directed; but, as may be suspected, the deputation were not in a position to pass any technical opinion respecting the merits of the different systems, and their report therefore reads much like a facile annotated catalogue of the show. A description of the exhibits, intelligible to a stay-at-home colleague, a selection from the notices published in our leading engineering contemporaries would have been more satisfactory, and a great deal cheaper. It is only fair, however, to notice that the deputation have expressed themselves in a more definite manner with the "advantages which must necessarily result from their visit." After this declaration it would be ungracious to criticise the opinions of the deputation recorded at the end of their report, which may perhaps be nothing more than faint hints relating to some portions of the "large amount of general information" which is not included in the published report. One remark, however, must not be passed over. It is stated that "one of the greatest problems—that of subdividing the light without loss—has been practically worked out." We are not able to tell what this statement means, unless it refers to the division of electric energy for producing small lights for domestic purposes as cheaply, in proportion to the power required, as the larger lights. As to this claim, however, the deputation should have stated their authority, which was probably that of Edison's or Swan's agent, since it is entirely unfounded; and its adoption, without explanation or qualification, is extremely unfortunate. In making these remarks, we do not wish to reflect upon the action of the Gas Committee in sending a deputation to Paris, but rather to complain that they did not take steps to make their report of some independent value, by obtaining professional assistance to explain the meaning of the appliances which were there shown to the Sub-Committee.

Meanwhile electricians have gained another market at Dudley, where, by the casting vote of the Mayor, it has been decided to allow a firm of electric lighters to erect their plant to put up lamps, and to keep them going for a year, for a total charge of £180, being £30 per lamp per annum; which the contractors admit will result in loss, although the charge is in excess of that made by the Gas Company for the street lamps which will be temporarily extinguished. We notice that the example of Cockermouth was cited in support of the new system; but, as we showed in our last issue, this instance should rather have been brought forward on the other side. It is said that the electric lighting contractors want a "concession" for 99 years of the right to supply electric lamps in the town, which is a somewhat curious demand to make of an English Corporation. We shall see what the Dudley people think of the new method of lighting after the "experiment" has been going on for a few months.

At Barnsley, where the Local Authorities had arranged for an eight days' trial of the Brush lamps, by way of frightening the Gas Company into reason, the result has been precisely of the kind desired. The Gas Company met their rivals on their own ground, and, much to their opponents' disgust, prepared a brilliant display, at short notice, of high-power burners, which were fixed in a position to compare directly with the work of the electric lighting contractors. The electricians worked hard for some weeks to get things in order for their grand attempt; but, as fate would have it, their lamps could not be set to work satisfactorily, either on the opening night or since, and the preference shown by the populace for the brilliant and steady display of the Gas Company is so galling to the new comers, that they have endeavoured to account for the failure, which is certainly not unique, by imputing foul practices to some person or persons unknown. This disgraceful excuse has actually been followed up by the offering of a reward for the discovery of the perpetrators of the imagined outrage; but, it is needless to say, without result. While the failures at other places, which we have lately recorded, remain unexplained, it is too ridiculous to expect even a population not altogether ignorant of the meaning of the term "rattening," to ascribe a very common disaster to a cause which had not been thought of as an excuse in other localities where it might have been equally applicable.

THE ELECTRIC LIGHT IN LIVERPOOL.

The Electric Light Experiment.—At the meeting of Liverpool City Council on Wednesday last—the Mayor (Mr. J. Hughes) in the chair—Sir James Picton asked the Chairman of the Watch Committee (Alderman Cleveland) to give him some information as to the progress of the electric light. The experiment had, he said, been carried out in a very perfunctory and lengthy way, and he wished to know whether there was any prospect of the Watch Committee's recommendation to the Council adopting the plan underground, but there were very great difficulties in the way of this proposal. Alderman Chambers said the experiment had not been a satisfactory one, and the Committee were waiting for a communication from the Electric Light Company who had the contract in hand, before any further steps were taken. Then his experience of the light in America it was a great advantage to Liverpool that the plan it had not been proceeded with. Mr. Rathbone said he thought the Council could very satisfactorily get rid of the contract that should some taken they took any further steps in the matter. The subject then dropped.

Danger from Electricity.

Another illustration has been given of the wisdom of our wa the needless exposure of the wires used in electric lighting. I in Philadelphia last Friday night was one which may have led petitions, if its cause has been correctly given. It is said that of a telephone wire with a wire used for electric lighting accid ner, so that no action like a stroke of lightning was the case filled the room in which the discharge took place, and they we only extinguished. It is possible to protect wires used in ele so that such accidents will not happen, and the proper precau be taken at the very beginning of the introduction of electric tical use.

In cities of Europe the wires for electric lighting are put und it is evident that they should not be strung upon poles in No the companies make no mistake in this matter. It will be by expensive to sink the wires than to hang them upon poles, and better in the end. The thorough insulation of wires laid in electric lighting is also a subject calling for the attention of Their pecuniary loss will be very heavy if their neglect to take cautious results in a destructive conflagration. They must un city to the flames by the improper use of wires for electric lig in the streets or in buildings.—*Mail and Express*, Dec. 27.

The deposit of metallic layers of different colours by means of electricity is now effected by M. Wolf (*Comptes Rendus*). He can cast any metal or alloy instantaneously, at ordinary temperatures and by means of a single copper bath, with an adherent bright layer of various subshades of copper, whose chemical nature is not yet studied. The same bath gives the whole series of colours at will, according to the depth of exposure of the pieces. There is no battery, properly so called. That the colours are produced by the electricity is proved not to offset of thin plates, M. Wolf proves that no Any metallic piece, polychromised by his process, is covered in case with a layer of pure copper, of fine red colour, when treated with nascent hydrogen.

now issuing ENGLISH MECHANIC AND WORLD OF SCIENCE, for any Dec. 16, 1881.

A curious application of electricity is described in *La Lumière Electrique*. It appears in a device to prevent military sentries from practising fraud as to the hours during which they have to keep. When the youth stands erect against the sentry-post, the head parts of the brace press on electric contacts, causing two bells to ring; the ringing ceases when there is the least bend in the leg. The sliding bar which furnishes the contacts has also a contact, which is pressed by the sentry's buttocks, whereby a third electric bell is affected, as a correct measurement, so that the bells sound a string simultaneously. This system, the invention of M. Gaulo, is now employed in the Spanish army.

Electric Lighting at Godalming.—Water power. —Several references have appeared in these columns in the course of the past few weeks to the works which for some time past have been in progress for lighting the town of Godalming, in Surrey, by electricity, generated principally by water power. On Thursday evening last these works were opened for the first time, with most satisfactory results. On a future occasion we shall endeavour to publish full particulars of this important experiment, which we know has been anticipated with considerable interest by those interested in the success of electric lighting.

on Saturday, transferred from the Birmingham Corporation to the Oldbury Local Board, and the day was made the occasion of celebrating the opening of the new gas works at Langley Village.

An alarming explosion of gas occurred at Hyndford, near Lanark, on the night of the 19th inst. George Morgan, on Wednesday evening, when two of the servants were severely burned. Wednesday night came the installation of the Anglo-American Brush Electric Light Company, Limited, for the supply of the electric light in the Edinburgh Town Council and the Assembly Rooms in George Street. On the lighting of Princes-street and the bridges with the electric light, and the lamps were at an early hour on Tuesday to be extinguished, not, for the present at least, to be lit again. Several important leakages have, it is stated, been discovered.

Mr. G. B. Bentley, formerly assistant engineer of the Rural Local Board gas works, having been (out of 87 applicants) appointed superintendent of the Gravesend and Milton gas works, Mr. John Grayham (from Darlington) has been put in charge of the Rural Board works.

The Gas Light and Coke Company have given notice of their intention to sell by auction, on the 22nd instant, £70,000 of new ordinary A Consolidated Stock of the Company. The auctioneer is Mr. Daniel Smith, of 2, Finch-lane, Cornhill.

The Directors of the West Kent Gas Company announce a further reduction in the price of gas of 3d. per 1,000 feet.

WANTED, READERS of a PAMPHLET—projected for One Copy, Twopence, to distribute to Consumers on CONSTANT SUPPLY and HEATING by GAS, &c.
Copies, by post, Threepence, direct from the Author, Magnus Oliver, Assoc. M. Inst. C.E., Gas Works, Isleworth, S.E.

ELECTRICITY.

JOURNAL OF THE ARC AND INCANDESCENT LIGHT.—We have received a prospectus of Philadelphia as well as the agents of outside companies are considerably excited over a petition which they received from the Penn Patrol this morning stating that the Brush Electric Light Company, whose dynamo was run on parts of Chestnut street, had run a wire from the Chestnut street station to the burning property and were lighting the large store of Hood, Bushelgirl & Co. on Market street. The American Fire Insurance Company, which had given a policy on the Bidgood property, has refused to renew the policy on account of the property, stating that if the Brush wire was not removed at once from their building the policy would be cancelled. All the companies announce their determination to act in a similar manner wherever they find electric wires running over property which they have insured.—N. Y. World.

ELECTRIC LIGHT FOR PHILADELPHIA.—An attempt is being made by the authorities to light the city by electricity.

rates.

Anglo-American Brush Electric Light Company.—The first annual general meeting of the shareholders of the Anglo-American Brush Electric Light Corporation was held on Thursday at the City Terminus Hotel, Cannon-street, under the presidency of Sir Henry W. Tyler, M.P. The report of the directors and balance-sheet to 31st December last showed a profit of £34,064, of which amount £29,500, in cash and shares, had been derived from the sale of patent rights, concessions, and licenses, and £3,846 from manufacture. The whole of the former amount, £29,500, had been placed to reserve; and of the £3,464, a sum of £1,279, being at the rate of 2 per cent., had been written off as depreciation of plant and machinery. After providing for all preferential charges, £30,750 was available for a dividend of 12½ per cent., and the directors recommended, leaving a balance of £2,054 to be carried forward to the year 1882. In addition to the patents originally purchased for electric lighting on the one system, the directors had also secured the valuable patents of Mr. Lane-Fox for incandescent lighting; and a separate factory for the manufacture of the lamps and apparatus connected with this system had been established.

The CHAIRMAN, in moving the adoption of the report, congratulated the shareholders on the results of their working for the last year. As they might imagine, they had had many difficulties to contend against in a new business such as theirs, and any one who knew what it was to collect together appropriate machinery of a new description for a new market would be able to appreciate to some something of what they had gone through. It was desired in the middle of last year by certain gentlemen that a meeting should be held and accounts rendered, but in addition to their articles providing that the meeting should be annual, it would have been most unfair to hold a meeting and render the accounts of a concern which had been working only six months, during which it had been impossible to make any satisfactory progress. What they had done at the year, however, was most satisfactory, for in one sense they had accomplished, that period more than half the capital of the company, and had not come into full operation in their business, for many had many rivals who would be very glad to know a little more than what they were doing. They had sold some patent rights, licenses, and concessions in this country, but they had other patents under consideration for other countries, as well as for various parts of England, and it would very much embarrass the directors were they to state in detail everything they had done. Their net profit for the year had been £34,064, of which £29,500 had been realized—about half in cash and half in shares—from the sale of patent rights, concessions, and licenses, while £3,464 had been derived from manufacturing operations. They had resolved to divide all moneys arising from the sale of patent rights and concessions, and to transfer to a reserve fund the profits obtained from the sale of patent rights and concessions. He thought that would be a wise course, as in such a business they did not know what in-

ventions might be made in the future. As time went on, too, should they continue to prosper, it might be wise for them to reduce their capital, and thus enable them to earn dividends on the capital they would retain. The shares were taken up in three companies only, and they had estimated them at the value at which they had written off all preliminary expenses, and, although indeed it was hardly necessary to do so with new machinery they had written 10 per cent. off for depreciation of plant and machinery. They proposed to continue that in future, so that in ten years their plant would have written itself. They commenced taking their premises very cautiously, but they soon found it necessary to extend them, and, indeed, take additional and larger premises. At Belvedere-road and Portpool-lane they now had 456 men employed, and so rapidly was their system developing that before long they expected to have 1,000 men fully employed. They now had orders of the value of £46,000 in hand. In addition to the Brush system of dynamo machines and lamps, they had acquired the patents of Mr. Lane-Fox for incandescent lighting. They had carefully considered the question of central lighting and what they should do as to undertaking the lighting of towns, &c., and they had felt that it was hardly for their company to undertake all this business, on account of the large capital and the enormous staff and superintendence it would require. They had therefore, sought rather to sell their concessions for different counties in England to other companies, and they believed that in this manner, they becoming ultimately the manufacturing centre for a large number of affiliated companies in the United Kingdom and on the Continent, they would gain the largest profits. They had been difficult to spend money in a way which brought in no direct return, such as in advertising. At the Paris Exhibition they had a very fine display, which had been conducive to extending their business there, and they were spending a good deal of money in connection with the exhibition at the Crystal Palace. While he begrudged spending money in that way, he felt that it would be fill that the shareholders would allow them to do all they could to extend the operations of the company. Up to the present they had sold 250 dynamo machines, and 2,721 are lamps in England; but in the United States, where they had been longer at work, they had sold 850 machines and 21,251 are lamps. They heard sometimes that the are light was going out of fashion and that the incandescent light was taking its place, but he believed there was a great future for both. Are lighting was more adapted for open spaces, streets, and large manufactories, while incandescent lighting was more suited for domestic purposes theatres, clubs, and buildings of that description. He did not think it was wise to try and hide the few failures they had had, which had been principally owing to the difficulties they had had in the first instance, of getting a good staff of efficient men to carry out the work. In any new system of the sort they must learn by their failures, and seeing that they knew the reason of their failure they had no fear as to the system but the application of it which had been at fault. In manufacturing the machines and lamps they had really had great success. It was true that there were dangers about the electric light, and a man had been unfortunately killed at Hatfield House by putting his hand on a naked wire; but the wires ought to have been properly covered. Fires would not have been occurred in the accident, as they only last momentarie. They did not carry out the work. The wires would require to be properly insulated in houses and put down in a substantial manner, but the precautions to be taken in that respect were most simple, and perfectly well known, and if lighting, which he contended, was no longer wherever in electric lighting, which he contended, was no longer wherever in electric competed with other systems of lighting, as only sparks were at gas. Wherever new discoveries should be made they would be kept in the van in connection with electric lighting.

Mr. JOHN SCUDAMORE SELLON seconded the motion, and expressed his belief that the concessions, working in the electric light, would probably be obliged to give a better price for their cost. He contended that the criticism to which they had been subject was a proof of their success.

After a few observations from Mr. WILLIAM ANDREWS and Major ARLIE, the report was unanimously adopted.

Mr. Charles Denman was elected a director in the place of Mr. J. Montgomery, the two other retiring directors, as well as the auditor, were re-elected.

The Hampstead Vestry and Electric Lighting.—In question of installing the electric light in the parish of Hampstead, which has been once or twice ineffectually discussed in the Hampstead Vestry, was definitely brought under notice at the last meeting of that body by a recommendation of the Public Improvements Committee and a motion, of which Mr. Chamberlain, one of the members for Town Ward, had given notice. Upon the recommendation of the Public Improvements Committee a number of gentlemen were elected to act with Mr. C. H. Lowe, the surveyor, the Electrical Exhibition, the Crystal Palace, and to report for the next meeting of the Works Committee for consideration and adoption, such plans as they deemed the best. Mr. Chamberlain, in moving his motion, said he thought this was a very opportune time for the vestry to get themselves better informed on electrical lighting. He offered the time would come when they would have to consider the question of lighting the streets by electricity, and the information to be got by a visit to the exhibition would help them to avoid mistakes.—The motion, of which Mr. Chamberlain had given notice, was as follows:—"That for the better lighting of the parish the Vestry take into consideration the desirability of introducing the electric light, and that the various companies and firms be written to for information as to the cost and particulars, and that one or more be asked to experimentalize free of expense, and that the parish shall in High-street be lent for that purpose; and also that arrangements be made with Messrs. H. and J. Kelly for the fixing of their steam-engine for the electric lighting."—Mr. Finch suggested that this motion should be deferred till after the exhibition.—Mr. Chamberlain said he would bring it forward in a month's time.—The consideration of the subject was accordingly deferred.

CINCINNATI ARTISAN.

Electric Lighting.

ITS FIRE RISKS AND THEIR REMEDIES.

BY HENRY MORTON, PH.D.,
President of Stevens Institute of Technology.

SOME very lamentable accidents have strongly directed public attention to the question of danger possibly accruing to life and property through the rapidly increasing employment of electricity as a source of light, and as the actual conditions of this danger, like the true properties of the agency from which it may arise, are but little known, a brief explanation of some simple facts related to this subject will be at this time reasonable and perhaps useful.

I would propose, then, to treat this subject under two general heads, namely: 1st. The sources of danger; 2d, The condition of their preservation, or of security.

The sources of danger in the use of the electric light are essentially two—from the conducting wires and from the electric lamps.

As long as the electric energy employed in any is conveyed by a perfectly good conductor it is perfectly harmless, like water flowing through a horizontal channel, and properties no rise above its banks; it is only when some accident causes it to overflow, or to be diverted or confined, or some partial obstruction of its course produces irregularities in regular flow, that trouble may arise.

The conditions of these difficulties are, moreover, very peculiar.

Thus, for example, if two electric conducting wires, forming the outgoing and returning paths of a powerful current are placed near each other, but are separated by a bad conductor, as, for example, when both are tacked on to a board partition wall, the current will follow the wire from end to end, with no development of heat in the same, or tendency to heat the conductor or gas into any adjacent object. If, however, between the two conducting wires we introduce some imperfect conductor, such as a small wire, some metallic dust, or a film of water containing mineral matter in solution; then a portion at the current will be diverted into the "short-cut" from wire to wire, and may heat the fine wire or the metallic dust or the wood wetted, with the injurious solution, so as to cause the ignition of inflammable matter.

Accidents of this nature have already occurred. Thus a fine copper conducting wire having fallen across one or more of the conductors and for want of proper insulation has been nailed side by side, without any fine partition, as the same board, or ceiling; and though used safely for a long time, and under circumstances in its normal state, have developed a very dangerous activity when the moisture of heavy rain has left with dirty or impure water. In that case the water offers a circuit through which a cross current is established which first heats the fine wire, and then chars it, and finally explodes it, a series of minute arcs or electric sparks along this charred surface, which would soon develop a conflagration if left undetected.

Again, two such wires as above, inaccurately attached near each other, may be brought into momentary contact and then separated, in which case an electric arc, with its intense light and heat, will be established between them. In like manner a conducting wire itself may be inaccurately connected at some point, and if the abutting ends are separated slightly during use, a similar "arc" with its intense heat may be there developed.

These examples will give a fair idea of the dangers arising from the conducting wires, and they are manifestly to be guarded against by a proper separation and insulation of the wires themselves. Of this, however, more anon. At present, I would only further point out that there is no risk whatever of any kind from any other injurious action arising in or from the conductor itself when an adequate cross section is used, as must be the case from motives of economy, since an inadequate conductor would involve a great expense in the use of the electric current.

Electricity is not to be regarded as a sort of fluid like passing along the conductor, and some popular notions on this head are so absurd as were similar ideas which prevailed in reference to illuminating gas, at the time of its first introduction, and which cannot rules to be made in some places that no gas pipe should be allowed to come in contact with any wood work.

Turning next to the dangers which might be expected from the electric lamps, it is to be remarked, in the first place, that those in the case of the are lights depend much upon the number of lamps operated on the same circuit. Thus, if thirty or forty lamps are operated in series, the electro-motive force of the current must be sufficient to maintain a corresponding number of arcs; and, therefore, if by any means many of these arcs are closed out the electro-motive force of the current available for the remaining ones would be so excessive that their arcs might become excessively long, and even the metallic carbon holders and other parts of the lamp constitute safe between which the are would spring, melting the metal work and establishing a very dangerous center of combustion.

To avoid this class of dangers two provisions should be made:

1st. That these some arrangement in the lamp itself by which, whenever the arc exceeds certain safe limits, the current will be automatically diverted from it and restored through a good and sufficient conductor; and, in the second place, some apparatus in connection with the electric generating machine by which the electro-motive force of its current should be varied automatically in correspondence with the resistance of the circuit, so that any diminution of such resistance, as by the closing out of several arcs, should cause a corresponding diminution in the force of the current generated.

Numerous contrivances for both of these purposes have been already created to greater or less perfection and efficiency, and it is manifestly possible by such means to secure the enemy from risks of this sort.

The securing of adequate insulation for the conducting wires in view of the endless ramifications of telegraphic and telephonic lines is to say nothing of the other conductors found in all buildings, is a problem of great difficulty. One important general principle would seem to be for the electrical workers of the future as well as of the engaging wires, as well as of the machines, and of a portion of all ground connections for any part of the circuit. Another general rule would be the separation of outgoing and return wires as far as possible from each other; and yet another, the centralization of conductors leaving no vulnerable places even where danger would not directly result from accidental contact.

Fully to discuss the details of this subject would be impossible within the proper limits of such a note as the present, and I will therefore only say in conclusion that, with well instructed and intelligent and intelligent provision, all danger from the use of the electric light may be made as certain and absolute by gas or by candles; but without such care and judgment the use of electricity on the grand scale, either for lighting or for transmission of power, would involve serious additions to the risks which accompany so many of the conveniences which constitute a large factor of our modern civilization.

What I have here written is but a fragment of the entire subject involved, and at some future time I hope to fill out and complete a preliminary sketch.—*The Sanitary En-*

64

"Chronicle"
London Dec 16th 1881

ELE[illegible]RO.

At a crowde[illegible] of the members of the Society of Arts [illegible] night at Kin[illegible] at John-street, Adel[illegible] W.H. Preece, M.I.C.E., read a paper entitled "Arch[illegible]ting at the Paris Exhibition." Sir Frederick J. Bramwell, F.R.S., chairman of the Council, presided. The room was illuminated by the Edison-Swan incandescent lamps.

Mr. Preece said the present International Exhibition of Electricity in Paris, marked an epoch in the history of the practical applications of that science to arts, manufactures, and commerce. He proposed on that occasion to refer only to its application to artificial illumination. It was as an exhibition of electric lighting that it was principally attractive, and those who saw it for the first time would never forget the vivid impression that the great blaze of mid-day sunlight upon their minds on entering the building. The Palais de l'Industrie, in which the Exhibition of 1855 was held, was considered by many of the foreign exhibitors even then to present that terrible solution of lights that flooded the interior of the Palais de l'Industrie with great brilliancy, but with an intolerable glare, and consequent means of screening and dodging the unbearable expanse. For instance, at the forthcoming exhibition of electricity in Paris, the building—splendidly adapted for the purpose, it would be divided into sections, each section being lit by one, and only one system. He only proposed to select what appeared to him to be the most striking features worthy of keeping in their notice as steps in advance since the night of Aug. 29 there were in operation 227 arc lights, 24 candles, 41 arc incandescent lamps, 1,500 incandescent lamps, or a total of 1,837 electric light in all, at the Paris Exhibition. Towards the end of the year, during which the show was opened this number was to be considerably increased, and it was stated that the number reached 2,000 in the beginning of November. The exhibition of engines and machinery was extensive, although English manufacturers failed to do what they might have done had they thought of sending their machines at first or they did afterwards. The only extensive display was by Messrs. Siemens, of Berlin, and Messrs. Gramme, Sautter, and Lemonnier, which was not in full motion. The display of lamps was the display of the building. There were very few novelties some are known. The lamps relied, which led to an intense interference with the eyesight. The incandescent lamps made a very effective display in the Hillman gallery, where there were 25 lamps in a circle, and 25 in the centre, besides lighting up the recesses in Wonderland, and in a fixed, strictly circular lamp, giving a soft yellowish light. No one could deny that the Jablochkoff candle had a very pretty effect, as described by Mr. Preece, but he was afraid that the candle system in Paris had exceeded the hull of all former failures, even those of the Westminster type. The rising features in the incandescent lamp, pure and simple. The display was said by Mr. Preece, in the habit of the exhibitors of the Crystal Hall, and in the Pavilion at the Port of Paris, to be the most perfect of the kind. The arc soft, uniform, and pellucid. The incandescent light is totally free from those bright rays which are so injurious to the eyes, so unsatisfactory in the examination, and so irritating to the nerves; if they were not entirely absent they were sub-divided, and in so small under size that it became an almost impossible labour to explain it to the eye. In the hotel anywhere it can be worked from the fixed and detached pendants of a room, and it does away from the use of gas and all its inconvenient heats can be worked by either continuous or alternate current machines. The only drawback in favour of the Jablochkoff was this, that these lights were only fit for external illumination, and it could not be considered as one eminently adapted for internal and for domestic illumination. The lesson had been carried into practice in the Grand Theatre, where nothing could be more effective than the illumination of the auditorium—the soft and comfortable tone of, and, cast about a theatre, was perfect. There were several incandescent lamps shown at Paris besides those of Mr. Swan, notably those at Maxim and Lane-Fox; but that which received the greatest novelty, and was decidedly the most efficient, was that of Mr. Edison. The distinctive character of the Edison lamp is the remarkable high[illegible] fibrosity of the feather, and high-giving power. Many of the lamps were of extraordinary beauty. The quality of electricity concerned it was proved by electric trains; but that adopted by Mr. Edison, was undoubtedly simple and accurate for all practical purposes. The proper distribution of light was a problem that remained to be solved, and certainly enough nothing whatever was done in the Paris Exhibition to show that the question of artificial illumination in England by electricity up to the present time was, as a rule, a questionable success. It was true that those rooms lighted by electricity were better than those where gas was used, but the lighting by electricity was not one which what it should be if the lamps were properly distributed. What was wanted was a lamp which could be put in the centre of the room, so that the light should be properly and uniformly distributed. The question remained for discussion, how the electric light been brought within the region of practical domestics? He had no hesitation in saying that it had not whether it could be brought into commercial contact with gas, which was the question of the day. Gas could be electrically illuminated by its agency. Gas was produced, and on a future occasion he hoped to be able, from the experience of his own household to answer the question which everyone was asking, "How much is it to cost to light your house with electricity?" There was no use dwelling theirs ears to the fact that the electric light was the most perfect of all the lights, and that the light should be removed beside of the skilled it had less danger than gas, or even oil. In Paris there was a fire in the Exhibition four, from the wires coming in contact with each other in the Exhibition building. The insurance in New York were so concerned that the Board of Fire Underwriters had refused to insure the building, but an additional security was provided by Mr. Edison, by inserting in every branch wire a "safety catch," which is a short piece of wire that fuses at exactly melts if the strength of the car are exceeds a certain value, and thus prevents the excess stopping the flow of electricity, and preventing safety. The Edison lamp, which is the most perfect in the Exhibition, was extremely effective in the Hillman Gallery. Many skilled thought had been paid to Mr. Edison's lamp by his provisors; perhaps more so than anyone in this direction than by Mr. Preece] but. It was some gratifying for him, therefore, to be able to announce his belief that Mr. Edison had at last solved the problem that he had set himself to solve. It was taken as a rule that lamps, the resistant on the resistance of abnormal energy is certain to produce a more brisk blown. All of the lamps of personal interesting, and personal supervision At home, was a species of abnormal energy. This was the great secret of the success of gas. It was the cause of the slow progress of the electric light. He was glad to say that Edison's light promised to be as in this respect, and in such a future was open to it. He had no doubt that the Crystal Palace Exhibition would be as interesting as that at Paris, and at the former they would see some of those beautiful specimens of the Jablochkoff candles which he had shown in a way seldom, if ever, seen before.

Mr. Edward H. Johnson, the representative of Mr. Edison, said that Mr. Edison had devoted his manufacture of electric lighting on a large scale from central stations, and the distribution of that electric by throughout every portion of the area of a district to be used by the centralized and practicable public supply. Many thousands of experts in the country of the system. They proposed to put such lamps as might be used in that system. They started with such conditions as to make the use of gas as entirely unnecessary, and which might be placed within the reach of ordinary house servants, and in their hands, no matter how ignorant they might be, as to danger. They had to produce a lamp which the current into light might be used in connection with power by the electric motor, and a current into was electricity for any purpose for which electricity had hitherto been used. Mr. Johnson then explained the system with which the light could be reduced or extinguished and renewed and increased, and a portable lamp was handed round the room.

Sir H. Tyler, M.P., Mr. Crompton, and others, thought that more possibilities should have been given to other systems.

Mr. Johnson said that they had before them an excellent example of incandescent light, and if it could be introduced on the same cost as gas. He was sure they would willingly use it. If they could have electricity laid on to their houses was no doubts that the problem would be in a great extent, solved.

Mr. Preece, in replying to a vote of thanks, said it would have taken a week of time for him to have given a description of the lamps and processes that had been brought before the society more than once.

The meeting then separated.

THE EDISON ELECTRIC LIGHT.

Daily News 17th Dec 1881

A paper was read last evening at the Society of Arts, by Mr. W. H. Preece, F.R.S., upon Electric Lighting at the Paris Electrical Exhibition. Considerable prominence was given to the Edison incandescent light, and Mr. E. H. Johnson, Mr. Edison's representative in England, seized the opportunity to give an illustration of its use in artificial illumination as applied to the lighting of private houses. The hall of the Society upon this occasion was a fine example of a brilliantly lighted apartment. A number of tiny lamps shed their cold, but clear light from shelf, where they hung suspended upon slim connecting wires, while in one corner burned a chandelier of these lights, and several portable lamps were in use upon the platform. The lights were of the famous horse-shoe pattern and enclosed in small balloon-shaped glass globes. The horse-shoe, which is in a vacuum, is simply formed of a thin strip of carbonised bamboo wood, no thicker than a piece of ordinary sewing thread. The electricity which excites the horse-shoe to glow and shed light is turned on and off instantaneously by means of a switch with as little trouble as in the case of an ordinary gas jet. Mr. Preece, in his paper, made a complimentary notice by the electrical engineers followed, framed the progress of the application of electricity to lighting in every nation from the early machines made by Professor Pixii, of Hauxtare, in 1840, and by Signor Pacinotti in 1857. The new lamps, which were described in detail, and the steps found, which hold an intermediate position between the Jablochkoff candle and the Edison light, had done good service. The lighting was, however, was the brass-discord light pure and simple. At the Paris Exhibition was that the arc light was solely only for external illumination, while the incandescent lamps were eminently adapted for internal and for domestic lighting. The last been properly recognised at the Paris Exhibition, and the electric lighting in private houses interested to be more fully dealt with by the lecturer when he stated that gas was not the only available for producing the necessary power for producing the new light. Referring to devices for measuring the quantity of electricity consumed, he showed Mr. Edison's apparatus, as was best like a small gasometer, in which the electricity decomposed two copper plates which have been previously coated with sulphate of copper. A definite proportion of the electricity passing through a known piece deposited this coil, depositing finely upon one plate, and the weight of copper, or, deposited upon the second used, therefore, the light had been sold, said the lecturer, about 1s. per lamp per week, and the electricity supplied has been nearer to 1d. per lamp. Gas therefore was therefore more profitable for him to be able to announce his belief that Mr. Edison had at last solved the problem that he had set himself to solve. It was taken as a rule that lamps consuming the greatest amount of electricity were the most brilliant. The lamps were shown, and the lights, which were of 20 candle power, were lighted by electricity produced, were turned on and off at will. The Lecture closed or increased in brilliancy instantaneously. Mr. Johnson explained that Mr. Edison contemplated the manufacture of electricity on a large scale for distribution over a wide area. It could be used without any meter or apparatus, and could be applied in any portion of a house by merely attaching it to the ordinary sewing machine, &c. The cost of the lamps was so slight that his company intended to supply them without any charge beyond that made for the electric current. A discussion afterwards took place. Sir F. J. Bramwell, in bringing the to a close, spoke of the superiority of the new light over gas both as to its healthiness and its cheapness. He thought that we were near a practical possibility of applying it to the illumination of ordinary households. A vote of thanks to Mr. Preece was carried unanimously.

55

FATAL ELECTRIC LIGHT ACCIDENT.—A fatal accident has occurred at Halifax, by the contact of the Electric Light Company's wires with those of the Telegraph Company. A young man named William Ackroyd, aged 17 years of age, [illegible] of mending a broken wire belonging to the electric light company for lighting the premises of Messrs. Crossley and Sons' Dean Clough Mills. The mills are lighted with 117 lights on the Edison system, worked by an engine of 16-horse power, and it is the new mills some distance from the house. Two wires are carried from the house to the mills, and two wires connect the new mills with the old. For some distance they are carried on poles, but for the last 200 yards they are carried underground in pipes. The pipes run along the garden walks, and at the Ground, and at the mills and the distance [illegible] of the pipes is [illegible] yards. The deceased [illegible] in the garden, assisting to lay a branch wire from the main wire to the house. He was not aware of the danger, and [illegible] getting out. While he was about it, [illegible] and [illegible] and [illegible] and

inner rings, however, instead of being on a level with the outer one, rise in the form of steps toward the centre of the burner. Each ring is supplied with gas by a separate pipe provided with a valve to control the quantity burned. The rings are of metal, and by conducting the heat downward present heated surfaces over which the air passes as it rises to the point of combustion. The novel feature of the new burner consists of several curved air deflectors which surround the burner and the lower part of the flames. The object of these deflectors, as described by Mr. Douglass, is "to force the outer flame or flames on to the inner flame or flames, and thus to condense the flames to the requisite extent, and deflect on to the internal and external surfaces of each of the flames the whole or nearly the whole of the ascending currents of air." An illustration of this burner which appeared in the "Register of Patents" of the *Journal of Gas Lighting* for August 9, 1881, shows three of these deflectors, the inner one having its upper edge nearly on a line with the top of the outer ring, while the outer deflector rises to the level of the inner ring. The burner is provided with a chimney—which, however, unlike the ordinary argand, is kept quite cool by the strong current of air, and does not require wiping oftener than once a week.

Of each of these burners having six rings and a nominal power of 600 candles, developed an illuminating power of 6.5 candles per cubic foot of gas. "Another and much smaller burner, giving about 80 candle power maximum, developed a power of 5.7 candles per cubic foot." A burner of 1600 candle power is reputed to develop from seven to eight candles per foot. "The combination of the gas is, of course, perfect and the design of the entire apparatus lends itself to the construction of ventilating pendants for apartments, in which there is a very wide field of utility awaiting a reliable appliance."

One feature of the burner, which is of especial advantage in the consumption of gas of high illuminating power, is the arrangement of valves by which the size of the flame from any ring can be regulated, and if necessary, one or more flames could be cut off entirely, thus adjusting the amount of combustible material to the supply of air. Properly the air supply should be made sufficient for the perfect combustion of the gas, but as most of these burners are designed for low candle power gas, it becomes necessary to diminish the quantity of gas or reconstruct the burner for the admission of more air.

THE SANITARY ENGINEER,

ELECTRIC LIGHT NOTES.

An electric light company has been organized at Lowell, Mass.

It is reported that St. Petersburg is to have an electrical exhibition.

The Maxim incandescent light is used for the illumination of a part of the Edinburgh Post-office.

It appears that the Brush company, of Boston, are to have a rival in the Weston Electric Light Co., which at present has 100 lights in operation.

It is announced that the experiment of lighting the Junior Carlton Club, London, with incandescent electric lamps has been discontinued, and gas burners substituted.

The Southwestern Brush Electric Light Co. have commenced operations in New Orleans, and the citizens are rejoicing over the illumination of some of their principal thoroughfares by electricity.

The Enterprise Factory at Augusta, Ga., has introduced the electric light in place of gas made from gasoline. In the weaving room seven Maxim "arc" lamps have replaced one hundred and thirty-seven gas burners.

We learn from *La Lumière Electrique* that the large silk factory of M. Dulac at Armentières, near Lille, France, is lighted by forty Jablochkoff candles. The weaving room, containing 300 looms, has twenty lamps, the adjoining rooms have sixteen more, while the bleaching room and dyeing basins are lighted by four lamps. The results are considered very satisfactory both by the owner and the workmen.

The *Metropolitan* states that the Brussels Telegraph Department is lighted by the Jasper Electric Lamps, and that this system is being largely introduced in industrial establishments in Belgium. Mr. Jasper believes that it is more economical to distribute the electric current from one centre, instead of placing a number of lamps on one circuit; and this arrangement is a prominent feature of his system of lighting.

According to the *American Architect*, a locomotive on a French railroad has been fitted up with an electric headlight, which is said to give entire satisfaction. As the ordinary arrangement of the engineer is the are light is not suitable for the purpose on account of the constant vibrations of the engine, the electrodes in the new apparatus are floated upon the surface of water contained in the two legs of an inverted syphon

Wires passing through walls or partitions must be surrounded by an insulating tube. Arc lights must be protected by glass globes closed at the bottom, and surrounded with wire netting if placed over combustible material. Wherever a current is used of such strength as to render possible the fusing of any part of the lamp, an automatic switch must be provided for throwing the lamp out of the circuit before the point of danger is reached.

Below and surrounding the arc be places a cylindrical reflector of ground glass which conceals the carbons, while above the arc is an umbrella-like reflector, which throws the luminous rays downward into the room, producing a soft and agreeable light. In the lighting of the Telegraph Department, the Gramme machines employed are driven by a gas engine. Previous to the introduction of these lamps, of which there are three, the lighting was done by 60 gas burners with a total consumption of 317 cubic feet of gas per hour.

The New York Board of Fire Underwriters have made some changes in the rules concerning electric wires. For arc lights the conducting wires must have a weight equal to that of the wires forming the main circuit of the lamp regulator or of the armature of the machine, if that is larger. For incandescent lighting the wires must never be unpleasantly warm by the passage of the current, and in no case must the wires be connected with the earth or with gas or water pipes. Exposed wires must be covered with two coatings, one of which must be water-proof if the wire is in contact with water. A switch must be provided at the point where the wires enter a building, to allow of its being "cut out" from the circuit in case of fire, and the two wires at this point must be at least one foot apart. Wires on walls and ceilings should not be nearer than eight inches to each other if for arc lights, and two and one-half inches if for incandescent lamps.

THE SANITARY ENGINEER.

[JANUARY 20, 1882.

ELECTRIC LIGHT NOTES.

The municipality of Turin have decided to try the electric light for illuminating the Royal Theatre and the Council Room, in place of gas.

It is reported that the party which Mr. Edison sent to Brazil to search for wood fibre suitable for his incandescent lamps has returned, and gives the information that the fibre desired can be obtained in any quantity.

The museum of the Louvre, which has had but one electric fire alarm, is to be supplied with six, to be distributed on the three floors. The alarms are connected with distinct dials which in turn are connected with the fire station. The cost will be about $1,500.

In Paris the work of establishing the large shops of the *Printemps*, the Boulevard Haussmann, and Rue du Havre is carried on at night by the aid of the electric light. The contractors and workmen express themselves as well satisfied.

A company is to be formed in Stromberg for the purpose of introducing the electric light into workshops, manufactories, and ship yards, at present lighted by gas. Similar companies already organized in Germany have met with success.

It is stated that the Paris Municipal Commission have decided to light the Council Hall by the electric lamps of five different systems successively. The one which proves most suitable and economical will be introduced permanently.

According to *La Lumière Electrique*, there is some talk of lighting the French senate chamber by electricity. A commission composed of M. M. Berthelot, Charles Robin, and Wurtz, and of a certain number of specialists is to have the experiments in charge. If they succeed, the electric light will be definitely used in lighting the session room and adjoining apartments of the Luxembourg.

The *Review of Gas and Water Engineering* states that the attempt to light the principal streets of Liverpool by electricity has proved a failure, the Brush Company having withdrawn from their contract after a considerable loss. The light was to have been introduced last spring, but several postponements followed, and only within the past few months have the lights been in operation. Even then no attempt was made to dispense with the ordinary gas lamps.

It is reported that the contract for electric lighting between the Council of Edinburgh and the Anglo-American Brush Company has been terminated, and that on account of the increased expense it will not be continued. The *Review of Gas and Water Engineering* gives the expense of ordinary lighting by gas as about $1,000, that by an improved method of gas lighting as $1,000, while the electric light costs about $5,500.

La Lumière Electrique states that the subject of lighting the port of Havre by electricity still continues the object of countless experiments and interesting study. Recently a meeting was held of the commission having the matter in charge, to receive the report upon the effect which this lighting produces and also upon the services which it can render to vessels entering the port. It was the opinion of several captains and pilots that the strength of the light was not sufficient for the purpose, and also that the lamps should be placed at about double the present elevation. It appears that changes are to be made.

THE SANITARY ENGINEER.

[JANUARY 19, 1882.

A NEW STORAGE BATTERY.

Whatever may be the practical value of batteries for the storage of electricity, the very general interest which the subject has awakened in the mind of the public makes every improvement or modification in the construction of such batteries worthy of notice. If, in future, experience shows that secondary batteries cannot be economically employed in the general applications of the electric current, certainly the study which the subject is receiving will add very much to our knowledge of the requirements and conditions affecting the storage of electricity by chemical means.

Mr. H. Sutton recently read a paper before the Royal Society giving the results of a long series of experiments on storing electricity. In one experiment the negative electrode was a sheet of lead placed in a solution of acetate of lead, and the positive one lead in dilute sulphuric acid. In charging this the acetate of lead was decomposed, metallic lead being deposited on the negative electrode, and acetic acid being formed. On discharging, the original solution of acetate is obtained. During the experiments it was found that the red oxide of lead is a very poor conductor of electricity, while the peroxide is a good one; and also that the amalgamation of the lead plates produces an increase in the polarization effects. The plates becoming more uniformly and rapidly peroxidized when used as positive electrodes, and lead action entirely disappearing."

Having satisfied himself that positive electrodes amalgamated with mercury were the best, he made further experiments to determine the best form of negative electrode, "having in view the conservation of the hydrogen." Metallic pellicles and spongy platinum were not considered on account of their expense. It was thought, however, that good results might be obtained by having as the negative electrode some metal whose oxide would be soluble in the solution, "and which could be re-deposited from the solution, or by having metallic solutions from which metal could be deposited, the resulting solution being such as should, on the oxidation of the deposited metal, combine with the oxide and again form the original solution. In this way it was hoped to obtain a cell which would not polarize itself during discharge, as is the case in both Plante' and Faure cells."

Zinc, iron and copper were tried as the negative electrode, the solution in each case being the sulphate of the metal experimented with. The results were both more powerful and more constant than with any other cell. Zinc was discarded, however, on account of the necessity of keeping the plate amalgamated in order to prevent local action. In the use of the iron plate in solutions when the cell was not in operation rendered the employment of that metal undesirable. "The cell having a negative electrode of copper, a positive electrode of lead amalgamated with mercury, and a solution of cupric sulphate" was adopted "as a thoroughly economical, lasting, and practical form of storage reservoir."

It consists of a sheet of lead, thoroughly amalgamated, and a thin sheet of copper, both of which are perforated with a number of holes and rolled in the form of a spiral, being separated by rubber bands to allow the free circulation of the liquid. The metals are then placed in a solution of sulphate of copper, and "the lead plate made the positive electrode of a suitable source of electricity." The chemical action results

proposed to employ plates of iron which have been made electronegative to lead like the carbon and the gas burner beyond their original use, and it is to be seen if the interest beyond their original use, and it is to be seen if the interest

Electricity and Chemistry.

MAGNETISM AND THERMO-ELECTRICITY.—There are facts on record which prove that the molecular structure of iron and steel, when submitted to magnetic action, generally undergoes a change which is different according to the direction of magnetization, and that, consequently, other properties depending on molecular structure, such as the conducting power for heat and electricity and the thermo-electric behavior of iron and steel, are likewise altered. With regard to the galvanic conductivity, it has been proved by Herr Beetz that in longitudinally magnetized wire there occurs an increase of the resistance; whereas in wires transversely magnetized, a change of resistance is not demonstrable. As to thermo-electric behavior, Sir W. Thomson found that a longitudinally magnetized wire is electro-positive, a transversely magnetized wire electro-negative.

This behavior of iron and steel has a special importance for the method proposed by Herren Stroubal and Barus, of measuring the degree of hardness of iron and steel wires. They have sought to do so, that is, by determining the galvanic resistance and the thermo-electric position. But if these properties are affected by magnetization, then this method of measuring hardness will only apply to unmagnetic, not to magnetic, wires. Now, the change of the electric conductivity in the case of transverse magnetization being found *nil*, and that in the case of longitudinal so small that a hardly perceptible difference of hardness was implied, Herren Stroubal and Barus have limited their attention to examining the change of the thermo-electric behavior through magnetization; especially as Sir W. Thomson's results were only qualitative, and quantitative results were necessary for the end in view.

The experiments (described in a recent number of Wiedemann's *Annalen*), were made with annealed iron wires, which, not magnetic, now non-magnetic, and called thermo-electrically with copper, at equal differences of temperatures, were examined as to their thermo-electric behavior. The observed electro-motive forces; copper with magnetic iron, and copper with non-magnetic iron afforded confirmation of Sir W. Thomson's result, that a longitudinally magnetized wire is more positive than one non-magnetized. The difference, however, were so small, that with slight differences of temperature the constants of a thermo-element of magnetic and non-magnetic iron could not be deduced. When the difference of the temperature was raised to that of ordinary temperature, and the fusing point of lead, the variation of the thermo-electric behavior by magnetization was found to be $= 0.017$.

Considering, over against the result, that the variation of the thermo-electric constants through hardening and annealing of steel reaches the value 13·6, it is clear that no objection can be taken to the use of thermo-electric constants as a measure of the hardness, even in the case of magnetic wires. The following circumstance, however, is noted as remarkable:—In change of the condition of hardness of a steel wire, its conductivity and thermo-electric position are varied simultaneously, and, with increasing resistance, the wire becomes thermo-electrically negative; in the case of magnetization, on the other hand, the resistance increases, but the wire becomes thermo-positive. Thus the thermo-current in the case of magnetic differences, flows in the opposite direction to that in the case of differences of hardness; which is explained by the different nature of the causes in operation.—*English Mechanic.*

ELECTRIC LIGHTING—ITS FIRE RISKS AND THEIR REMEDIES.

BY HENRY MORTON, PH. D.

Some very lamentable accidents have strongly directed public attention to the question of danger possibly accruing to life and property through the rapidly increasing employment of electricity as a source of light, and as the actual conditions of this danger, like the true properties of the agency from which it may arise, are but little known, a brief explanation of some simple facts related to this subject will be at this time seasonable and perhaps useful. I would propose, then, to treat this subject under two general heads, namely: 1st. The sources of danger; 2d. The conditions of their prevention or of security. The sources of danger in the use of the electric light are essentially two —from the conducting wires and from the electric lamps. As long as the electric fluid or electric energy, is conveyed by a sufficiently good conductor it is perfectly harmless, resembling a river flowing in its natural channel, and powerless to rise above its banks; it is only when some outer channel into surrounding objects is offered or some partial obstruction of a certain character impedes its regular flow that trouble may arise. The conditions of these difficulties are, moreover, very peculiar. Thus, for example, if two electric conducting wires, forming the outgoing and returning paths of a powerful current, are placed near each other, but are separated by a bad conductor, as, for example, when both are locked on to a board partition wall, the current will follow the wire from end to end, with no development of heat in the *same*, or tendency to leave the conductor or pass into any adjacent object. If, however, between the two conducting wires we introduce some imperfect conductor, such as a small wire, some metallic dust, or a film of water containing mineral matter in solution; then a portion of the current will be diverted into this "short-cut" from wire to wire and may heat the fine wire or the metallic dust or the wood wetted with aqueous solution, so as to cause the ignition of inflammable matter. Accidents of this nature have already occurred. Thus a telegraph or telephone wire having fallen across one or more of the conductors used for street lighting purposes has been fused, or, itself escaping, has caused the fusion of finer wires connected with it.

Again, two wires being the outgoing and return circuits of a powerful current, have been nailed side by side, without other insulation, on the same board of a floor, partition or ceiling; and though used safely for a long time, while the woodwork was in its normal state, have developed a very dangerous activity when the wood between them was wet with dirty or impure water. In that case the water offers a circuit through which a crosscurrent is established, which first heats the adjacent wood, then chars it, and finally establishes a series of minute arcs or electric sparks, whose fiery surface, waving and soon diffusing, excites ignition if left unarrested. Again, two such wires as above, insecurely attached near each other, may be brought into momentary contact and then separated, in which case an electric arc, with its intense light and heat, will be established between them. In like manner a conducting wire itself may be insecurely connected at some point, and if the abutting ends are separated slightly during use, a similar "arc" with its intense heat may be there developed. These examples will give a fair ideal of the danger arising from the conducting wires, and they are manifestly to be guarded against by a proper separation and insulation of the wires themselves. Of this, however, more anon. At present, I would only further point out that there is no risk whatever of any heating or other injurious action arising in or from the conductor itself when an adequate one is used, as must be the case from motives of economy; since an inadequate conductor would involve ruinous expense in the use of the electric current. Electricity is not to be regarded as a sort of fluid fire passing along the conductor; and some popular notions on this head are as absurd as were similar ones which prevailed in reference to illuminating gas, at the time of its first introduction, and which caused rules to be made in some places that no gaspipe should be allowed to come in contact with any wood-work.

Turning next to the dangers which might be expected from the electric lamp, it is to be remarked in the first place, that these in the case of the arc light depend much upon the number of lamps operated on the same circuit. Thus if thirty or forty lamps are operated in series, the electro motive force of the current must be sufficient to maintain a corresponding number of arcs; and, therefore, if by any means many of these arcs are closed out the electro-motive force of the current available for the remaining ones would be so excessive that their arcs might become excessively long, and even the metallic carbon holders and other parts of the lamps constitute poles between which the arc would spring, melting the metal work and establishing a very dangerous centre of combustion. To avoid this class of dangers two provisions should be made. In the first place some arrangement in the lamp itself by which, whenever the arc exceeds certain safe limits, the current will be automatically diverted from it and carried through a good and sufficient conductor; and, in the second place, some apparatus in connection with the electric generating machine by which the electro-motive force of its current should be varied automatically in correspondence with the resistance of the circuit, so that any diminution of such resistance, as by the closing out of several arcs, should cause a corresponding diminution in the force of the current generated. Numerous contrivances for both of these purposes have been already carried to greater or less perfection and efficiency, and it is manifestly possible by such means to secure immunity from risks of this sort.

The securing of adequate insulation for the conducting wires in view of the endless ramifications of telegraphic and telephonic systems, to say nothing of the other conductors found in all buildings is a problem of no small difficulty. One important general principle would seem to be the equal insulation of the return, as well as of the outgoing wires, as well as of the machines, and the voltmeter of all ground connection for any part of the circuit. Another general rule would be the separation of outgoing and return wires as far as possible from each other; and yet another, the continuous insulation of conductors leaving no vulnerable places even where danger would not directly result from accidental contact.

Fully to discuss all the details of this subject would be impossible within the proper limits of such a note as the present, and I will therefore only say in conclusion that, with well matured plans and skilful and intelligent provision, all these dangers may be provided against and electric lighting may be made as safe as that obtained by gas or by candles; but without such care and judgment the use of electricity on the grand scale either for lighting or for transmission of power, would involve serious additions to the risks which accompany so many of the conveniences which constitute a large factor of our modern civilization.—*Sanitary Engineer.*

St. Louis Daily Globe-Democrat,
Sunday Morning, March 5, 1882.

NEW YORK LETTER.

Edison's Inventions Put to a Practical Test in the Metropolis.

A Frank Account of the Adaptation of the Electric Light to Household Use—Point and the Holbrook Company —A New Star.

Special Correspondence of the Globe-Democrat.

NEW YORK, March 4.—From being one of the most lighted cities in the world, New York is now one of the most darkened. Gas and candles are not entirely out of use, but they are thought of lighting because by electricity as a thing that would possibly happen before I died, but I find that is has come to pass already, and as it is a fact that electric light can be furnished households cheaper than gas, it becomes a question of interest to everybody to know all about it.

Mr. Edison, the great inventor, has taken up his abode in New York City, on Fifth avenue, directly opposite the headquarters of his electric lighting bureau, and will remain until the head drives him back to his newly made seat at Menlo Park. I went down to the office the other evening with some friends, and we were kindly shown through the place. It is a handsome dwelling house, which has been adapted to the uses of the bureau of the Edison electric light. The rooms shown the different manners of using the light are:

The Bunsen light has a cold, steely glitter, which is painful in the eye when first thrown, but mixed on high as a street light, or in a room where the eye is not constantly affected, has the Edison light in use is only not painful, but restful to the eye, while shedding a soft and mellow radiance, which is very pleasing to see.

The incandescent Sawyer-Man burner is inclosed in a globe lamp, shaped somewhat like the ordinary gas burner globe, and the manner of burning of Sawyer-Man, a piece of the burner itself, until it brings two wires in contact with the platinum-iridium strip, when the light is turned on. The two wires then pass through the lamp one of colored and one of ground glass, and they never seem to wear. Gas burns super hot over the lamp to prevent the glass from cracking, and the light from these lamps is a great improvement to gas, with all the lamps turned downward, thus throwing the light on the ceiling, which is a soft reflector to shield the eyes, lamp lights are made, which have an insulated cord attached. The lighting of these lamps is done by a match, and they have private glass or porcelain stoples. They are just the thing for invalids or sufferers who hate the sulphur fumes. A lantern on the floor, in a corner, which contains a battery, is the source of the light, and the battery is charged in the morning, and then is lighted by means of a similar lantern. In appearance

THE ELECTRIC LIGHT IS HORRID.

when passing around from room to room are used, the lamps being attached to a handrail. A child, or even an ordinary servant girl, can light them, and there is no mess, no smell or danger whatever. One can take hold of the wires without getting a shock, for these wires can contain from a fifty pocket battery and upward, and the shock from them is not felt unless one embrace. There is a meter, by means of which the amount of electricity used can be measured, and the bill for it is sent in monthly. The meter is placed by a subject of interest, and in some manner beyond the power of consumption. Power for running sewing machines and other uses is furnished also at moderate rates, and can be furnished now at houses. Edison's system is the one to dispel all his square inches, and it only remains for the people to call for it, and the supply will be furnished for all the requirements of that district. Subterranean cables, wires inclosed in gutta-percha and lead, are laid under the streets to the houses and a half under the surface, and leading from these will be the wires that supply the interior.

It is hard to say the public to adopt any new thing, but if it is good, and there has been a great deal of talk about the electric light being injurious to the eyes. I am satisfied from what I have seen that it is a perfect success. Edison's people forward here ordered wires laid in many houses and offices.

In 1871, Alnar Smith is a factory in Connecti-

THE EDISON LIGHT.

In *Chambers' Journal*, and in some of the technical papers for July, 1881, there is to be found an article on the electric light. This article, like all others of its kind, is extremely interesting, dealing as it does with the history of the subject. The literature on the theory of the subject is interesting to another class of readers. In this article the work of Messrs. De la Rue & Stubbs, exhibitors at Paris, which was given in 1877 at several places in London, is discussed, and the following sentences are to the point:—"They devised a method of grinding small lumps of pure carbon in skilful vessels, and rendering them incombustible or luminous by means of a voltaic electricity." The lamps used, involving a train of clockwork to keep the relative position of the carbon points constantly perfect. Of such we need not speak. "But three ingenious inventors, notwithstanding all their preliminary endeavours, have not yet made a regular light; it would flicker and intermit, and failed to become practically useful, although they had succeeded in producing a light so powerful that buildings might thus be lighted at one-sixth the cost of gas." Four of the lights, and how they were connected, are described, the inadvertencies which the soul calculating power, and the unsteadiness of the light, were observed; but the burning of carbon could be avoided, and the electric light was far from commercial, and could not become of the cost some practical use into use. Three years, however, sufficience replaced the galvanic battery; the electric current was cheapened by the cessation of nothing but the carbon.

Edison, as we have seen, has not yet instead of zinc; the electric world was moved in the matter by certain successes; yet the old idea of incandescent lights for the public was pooh-poohed till Messrs. Swan and Edison showed not to be wrong. Swan experimented at first on for twenty years. Edison commenced, we believe, after the Eclipse expedition a few years ago, during which a considerable instrument of his had been on trial. The Wallace-Farmer patent embodies the inventive faculties, and he turned to test the possibilities of electric lighting. He proved through the agency of platinum the practicability of the incandescent metal, and at length came to be employed in every other expedient, and since has come; that carbon and carbon only—is the substance to be used. We wonder who will be the first to discover and steal his secret! Having decided to use carbon, the next question was the material from which the carbon should be obtained. A process of differentiation soon showed that vegetable carbon only was needed, and that obtained from grasses was selected. From north and south, from east and west, materials were obtained and tested. In Shanghai, on page 118, specimens of bamboo were found; in South America, Japan, Africa, for the purpose of these trials. Each fibre was carefully tested, till at length a bamboo from Japan was selected for use. The fibre is prepared in the manner of the carbon illustrated in the figures:—(1) Bamboo, from Japan; (2) Nelson, chinese, from Japan; (3) Silk, fibre, from Japan; (4) Sugar Cane, from Venezuela; (5) Horsehidden, from Japan; (6) Kondakkay, from Japan; (7) Moisiea, from Japan; (8) Hazelbun, from Japan; (9) Jute, from Calcutta, India; (10) Sunnah Bunboo, from Japan; (12) Shikkashikkee, from Japan; (13) Bamboo, from Para, Brazil; (14) Shikkashikkee, from Japan; (15) Japanese, from Yokohama, Japan; (16) Tornskkee, from Japan; (17) Chinese, from Hong Kong, China.

When the selection had been made, the method of manufacture was carefully considered and every detail arranged, so that the finished article should be produced at the lowest cost. The carbon is made from the fibre of the bamboo, which is "cut into splints" (Figs. 1 to 5, and 6 to 9). The "splint" of these parts is divided into three smaller parts, which are pared down to separate the pith from the stronger fibres of texture, shown in 3, 4, 6, 8, and 7. When No. 7 stage is arrived at, the strip is cut in size shown in 8, the thicker end being being so left to obtain good contact, or shaped as in No. 10, when perfect the strip is cut in size shown in 8, the thicker end being

A series of Incandescent Electric Lamps.—Gradually we are obtaining what was so long needed—accurate data on the intensity and consumption of power of incandescent electric lamps. We have had occasion recently to give the results of some experiments, and may now add additional figures, which were published by Sir William Thomson and Mr. James T. Bottomley in a paper read recently before the British Association at York. The electro-motive force for the three lamps used, the number of which, however, is not given, was derived from Faure secondary batteries, the number of cells and horse-power of which are given in the tables:

No. OF EXPERIMENT.	Lamp No. I.			Lamp No. II.			
	Volts.	Horse-power.	Candles.	Candles per horse-power.	Volts.	Horse-power.	Candles.	Candles per horse-power.

The carbon of lamp No. I. broke during the 14th experiment, immediately after the measurement of the light was completed, while the carbon of lamp No. II. was ruptured by the application of 70 cells. A third lamp was ruined by the use of 60 cells, after having resisted 40 and 50.

The point of particular interest in the preceding table is the irregularity of the results, showing the effect of the blackening of the glass by volatilization of the carbon when too high electric power was applied. The durability of the lamps at any particular power must be tested by months' experience before the proper intensity for economy can be determined.

THE ENGINEERING AND MINING JOURNAL.

PROGRESS IN SCIENCE AND THE ARTS.

Electric Lighting in Coal Mines.—On Thursday and Friday, June 9th and 10th, the Royal Commissioners upon Accidents in Mines witnessed some very interesting experiments on the application of electric lighting to coal mines. The plan selected for the experiment was the Pensby Colliery, near Hanwell. The pits are about 1800 feet deep, and the workings are very extensive; but in the present instance, the light was applied to three workings only, situated at a distance of about one third of a mile from the bottom of the pits. The Swan system was employed, the mines themselves were inclosed in lanterns of a very ingenious construction, which will be made by Messrs. R. E. Crompton & Co., which enabled the experiments to be carried about without fear of accident. The number of lamps used in all was ninety-four, which were worked by the current of an ordinary Gramme machine, driven by a portable engine placed near the top of the principal shaft. All the arrangements were carried out under the personal superintendence of Mr. Harold Thompson, of the firm of R. E. Crompton & Co. The commissioners, including Mr. Warrington Smyth, Professor Tyndall, Professor Abel, and others, spent two days in examining and testing in various ways the success of the experiment, and expressed themselves highly satisfied with the results obtained.

OCT. 8, 1881.

Portable Electric Light.—The Faure accumulator has been used in connection with a Swan incandescent electric lamp to produce a portable lamp of two candle-power, thus showing, theoretically, at least, the possibility of providing a light that will not cause explosion in coal mines similar to that of Edison, stated at the meeting of the British Association a few days since. The battery could keep the light going for six hours.

ENGLISH MECHANIC AND WORLD OF SCIENCE: No. 874.
DEC. 23, 1881.

Inventions of storage batteries for electricity are becoming rather common—there are several in France, Mr. Brush has one, Edison has one, and now we hear that Mr. Henry Sutton, of Ballarat, in Australia, has also devised an accumulator, which is reported to be superior to all the others.

THE ENGINEERING AND MINING JOURNAL.
JUNE 11, 1881.

Storing Electric Energy.—From a report of Sir Lyon Playfair's speech at the Institution of Civil Engineers, on the 31st, Sir William Thomson states that by measurement no appreciable loss was incurred in transmitting the last of stored electricity from Paris to Glasgow. He says: "The million 'foot-pounds' kept in the box during the seventy-two hours' journey from Paris to Glasgow was no exaggeration. One of the four cells, after being discharged, was recharged again by its laboratory battery, and was then left to itself absolutely unattended for ten days. After that, it yielded me 980,000 'foot-pounds,' or a little more than a quarter of a million. This not only confirms M. Planté's measurements, but it seems further to show that the waste of stored energy for time is not great, and that for days and weeks, at all events, it may not be of practical moment. I have already ascertained enough regarding its qualities to make it quite certain that it solves the problem of storing electric energy in a manner and on a scale useful for many important practical applications. It has already had in this country one interesting application of the smallest in respect to dynamical energy use, but not of the smallest in respect to beneficence, of all that may be expected of it. A few days ago, my colleague, Prof. George Buchanan, carried on a very heavy carry one of the leal cells, weighing about 18 pounds, in my carriage, and by it ignited the thick platinum wire of a galvanic cautery and bloodlessly removed a tumor from the tongue of a young boy in about a minute. The operation would have occupied over ten minutes if it had been effected by the ordinary knife, and screams, as it must have been had not the tongue of the boy been completely benumbed, the circumstances, the surgical dexterity with his accustomed use of voltaic battery to be set up beforehand, would not have been practically admissible. The largest useful application is waiting just now for the Faure battery, and I hope that a very nuisance thus will be allowed to pass until the battery supplied for this application is to do for electric light what a water cistern in a house does for an incomplete water supply. A little battery of seven dozen millions to give the incandescence in the Swan or Edison lights to the extent of one hundred candles for six hours without any perceptible diminution of brilliancy. Thus, instead of needing a steam-engine or steam-engine to be kept at work as long as the light is wanted, with the liability of the light falling at any moment through the slipping of the belt or any other breakdown or stoppage of the machinery, and instead of the wasteful inactivity during the hours of the day or night when the light is not needed, the engine may be kept going all day and stopped at night, or it may be kept going day and night, which undoubtedly will be the most economical plan when the electric light comes into general enough use. Another very important application of the accumulator is for the electric lighting of steamships. A dynamo-electric machine of very moderate magnitude and expense, driven by a belt from a drum on the main shaft, working through the twenty-four hours, will keep a Faure accumulator full, and thus, notwithstanding the irregularities of the speed of the engine alone, or the occasional stoppages, the supply of electricity will always be ready to feed the Swan or Edison lamps in the engine-rooms and cabins, or any lights for the mast-head, and red and green side lamps, with more completely safety regularity. I have not yet been achieved in the gas supply for any house on terra firma."

THE ENGINEERING AND MINING JOURNAL.
1881.

Oct. 8, 1881.

The Faure Battery and the Electric Light.—Mr. Keates, of the London Metropolitan Board of Works, has made some experiments recently in which the Faure accumulator was employed to feed electrically the electric light. Though they do not appear to have been intended for the value of the results, they are of some interest in other respects, and we reproduce the following account of them, given by the *Engineer*. The lamps used were those of Maxim and Swan, one of each kind being attached at a time. M. Faure states that his battery of 40 cells represent about half an available horse-power for three hours. The Maxim light being placed in connection with the accumulator, 39 cells were found to give the light of 16 candles. With the same number of cells, the Swan apparatus gave the light of 22·5 candles; with 35 cells, the lights became respectively 45·4 and 60·6 candles; and with 40 cells, the Maxim light rose to 101 and the Swan to 111 candles. Thus for the Swan light gave the greatest amount of candle-power. But with 45 cells the Maxim light rose to 228 candles, while the Swan only displayed 201. The capacity of the latter was evidently being overtaxed, for in about a minute the carbon loop broke. A power of 50 cells was then connected with the Maxim light, which then rose to 151 candles; but in about a minute the carbon loop shared the same fate as that of the Swan. The experiments are also interesting as showing the great increase of light by a comparatively small increment of power. Thus, in the case of the Maxim lamp, taking 39 cells as the standard, an increase of one sixth nearly trebled the light, an increase of two sixths augmented the light more than six times, three sixths increased it fourteen times, and four sixths twenty-one times.

The Times.
NEW BRUNSWICK, N. J.
THURSDAY, FEB. 16, 1882.

The Failure of Electric Lighting.

Some time since the Merrimack Woolen Mills placed sixteen 2,000 candle power electric lamps in its weave room, but after a thorough trial they have been removed for several reasons. It was found that they were twice as expensive as the gas manufactured and used on the premises, and though there was a sufficient volume of light it was too much diffused about the room, and could not be concentrated upon the looms in a satisfactory manner. The frequent flashing of the lights and the necessity of extinguishing all when any one was out of order was unsatisfactory, and moreover there was a possibility of the insurance company increasing their rates. The inflammable character of the dust arising from the work renders light of such intense heating capacity somewhat dangerous, and will do much to prevent their introduction in such places as the interior of a cotton or woolen manufactory. This action does not seem to be final, however, as it is added that a trial of the Edison lamp may be made some time in the future.—[Lowell (Mass.) Mail.

THE JOURNAL OF GAS LIGHTING, WATER SUPPLY, & SANITARY IMPROVEMENT.
Jan. 10, 1882.]

The *York Herald* says: A correspondent writes that the electric light has failed at Newcastle-on-Tyne, at Edinburgh, at Dublin, at York, at Scarborough, and now at Leeds, and he asks what Leeds proposes to do. It is proposed to adopt the electric light in Coventry." Our correspondent remarks: "I save it. I have it would 'go to Coventry.'"

The Swan Electric Lights at the Savoy Theatre.—An esteemed correspondent informs us that the Savoy Theatre was lighted last Saturday week in the evening, when the electric lights in the auditorium were in use; but on the stage the proscenium, with four Bray lights, did the work. This arrangement, he has reason to believe, was in force except on the occasion of the much-hoped-for experiment the previous Saturday evening. On this night, too, notwithstanding all that has been said about the electric light always being ready for the audience at a moment's notice, the electric light failed, and "the electric light did not come well to the rescue when the last gas escaped, and the four Bray lights were kept going all the time."

With the failure in Liverpool—referred to in another column—before them, the members of the West Derby Local Board last week declined to appoint a Committee to collect information regarding the electric light. One member said that, the several systems of electric lighting that had been adopted by the Corporation of Liverpool had proved to be a complete failure, and therefore either the Committee or themselves, if it was proposed to attempt to light the West Derby district, a great part of which was green fields, with electricity. Another member said it would be far better for the Board to attend to work which was now neglected than waste their time on experiments. On being put to the vote, the proposal was lost by 7 votes to 5.

Hull and the Electric Light.—Yesterday week the Lighting Committee of the Hull Corporation met for the purpose of receiving tenders for the introduction of the electric light into Whitefriargate, the Market Place, the Pier, and the Town Hall. The tender of the Brush Company's amounted to £3000 for plant, and £966 6s. for working for twelve months; the subsidiary purchase being one of the conditions. Messrs. Siemens's tender—one, in which purchase was optional, was for £3228 for plant, and £750 for labor and coal, with £1000 for purchase outright, or £3978 for plant, and £750 for working. The first tender from Messrs. Siemens was, after some discussion, recommended to the Council for adoption.

PRECAUTIONS TO OBVIATE THE DANGERS OF ELECTRIC LIGHTING.*

It is scarcely necessary to commend the following to our readers, as it is a subject in which we are all so interested that anything from such a source commands attention:

The committee, to whom was referred the question of "the dangers incident to electric lighting, if any, and the means of overcoming the same," specially report as follows, viz.:

That from a careful consideration of the evidence submitted they believe that the use of electricity as a means of illumination, when properly developed, is not attended with any danger to life, person or property, that cannot be reduced by the adoption of the precautions hereinafter set forth.

In order that the reasons which give rise to the necessity for these precautions may be more thoroughly understood by the general public, for whom they are designed, the committee believe that the following statements of the general principles involved in systems of electric lighting as now practiced, may not be amiss.

There are two systems of electric lighting now in general use, viz., the "incandescence system" and the "arc system."

In the "incandescence system" an electrical current, flowing through a thin wire of platinum, or other difficultly fusible metal, or through a thin filament of carbon, heats it by incandescence to nearly a white heat, by reason of the resistance it offers to the passage of the current.

In the "arc system" an electrical current flowing from one rod of hard carbon to another, heats the rods sufficiently to cause a stream of carbon vapor to pass between them. This vapor, heated to intense whiteness by the electricity, forms what is known technically as the "voltaic arc."

In the "incandescence system" it is necessary, in order to prevent the oxidation and destruction of the wire or carbon filament, to surround it completely by a glass globe or cover from which all the air has been removed. In this system, therefore, external oxygen cannot come in contact with the source of light.

In the "arc system" it is not necessary to exclude the atmosphere from contact with the carbons, or electrodes as they are sometimes called, as the light can, therefore, be viewed in the open air. They are generally much brighter than incandescent lights, and are, in practice, usually surrounded by a globe of glass, in order to lessen the intensity of the light of the glare. They can, however, be placed in a globe from which all the air has been removed, since the light produced is not dependent on the burning of the carbon electrodes—but is, on their combustion.

The source of the electricity employed in all systems of lighting is the dynamo-electric machine. This machine produces, more cheaply, a current of those properties are similar to the current obtained from the ordinary voltaic battery.

In the dynamo-electric machine, mechanical energy, derived from a steam engine, water wheel, or any other suitable source, is converted directly into electrical current. The change of mechanical into electrical energy is obtained by the motion, at most powerful magnets, of a number of coils of insulated wire wrapped on cores of iron. The combination is called the armature. The armature moves close to the poles of the magnets already referred to, but does not actually touch them. There is, therefore, no friction in the dynamo-electric machine, as in the ordinary electrical machine. The attraction of the magnet poles, as it tends to hold the armature in fixed positions. Mechanical power is required to move it out of such positions, and when so exerted is converted into electrical currents which flow through the coils of wire on the armature.

The current in the armature flows alternately in different directions through the wire wound thereupon. It is generally caused to flow continually in one and the same direction by means of a contrivance called the commutator.

The current so produced flows out of the machine, through a conducting wire, into and through a number of lamps placed at suitable points in the circuits of the wire, and finally through a continuation of the wire back to the machine.

The path of the current from the machine to the lamps, and out of the lamps back again to the machine, is known technically as an "electric circuit."

Any conductor is said to be placed in an electric

* Report of the committee of the Franklin Institute, &c., &c., on the recent investigations into the dangers that may arise from systems of electric lighting.

circuit, or to form part of an electric circuit, when it is so arranged that the current from the machine or battery causing the electricity can flow through it and back again to the place where the current was produced. That is, anything placed in an electric circuit forms part of the conducting path through which the current is circulating.

Dynamo electric machines are now made to furnish very powerful currents; currents capable of conducting fifty or more arc lights in one circuit or line. Such currents require care in their management, and judgment in the selection of the best buildings or public places for purposes of illumination.

Fortunately, however, the currents produced by dynamo-electric machines have some properties very different from those produced by the ordinary frictional machine. The former possess little or no power of leaping from one conductor to another across an intervening non-conducting body, for example, as air; the latter can, as is well known, readily so pass, often through several feet or more of dry air.

The current from dynamo-electric machines, or the currents employed in systems of electric lighting, are, we, therefore, at all comparable to streams of lightning, to which they have often been ignorantly likened. Lightning discharges frequently pass through miles of air, but, even in the largest machines, the arcs between the arc lamps must first be brought into contact and afterwards separated, before the arc is established and the current passes between them. The current will not, in fact, leap through the air. It may, however, contact of the two carbons develops sufficient heat to form a cloud of carbon vapor between them, and this cloud, being an electrical conductor, permits the current to pass.

When, however, the cloud of vapor is once established between the two carbons it will continue to pass it till the carbons are sufficiently divided to have the difference of potential due to their conducting powers.

Suppose, now, that two different portions of an electrical circuit be bridged over by any conductor of any material. Say, for example, that a wire from a line of telegraph or telephone falls across a line of electrical conducting wires, so as to connect the wire carrying the current from the machine with the ground, and the wire carrying the current back to the machine. If such electrical conducting wire be suddenly, or by a series of successive steps, would first be heated, and two different paths be opened to the current. Since the resistance to a power of the short wire, forming the cross circuit, would probably be much greater than that of a mile or more of fine wire with its included lamp, the greater part of the current than "cut off" or "short circuited" would pass through the cross wire, either fusing it, or burning through one or more of them when the contacts were at times but partial.

This danger may be entirely obviated by insulating the wire. It is therefore permissible to insulate all parts of the wires that lead either from or to the machines producing the current.

As these arcs are at times very hot, their occurrence should be carefully guarded against in all buildings or spaces to be lighted.

Dangers of this character may, however, be avoided by carefully insulating all the wires which carry the electrical current from the machine to the building or space to be lighted.

The comparatively feeble leaping power of the currents developed by dynamo-electric machines, as already referred to, does not, however, prevent there are very slight degrees of insulation for wires. Whatever the character of the insulation employed, care should be exercised to see that it is being preserved intact on all parts of the wire. The removal of the insulation from a few points of the wire might cause a dangerous discharge at such points.

When two different paths are open to the current, it will flow through both such paths in the same proportion of different conducting powers. more current will flow through the path set to the better conductor. If one of the paths be twice as good a conductor as the other, twice as much current will flow through it. If it be a hundred times a better conductor, a hundred times more current will flow through it; and so for any other proportion. In other words, the currents will be consumed to equal the distances between them to become too great to be bridged over by the vapor. While, therefore, the current will always divide or no power of a leaping through air, yet it is even-any that no opportunity be offered it to form such conducting clouds between it and neighboring conductors. A brief

OF THE JOURNAL OF GAS LIGHTING, WATER SUPPLY, & SANITARY IMPROVEMENT. Jan. 10, 1882.

NOTES.

THE WASTE OF POWER IN INCANDESCENT ELECTRIC LIGHTS.

There is considerable difficulty in the way of ascertaining, with any approach to exactness, the actual expenditure of power in the production of light from incandescent electric lamps. Laboratory tests are quoted by the agents of Messrs. Swan, Edison, Maxim, and Lane-Fox, to show that an illuminating power of at least 100 or 120 candles per horse power may be produced from these arrangements; while sometimes the useful effect is stated at a much higher figure. It is manifest, however, from such information on the subject as transpires occasionally with respect to the experiences of users of these lamps, that there is a disastrous discrepancy between their nominal laboratory duty and that which is practically available in actual working. At the Savoy Theatre, although the working details of the lighting of the stage and building with Swan lamps by Messrs. Siemens's machinery are not published, it is very improbable that an average illuminating power exceeding 30 or 35 candles per horse power is realized nightly by night. From an independent and very trustworthy authority in America—where greater wonders than here—was learnt that the best performance of the Maxim light is to maintain 8½ lamps, or about 12-candle power, per horse power. This result accords tolerably well with that estimated to be obtained at the Savoy Theatre, allowing for differences in the design of the lamps and fittings. Taking the resultant these two examples together, and averaging the illuminating power of the lamps in ordinary working to be at least 40 candles per horse power expended, the following observations will be found to apply:— Every horse power developed in an ordinary portable steam-engine or horizontal steam-engine of the usual design, requires at least 6 lbs. of coal an hour, besides water and other materials. In the average working of the London Gas Companies this weight of coal would represent about 27 cubic feet of gas delivered to the consumers' burners, and developing a normal illuminating power of 27×2 candles. Besides affording this superior amount of light, the gas companies would remain the richer by a definite quantity of coke, tar, and other residuals, which the electricians buy up with the gas in their steam-boiler. The gas companies probably pay less for their coal in the first place than the electric lighting estimates; and yet, although the incandescent system of lighting by electricity renders less light per unit of power expended, wastes all the residuals of coal carbonization, is more uncertain than gas lighting, and can only be modified in intensity by the introduction of another source of loss, it is fashionable to call this particular method of lighting more *scientific* than the use of gas!

THE ENGINEERING AND MINING JOURNAL. March 19, 1881.

Electricity in the Wrong Place.—*The Albany Journal* records an incident that exhibits the good servants in the character of a bad master. In one corner of Wood, Parsons & Co.'s printing establishment stands the machine that furnishes the electric light for an adjacent store, the power coming from the engine of Wood, Parsons & Co. The wire from the machine in the armature, a wheel containing coils of insulated wire through which the electricity flows in powerful currents when the apparatus is in operation. This armature revolves with terrific velocity, and constitutes a powerful motor for the use of machinery. Yesterday, a young man came in and ground a pair of large scissors at an emory wheel near the generator. Turning to get out the machine, he carried the scissors carelessly in his hand, when they were immediately drawn into the armature, and were soon revolving with it at frightful speed. The young man got out of the way as quickly as possible and was unhurt. For a few minutes, the machine presented a very startling spectacle. The whirling scissors, twisted and broken, but still adhering to the revolving armature, began to cut the wires, and then broke the electric current, which escaped in streams from the fractured ends of the wires, and in a moment each of the portions of the wires was literally rolled to the ceiling with vivid lightning. No one dared to approach the machine for some little time, but the belt was finally thrown off, and the dangerous show was at an end.

Perils

THE ENGINEERING AND MINING JOURNAL. (Oct. 8, 1881.)

The application of electricity for many practical purposes has grown so rapidly within the last few years, and the success in some fields has been so startling and has suggested such possibilities, that the general public takes an eager interest in all that relates to it, and many busy and ingenious inventors and engineers are working in its various specialties Appealing as they frequently do to the senses for aid, they have often allowed themselves, or others for them, to speak in a sensational style that has done much injury to the cause of real progress, and it is with much satisfaction that we note a tendency in a better and safer direction. Calm examination and the presentation of specific data are commencing to supersede the glowing generalities which often sounded very nearly like passages from one of JULES VERNE'S works. The public has learned that a very meritorious invention may be unsuccessfully handled by speculators, and the early enthusiasm has given way to a desire to obtain more and better information on such matters. The Electrical Exhibition now being held at Paris is contributing much toward that end, and it gives evidence, too, of the efforts making to apply electricity to various departments of mining and metallurgy. At the present early stage of progress, many points are not thoroughly under, stood, and there is noticeable the absence of co-operation between the electrician and the engineer; and before the one has fully appreciated the requirements of the other, and has command of the means at his disposal, errors will be made, and the new inventions will not have assumed a practical shape. We hear of electrical hammers, rock-drills, elevators, tramways, and processes, and it is likely that they will in the near future obtain and receive much attention. While there is much that gives promise of ultimate success, and developments ought to be closely watched, it should not be forgotten that all these appliances will have to go through a period in which means are adapted to the ends. As probably capable of adding valuable methods to those now in use for the utilization of our mineral wealth, engineers will welcome the electrician, but they should move forward with the caution that vast experience has shown them to be necessary.

THE SANITARY ENGINEER.

[DECEMBER 29, 1881.]

ELECTRIC LIGHT NOTES.

St. Paul and Minneapolis, Minn., are to have the electric light.

The Chief Engineer of the Springfield (Mass) Fire Department advocates the passage of an ordinance forbidding the running of telegraph wires over those of the fire-alarm line.

It is reported that an Electric Light and Power Co. is to be formed in Bristol, Eng., for the purpose of utilizing the tidal force of the Avon in the production of electricity.

The London Commissioners of Sewers have granted Mr. Edison permission to light Holborn-viaduct with his incandescent electric lamps. The work is to be done at his own expense.

The Edison incandescent lamps have been introduced at the Baldwin Locomotive Works, in Philadelphia; and the Brush Company are preparing to light the Market street depot of the Pennsylvania Railroad Company in the same city.

The corporation of Hull, Eng., have decided to ask the Siemens and the Brush Electric Light Companies, for estimates for lighting the town for twelve months. A proposition to experiment on a small area met with decided objection.

It is stated that in lighting two streets of Albany, forty-eight gas lamps have been replaced by twenty electric lights. The yearly cost of maintaining this number of gas lamps is $1,580, while the yearly electric lamps are to cost $6,320. Not much economy in that.

A correspondent of the *Gas Engineer* states that electric

lighting in Dublin meets with considerable opposition from certain members of the corporation who are shareholders in the Alliance and Consumer's Gas Co. The law agent of the corporation has been instructed to ascertain the legality of the participation in discussing on public lighting by municipal business interests are concerned.

The carbons which Mr. Edison uses in his incandescent lamps require for their production a temperature which softens iron. In order to effect the carbonisation the filaments are placed in small boxes made of nickel. Each box accommodates one filament, which on account of the shrinkage cannot be fastened down, but is held loosely in place by nickel weights.

A California inventor has devised a plan by which it is claimed that every railroad train while in motion can have its own telegraph office. His idea is to stretch two wires parallel with the track, and extending from one end of the road to the other. The wires are over the moving train and are connected with it by sheet wires and wheels, by which connection with either end of the line is established.

The Brush Electric Light Co. have asked permission of the Philadelphia Councils to lay electric wires anywhere in the city. The Company agree to the granting of any such right, and adds that Chestnut street is already displayed by telegraph poles and wires. It would grant the permission only upon condition that the poles on Chestnut street be removed, and that in future all wires be in underground tubes.

Engineering states that forty Jablochkoff electric lamps which have been in use in one establishment for three years are in as good condition now as when first started. The same applies to the machines employed to furnish the current. Other establishments are mentioned in which these lamps have been employed for one and two years, and have given very general satisfaction. The Thames embankment has been lighted by this system, with occasional interruptions, since Dec., 1878.

THE METROPOLITAN.
DECEMBER 10, 1881.
Gas, Water, and Electricity.

Gas Companies and Electric Lighting.—As we fully expected, gas companies are very far indeed from being united as to the best course to adopt in relation to the subject of electric lighting in the ensuing Session of Parliament. The numerous notices of Bills, to which we alluded last week, show that in a variety of ways the question will force itself upon the attention of the Legislature, and certain Bills in which whose offices are situated not a hundred miles from the Houses of Parliament itself, have issued a letter, addressed to gas companies generally, counselling, apparently, an alliance offensive and defensive. But there would appear to be a very considerable difference of opinion as to what should be the basis of any such common action. On the one hand, it is contended—and this would seem to be the view of the supposed authorities in regard to legislation affecting gas interests—that electric lighting is altogether too much in its infancy, and too costly and unreliable a luxury, to justify gas companies in seeking powers to supply it, but that at the same time they should in no way be parties to the granting of such powers to independent companies. Many of our readers will doubtless be able to place their own interpretation upon advice of this character, especially when direct and active opposition to the applications of electric lighting companies is more than suppressed. On the other hand, we find that not unfrequently the electric light as a practical and useful agent for illumination not considered accessible to commercial means of a number of gas companies have announced their intention of applying to Parliament themselves for permission to undertake its supply to residents within their respective districts. One cause for consolation in the matter is that if these two very different lines of policy are really understood

in the committee rooms of the House of Commons, the result may possibly be more to the advantage of the public than would otherwise be the case. To paraphrase a well-known adage, when gas companies fall out the consumers may get their dues.

Electric Lighting at the Mansion House.—The preparations for the lighting of the Mansion House by means of the Crompton electric light, are making satisfactory progress, although the alterations and repairs consequent on the change of ownership now being carried out, do not render it necessary that the installation should be completed with that speed which, under other circumstances, might have been desired. The machinery now being placed in position in the basement of the building consist of a 16-h.p. gas engine, which is guaranteed to give off 20 h.p. effective, with a short length of shafting on which are keyed four pulleys driving four of Crompton's Bungin Dynamo-electric machines. The conducting cables from the dynamo machines are led up as follows—two pairs to the saloon, and three pairs to the roof of the Egyptian Hall. From the centre of the Egyptian Hall will be suspended by a new arrangement of hanging gear four arc lamps (possibly six), of a similar pattern to the large lamps suspended over Messrs. Crompton's stand at the Paris Exhibition. The lamps, fittings, counterweights, and suspending chains, will be of a very handsome pattern, the City arms being worked into the design. In each side aisle behind the pillars will be suspended two incandescent lights; and in the saloon will be suspended two incandescent lights; and in the saloon whole of the decorative brass work has been specially designed for this installation. The work is well in hand, and the contractors hope to be lighting experimentally in the course of a week or two.

THE SANITARY ENGINEER.

[DECEMBER 29, 1881.]

ELECTRIC LIGHT BILLS IN PARLIAMENT.

It is interesting to note that a large number of bills have been introduced in Parliament for securing power to employ electricity in illumination. These bills are presented not only by electric light companies, but also by corporations and gas companies. Seven electric light companies have applied for power to break up the streets and to erect or lay wires, and prominent among the systems represented we notice the Brush, Edison and Siemens. No less than fifteen corporations and eight gas companies have applied for like powers, although in the latter we do not find any of the London companies. In Liverpool, Manchester and Glasgow the gas undertakings are in the hands of the corporations and in each case power to introduce the electric light has been asked for. It seems probable that a very thorough investigation of the subject will be made before these bills are reported. Mr. W. Livesay, in a letter to the *Journal of Gas Lighting*, questions the wisdom of gas companies in seeking these powers at the present time—a course which imperils other and less objectionable features of the bills. The companies who are not seeking electric light powers represent a capital several hundred times larger than those who are seeking them; and it is not to be expected that the larger companies "will abstain from taking such proceeding as they think necessary for their own security, even to the extent of opposing the applications of other companies, if it is found expedient to do so."

The English Mechanic
AND
WORLD OF SCIENCE AND ART.

FRIDAY, DECEMBER 9, 1881.

DU MONCEL ON INCANDESCENT ELECTRIC LIGHTING.

THE fact that the Electric Lighting Company of which M. Edison is the soul are about to instal their system on the Holborn Viaduct, is an item of news which demands more than passing notice. Count du Moncel, the distinguished French electrician and supporting critic of the Anglo-American mouth which, from time to time, have been made in the United States with regard to Edison's inventions, having had an opportunity of studying the system, at the Paris Electrical Exhibition, has pronounced it complete in all particulars, and worthy of trial on an extensive scale. He does not, as might be expected, endorse all the visionary ideas of the newspaper reporters; but he thinks that sufficient has been done to establish electric lighting on the inexhaustible basis of a system, leaving its perfectibility to be decided by the results of a practical trial that we are about to have on a tolerably large scale before the present month runs its course, for, in addition to the public lamps on the Holborn Viaduct, which the company have agreed to supply gratis for two months, no fewer than 150 incandescent lights are to be fitted up in the City Temple, while the Hotel at the Holborn Viaduct Station is also to be illuminated, at least, in part, by means of electricity. Many of the shops, showrooms, and offices on the Viaduct will, doubtless, be illuminated by the Edison light, as there are special facilities for "laying on" the current, and the site is admirably adapted to the purpose of the inventor of the scheme. As we have already mentioned, a section of New York has been handed over to the Edison Company, and the works will shortly be completed in Paris. The work of putting down the conductors is being done in a thorough and substantial manner, showing that the company, at least, is sanguine as to the permanence of their plant, and their action in the City of London shows that they are confident of success in the future. In New York the conductors are of half-round section approximately, and preferably imbedded in iron pipes by means of bituminous material, the connections at the corners of streets being made by junction pieces and sockets, or we may term them, which are accessible from the pavement for the purposes of testing, &c. To give some idea of the magnitude of the experiment on the Holborn Viaduct, it may mention that the central station will have twelve large dynamo-machines, requiring 2,200 horse-power to drive them, and we believe it is intended to employ a number of for small machines, requiring motive power, as well as for electric lighting. Probably before details of the New York experiment reach us we shall be able to form an opinion of the future of incandescent lighting from the trial to be made on the Holborn Viaduct, which, if no unforeseen hitch occurs, will be experienced on the 12th inst. Of the systems of incandescent lighting, those of Swan and Edison are best known; but, according to Du Moncel, there are about fifteen different inventions of the kind besides those just mentioned and the systems of Lane-Fox, Maxim, and Sawyer, all of which seem equally as well adapted to the purpose as those which have been brought prominently before the public. The earlier experiments in incandescent lighting were made with platinum wire, or alloys of platinum; but owing to the disintegration and consequent loss of the metal —in spite of the improvements introduced by Edison—the use of metal had to be rejected absolutely, at least for ordinary purposes. The use of threads of carbon had been suggested for some time—a natural development to a mind accustomed to the carbon rods of the ordinary electric lamp—and efforts had been made to utilise them by inclosing them in exhausted globes or in globes filled with an inert gas, or a gas capable to a certain extent of resuscitating the waste of carbon. In 1859 Du Moncel, the distinguished French electrician and supporting critic of the Anglo-American mouth which, from time to time, have been made in the United States with regard to Edison's inventions, having had an opportunity of studying the system, at the Paris Electrical Exhibition, has pronounced it complete in all particulars, and worthy of trial on an extensive scale. He does not, as might be expected, endorse all the visionary ideas of the newspaper reporters; but he thinks that sufficient has been done to establish electric lighting on the inexhaustible basis of a system, leaving its perfectibility to be decided by the results of a practical trial that we are about to have on a tolerably large scale before the present month runs its course, for, in addition to the public lamps on the Holborn Viaduct, which the company have agreed to supply gratis for two months, no fewer than 150 incandescent lights are to be fitted up in the City Temple, while the Hotel at the Holborn Viaduct Station is also to be illuminated, at least, in part, by means of electricity. Many of the shops, showrooms, and offices on the Viaduct will, doubtless, be illuminated by the Edison light, as there are special facilities for "laying on" the current, and the site is admirably adapted to the purpose of the inventor of the scheme. As we have already mentioned, a section of New York has been handed over to the Edison Company, and the works will shortly be completed in Paris. The work of putting down the conductors is being done in a thorough and substantial manner, showing that the company, at least, is sanguine as to the permanence of their plant, and their action in the City of London shows that they are confident of success in the future. In New York the conductors are of half-round section approximately, and preferably imbedded in iron pipes by means of bituminous material, the connections at the corners of streets being made by junction pieces and sockets, or we may term them, which are accessible from the pavement for the purposes of testing, &c. To give some idea of the magnitude of the experiment on the Holborn Viaduct, it may mention that the central station will have twelve large dynamo-machines, requiring 2,200 horse-power to drive them, and we believe it is intended to employ a number of for small machines, requiring motive power, as well as for electric lighting. Probably before details of the New York experiment reach us we shall be able to form an opinion of the future of incandescent lighting from the trial to be made on the Holborn Viaduct, which, if no unforeseen hitch occurs, will be experienced on the 12th inst. Of the systems of incandescent lighting, those of Swan and Edison are best known; but, according to Du Moncel, there are about fifteen different inventions of the kind besides those just mentioned and the systems of Lane-Fox, Maxim, and Sawyer, all of which seem equally as well adapted to the purpose as those which have been brought prominently before the public. The earlier experiments in incandescent lighting were made with platinum wire, or alloys of platinum; but owing to the disintegration and consequent loss of the metal —in spite of the improvements introduced by Edison—the use of metal had to be rejected absolutely, at least for ordinary purposes. The use of threads of carbon had been suggested for some time—a natural development to a mind accustomed to the carbon rods of the ordinary electric lamp—and efforts had been made to utilise them by inclosing them in exhausted globes or in globes filled with an inert gas, or a gas capable to a certain extent of resuscitating the waste of carbon. In 1859 incandescent carbon lamp of Edison was announced, and, without entering into the question of prior invention between him and Mr. Sawyer, of Newcastle, we may say that it undoubtedly gave an entirely new view of electric lighting. The fate of the so-called "horseshoe" we all know, and we also appreciate the difficulties which attended the failure, caused by one or a dozen failures, steadily pursued his course until success crowned his object. Du Moncel, as he acknowledges, doubted the exactness of the allegations which reached him from America concerning the inexpensive carbon; but, since he has seen the lamps at the Exhibition, he has nothing but praise for them. Of the many inventions for preparing the carbon-threads we have seen, all particulars from time to time; but practical experience alone can show which method yields the best results, instead of carbonised paper, or parchment paper. Edison uses new fibres of bamboo, little larger than a horse-hair, which are bent up in a variety of forms in a state of incandescence. The difficulties attending the expansion of the platinum conducting-wires have been overcome, and though the duration of the lamps, as Du Moncel remarks, has been assured, "long enough," he is careful to add, "to satisfy practical requirements." Some of Edison's, it is said, have served for 1,200 hours, and, being note-worthy, that new lamps are supplied at, according to Du Moncel, 15s., and when they get "out," is not the cost to the public. Great, however, the lamp-lives and results from Count du Moncel his high appreciation of the Edison system of electric lighting; but the completeness of the installation from the motor through the current-generating machine to the lamp itself, every detail being carefully studied, as we have before remarked, nothing remains to be desired in practice," such an expression is, of course, an much above the mark as some of Count du Moncel's statements are below it. Therefore, in the matters of generator, distribution of current, insulation, and regulation of intensity, Edison's methods are, of course, absolutely the most perfect that the present state of knowledge will permit; and although we are not altogether so super-confident that "nothing remains to be desired," as to the practicability of the apparatus is arranged on the Siemens principle, bare of copper being employed instead of wire. These bars lie close to each other around the cylinder which forms the armature, and they are secured to discs of copper in such a way that they form a single circuit. The centre of the cylinder outside the axis is made of wood, which is surrounded by a thick tube built up of very thin discs of iron, separated by pieces of tissue-paper. These thin discs are held together by thick clamping discs, and outside at each end are the copper discs to which the copper bars are secured. This arrangement is said to facilitate the rapid changes of which is characteristic of the real inventor; that is to say, each part is complete and appropriate to its purpose, but is not adopted as final or the best that could possibly be devised, for, in that respect, Mr. Edison is far wiser than his gaslight and former critic. He, at least, has had experience enough to know that nothing is final or altogether perfect. The lamps and the lamp supports have been carefully designed for simplicity and effectiveness. The glass envelopes are cemented into copper sleeves which form the supports, and the latter are provided with joints or articulations, in which communications are made by two plates of the hinges, which are insulated from each other in such a manner that the circuit can be broken without causing anything worse than the slightest spark. Connections of conductors with the lamps are made by pieces of lead wire, which will melt and interrupt the circuit if the current should become of such intensity as to endanger the lamps. According to Du Moncel, Edison's system of electric lighting is as perfect as that now used by gas, It can be laid on to any house, and is controlled and regulated by the simplest turning of two cocks like system thoroughly complete, Mr. Edison has constructed portable candelabras and a portable regulator, which permits of the light being increased or decreased at pleasure. This regulator is, in reality, a rheostat, made up of rounds of carbon of different sizes, and the current, being made to pass through one or the other, its intensity can be regulated within the limits possible to the carbon rounds. The apparatus is simplicity itself, a cylindrical cover perforated with holes, and an ornamental screw-top, being added, to allow the escape of heat, and it is regulated by turning a disc at the bottom which brings a spring into contact with any one of the rods of carbon, or rather into contact with the metal blocks in which they are mounted. Edison has also invented what he terms "meter" to measure the quantity of current consumed, though any lengthy description of which is identical in principle with the meter patented by Mr. J. T. Sprague; but Edison has also devised another method, and it remains to see which will prove the best in practical work. It is obvious that if electric light is to be laid on as gas is now, some method of measuring the quantity used must be employed, and, generally, Dr. Hopkinson and Mr. Edison have satisfactorily solved that part of the problem. The former has found that a combination of arc and incandescent lights is not to be recommended, for the former destroy the effect of the latter, which gives an agreeable light free from the "glaring" fire, as it has been called, of the arc. The light given by the incandescent lamps is really whiter than that of gas-burners, and it can be made as dazzling as that of the arc, but that is not the object of Mr. Edison, or of his rivals, Messrs. Swan, Lane-Fox, and Maxim. It may interest some to know that in the dynamo, which is worked by a steam-engine on the same bed-plate, the

lighting in Dublin meets with considerable opposition from certain members of the corporation who are shareholders in the Alliance and Consumer's Gas Co. The law agent of the corporation has been instructed to ascertain the legality of the participation in discussing on public lighting by members whose business interests are concerned.

The carbons which Mr. Edison uses in his incandescent lamps require for their production a temperature which softens iron. In order to effect the carbonization the filaments are placed in small boxes made of nickel. Each box accommodates one filament, which on account of the shrinkage cannot be fastened down, but is held loosely in place by nickel weights.

A California inventor has devised a plan by which it is claimed that every railroad train while in motion can have its own telegraph office. His idea is to stretch two wires parallel with the track, and extending from one end of the road to the other. The wires are over the meeting train and are connected with it by short wires and wheels, by which connection with either end of the line is established.

The Brush Electric Light Co. have asked permission of the Philadelphia Councils to lay electric wires anywhere in the city. The *Telegraph* objects to the granting of any such right, and adds that Chestnut street is already disfigured by telegraph poles and wires. It would grant the permission only upon condition that the poles on Chestnut street be removed, and that in future all wires be in underground tubes.

Engineering states that forty Jablochkoff electric lamps which have been in use in one establishment for three years are in as good condition now as when first started. The same applies to the machines employed to furnish the current. Other establishments are mentioned in which these lamps have been employed for one and two years, and have given very general satisfaction. The Thames embankment, which has been lighted by this system, with occasional interruptions, since Dec., 1878.

THE METROPOLITAN.

rent, and the site is admirably adapte
the purposes of the promoters of the sche
As we have already mentioned, a scien
New York has been handed over to
Edison Company, and the works will be
be completed, when no fewer than 1
lamps will be supplied with current fr
central station, the area over which the
pectant is to be tried being a little
of three-quarters of a mile. The wor
putting down the conductors is being
in a thorough and substantial manne
showing that the company, at leas
sanguine as to the permanence of t
plant, and their action in the
of London shows that they are confi
of success in the future. In New York
conductors are of half-round section
proximately, and uniformly imbedded in
pipes by means of insulating material,
connections at the corners of streets be
made by junction pieces and bridges, a
may form them, which are accessible from
pavement at the entrance of each house.
To give some idea of the magnitude of
experiment in New York, it is sufficie
mention that the central station will h
twelve large dynamo-machines, requir
2,200 horse-power to drive them, and
believe it is intended to supply "current
for small machines, requiring motive po
as well as for electric lighting. Prof
before details of the New York experi
reach us we shall be able to form an opi
of the future of incandescent lighting
the trial to be made on the Holborn Via
which, if no unforeseen hitchcocures, will
commence on the 15th inst. Of the system
incandescent lighting, Howard Swan and Hi
son are best known; but, according to D
Moncel, there are about fifteen different inve

speed is about 550 revolutions per
minute. Dr. Mossel naively says, that "this
is not a very great speed, but the armature
is very heavy, weighing over three hundred
a half." The advantage of driving the
armature direct from the engine is very ap
parent when an ordinary reciprocating
piston is employed, but in the case of a
three-cylinder or a rotary engine steady
running is not difficult, however, especially when
the sensible power is in excess of the
requirement. From what has been said, then,
it will be understood that the Edison system
is, according to the opinion of Count du
Moncel, calculated to do the work of electric
lighting in private houses; and the experi
ment about to be made in London will no
doubt be watched with interest, for, if it
succeeds, it will not be long before the shops
and warehouses in the City will be illuminated
by electricity.

epoch of sunspots and auroræ, the introduc
tion of the present period of decrease of sun
phenomena was accompanied by a notable
disturbance of the magnetic elements on 11-
14 August last. Instruments seem to have
been simultaneously affected on different
parts of the globe widely apart, and the oc
casion has been taken by Herr Wild, of
the Pawlowsk Observatory, near St. Peters
burg, to compare the records (curves,
magnetographica, &c.) at that place with
those at Kew, at Zikawei in China, and at
Melbourne.

On the days referred to three were three
distinct disturbances of the magnetic decli
nation (three second-and-third tenths declining);
and it appears that the beginnings and
ends of them, especially the beginnings,
were simultaneous at all four places. With
regard to the individual waves of each dis
turbance, those in Zikawei and Melbourne
are quite different from those in the two
other places (where the waves are pretty
similar). In the case of the first two disturb
ances, one finds (as normally) a decrease of
the amount of variation in the direction of
lower latitudes; but it is the reverse with
the third.

In the curves of horizontal and vertical
intensity, the same three disturbances are
distinguished, and the beginnings and ends
correspond accurately with those of declina
tion. Generally, Herr Wild remarks,
of disturbance of a mile. We may
it would appear that, if he not a single
force that causes these disturbances of all
three elements of magnetism, they must be
due to forces that simultaneously begin to
act and disappear.

Analyzing the phenomena further, and
comparing the components of intensity, the
author finds certain marked differences be
tween the places; but into these we will not
here follow him in detail. Two facts ap
pear from a comparison of the curves of
normal (August) values, and of the disturbed
values for Pawlowsk and Kew. (1) While
the disappearance of declination at Pawlowsk
and Kew reach nearly the same amount,
those of intensity at Pawlowsk are double
those at Kew, and those of the whole in
tensity nearly five times as great. (2) On
all three days the amount of disturbance of
the three elements, and especially intensity,
presented no sign which essentially agreed
with the normal daily variation of those ele
ments.

These facts (says the author), partly now
on account of their precision, seem to throw
new light on the extraordinary nature
of the disturbing forces. From the second
fact, especially, we may infer that these
forces are to be conceived merely as eastern,
and everywhere simultaneous intensifications
of the forces which produce theuormal vari-

THE ENGINEERING AND MINING JOURNAL. DEC. 31, 1881.

Electricity in the Manufacture of Porcelain.—Dynamo-electric machines are used in France in porcelain manufacture. The paste used for porcelain often contains ferruginous particles, which give the baked articles a color or a spotted appearance, which is rare while ivory have been desired. In this way, certain articles may lose as much as fifty per cent of their value. The attempts hitherto made to remove these traces of iron with magnets have met with poor success. Recently, however, at two important French works, the Faience-works of Creil, and the establishment of MM. Filleuzy & Co., of Menlum-sur-Yeres, it was decided to set up powerful apparatus in which the electricity, instead of being supplied from batteries, was obtained by means of a small Gramme machine driven by a steam-engine. The arrangement, which is said to work well, comprises a strong horizontal electro-magnet, with the poles very near each other, and between them a thin belt. The paste, very liquid, enters the upper part of this box, and is deflected toward the polar sides by a hard piece of fiber. As it flows down these sides, the iron corpuscles are caught on them by the magnetic force. The apparatus is cleaned twice a day by means of a jet of water, the magnet being demagnetized for the time. About one gram of iron particles is stopped in the passage of twelve kilos of paste, and from 500 to 600 kilos of paste may be passed through one apparatus in a day.

THE ENGINEERING AND MINING JOURNAL. [NOV. 5, 1881.

Those who have watched the developments of the electric lights in this city during the past year can not fail to have noted what great progress has been made in their steadiness and in the economy in providing lights of medium power. In industrial establishments, the use of arc lamps is becoming more general, and it appears to us that the time has come when mine and mill managers ought to give this subject careful attention. We do not look to any extended use of such powerful lights in underground excavations, but we would urge the expediency of employing them in shaft-houses and mills, where work is done day and night, and where good illumination is so essential to good work. As a rule, the power in such establishments is so irregularly taxed that it would not be expedient to run the dynamo-electric machines from the main engines; but usually there is steam enough to supply a small auxiliary motor, which could furnish what is so much wanted, steady power. Where wood is cheap in the West, but freights high, the economy of electric lighting would be apparent, while elsewhere the advantages of good illumination, though indirect only, would, we believe, fully counterbalance increased cost.

American Gas Light Journal. Feb. 21, 1882.

Dangers of Electricity.

The *New York Evening Post*, of January 25th, contains an account of the new rules adopted by the Board of Fire Underwriters governing electric wires. The capacity of conducting wires was considered, and for arc lights it was stipulated that the conductor must have a weight per running foot at least equal to that of No. 6 wire (or parallel group of wires) constituting the main circuit of the magnetic regulator of the electric lamps, or of the remainder of the machine employed, whichever of these is the largest.

For incandescent lights the conducting wires must be large enough never to grow unpleasantly warm to the touch. In no case must electric wires be connected with the earth, or with gas or water pipes running to the earth.

Exposed wires must be covered with two coatings, and where there is exposure to water one of these coatings must be waterproof. At the point where electric wires enter a building a switch or "cut-out" must be provided, so that in case of fire there will be no danger to the firemen. The outgoing and returning wires for arc lights should enter and leave a building at points at least one foot from each other.

In running along walls or ceilings the wires of an arc lamp should not be nearer than eight inches from each other; for incandescent lights two and a half inches' distance is sufficient. Wherever wires are carried through walls, floors or partitions in buildings, they must be surrounded by a special insulating tube of substantial material. Arc lights must be protected by glass globes, enclosed at the bottom to prevent the fall of ignited particles, and where inflammable materials are present below the lamps, a wire netting must be added to keep the parts of the globe in place in case of its

mixture during use. Wherever a current of such high electro-motive force is employed that, if consentient on one lamp of the series, it would produce no arc capable of destroying or fusing parts of such lamp, an automatic switch must be introduced in each lamp by which it will be thrown out of circuit before the current approaches any dangerous intensity.

The Spectra of Sunlight, Gas, and Electric Light.

Some weeks since a question was put by a correspondent in *Nature*, with the obvious intention of obtaining confirmation of a statement that the spectrum of the electric light was similar to that of sunlight; the teaching of which correlation would be that, for optical purposes, the electric light was equally good with that of the sun.

In a later number of our contemporary, however, the characteristics of the spectra of sunlight, electric light, and gas flames are explained by Mr. J. Read Capron, but not precisely in the way desired by the querist. While admitting that the relative effect of the "same golden glow, the gas flame's duller yellow light, and the electric light's moon-like whiteness," on the optic nerve, have not been scientifically determined, Mr. Capron recognizes the fact that peculiar opinion assigns injurious results to the whiter light. He also states that the illuminating position of a gas flame presents in the spectroscope the appearance of a dull sun spectrum, with all the dark lines. This is equivalent to placing the illuminating gas flame in closer approximation to the sun's light, for optical purposes, than it is possible to claim for the electric arc light.

It is evident that the spectroscopic examination of high power gas flames should now be undertaken with a view to determining the differences which such flames present when compared with the flame of the ordinary small burner.—*Journal of Gas Lighting.*

THE OFFICIAL ON GAS LIGHTING WATER SUPPLY, & SANITARY IMPROVEMENT. [Dec. 27, 1881.

ELECTRIC LIGHTING FAILURES.

Some few weeks since it was announced, with the usual amount of clamour, that the smoking-room of the Junior Carlton Club was to be the scene forth lighted by incandescent electric lamps, to be maintained by relays of Faure accumulators. The attempt to make use of this particular method of lighting was, of course, simply an experiment; but, in the common manner of electric lighting contractors, the commencement of the trial was advertised as the consummation of success which, in reality, remained to be proved. It has now transpired that after a prolonged experiment the electric light has been removed from this particular club-room, and gas has been reinstated. This collapse of the undertaking that was inaugurated in such a very notorious fashion has naturally been allowed to pass unnoticed by the friends of the new order of lighting, and the announcements that were made of the satisfactory success—which did not succeed after all—may still be going the round of the Press, and cropping up in various speeches and newspaper correspondence.

Some attempts have been made to light by electricity the immense buildings of the General Post Office, St. Martin's-le-Grand. The experiments have been conducted by Mr. W. H. Preece, but although several well-advertised systems have been tried under his experienced supervision, the matter is at this moment in a state of suspense because of repeated failures. We are not at liberty to assume that the attempt will be finally abandoned until every known system and arrangement of electric lighting has had a fair trial at the hands of Mr. Preece, who can have no other interest in the matter than that of discovering the best among all the methods of lighting that are pressed upon his notice. His ultimate failure to light the Post Office by electrical agency in some form would be a heavy blow to the contemporary progress of the systems so tried and found wanting. It is not for us to prophesy the result of Mr. Preece's experiments in this direction; but in no way can, whether he abandons the use of gas or not, it will be very desirable that he should give us the public an account of his proceedings in this matter. The experiments at St. Martin's-le-Grand, it may be assumed, are conducted in the public service; and therefore the result, with the lessons which the event cannot fail to convey, should be shown to the public by the responsible officials, without regard to the more selfish interests of the inventors and speculators, who might object to have their condemnation published. If Preece does not, as a rule, shun publicity, and it may be hoped that he will not deny to the public the advantage of a record of electricians' failures. They themselves may be trusted to keep the world well informed of their success, both real and imaginary.

of the Royal Institute of British Architects, giving instances of accidents from lightning and accompanied by illustrations of the buildings struck. Appendix E contains the instances collected by Mr. Symons in 1876-7-8-9, and Appendix F, which occupies nearly 100 pages, contains the observations of the various papers and books published on the subjects. Appendix G is a catalogue of works upon lightning-conductors; the other Appendices contain correspondence on the subject, including Faraday's letters to the Secretary of the Trinity House. Messrs. Preece and Symons give some notes on lightning-conductors, collected in Paris last spring, and Messrs. Howard and Spencer report on the conductors at the Electrical Exhibition. A number of plates and small diagrams, and a copious index, complete the volume.

CRYSTALS AND ELECTRICITY.

QUITOSE (say MM. Jacques and Curie, in a recent paper to the Paris Academy) that a solid body—e.g., a prism of glass—0·01m. in surface, undergoes a quantities equal to a thousandth of an inch—the quantity would be very difficult to ascertain by a direct process.

If, however, this variation of length be opposed absolutely, the solid will undergo a variation in the pressures of each of its faces, which, by means of a manometer, enabling one by measuring or measure the pressure, would afford the possibility of inferring the variation of length produced. It will be seen that this method is based upon the law of the elevation of coefficient of compressibility of solid bodies.

The authors have devised such a system, utilising the property possessed by quartz, of generating pressures in applied to it in certain directions, quantities of electricity proportional to the pressures. They have made an interesting application of the apparatus—viz., to demonstrating the reciprocal phenomena of the electric polarity of hemihedral crystals—i.e., crystals having but half the normal number of planes, or, in general, wanting some of the planes.

It is known that when a hemihedral crystal of this tetrahedral class is subjected to a variation of pressure along an axis of hemihedry, there are developed at the two ends of this axis, quantities of electricity that are equal, and of opposite signs, the direction being according to the sign of the variation (pressure increasing or decreasing). Now MM. Jacques and Curie have been able to prove, that, reciprocally, if the two ends of the axis of a hemihedral crystal be charged with electric quantities, it undergoes along the axis, either a contraction or a dilatation, according as the direction of the axis to which the electric tension has been applied to it.

M. Lippmann, indeed, has enunciated the law of the reciprocal phenomena, which is simply a generalisation of the law of Coulomb. The phenomena always such that the reciprocal phenomena are of the same order, "the production of opposite electricities." And, taking the principles of conservation of electricity and conservation of energy, he has been able to foresee and demonstrate in anticipation all the peculiarities of the reciprocal phenomena.

MM. Jacques and Curie first measured the quantity of electricity liberated by a quantitative unit by quartz, for a pressure of one kilogramme. It is noted, by calculation, that prisms of these substances should undergo variations of length of about 1-20,000mm. for a difference of potential corresponding to a spark of 0·01m. in air.

The experiments were then arranged so that the apparatus was formed of two solid bronze plates united by three columns which, in fixed connection with one of the plates, traversed the other, and terminated in screws and nuts. Thus, with the nuts, the plates could be approximated to each other on a pile of objects placed between them. These objects were in two systems.

The lower system served simply to measure variations of pressure. It consisted of three bezel and thin plates of quartz, separated by metallic plates put in communication with the electrometer, which indicated the electricity liberated by variations of pressure undergone by the quartz plates.

JAN. 6, 1882.

Electric Lighting.—Regarding his report upon the different systems of lighting which were exhibited at the Paris Exposition, Dr. Monod says that the systems of incandescence are already numerous, and doubtless many others will soon be added. Most of these differ from one another only by the form of the carbon conductors and by the method by which the carbon is rendered incandescent. Any correct judgment on the same or less brilliant aspect of the lamps, for, as they are fed by electric generators of very different intensity, those which have the strongest currents naturally furnish the most brilliant lights. Dr. Monod has, therefore no hesitation, in thinks, in pronouncing in favour of any single system until a serious examination and comparison has been made by a commission of disinterested scientific men. There is, however, reason to hope for a satisfactory solution of the problem of household illumination by electricity.

ENGLISH MECHANIC AND WORLD OF SCIENCE:

JAN. 6, 1882.

The Danger of Electric Lighting.—A committee of the Franklin Institute recently reported on the dangers of electric lighting. That committee specify a number of precautions to be taken, which are, in substance, as follows:—1. The conducting wires, both to and from the machine, should be kept well insulated throughout. 2. The machine should be supported on insulating cushions, being liable to impairment, especially at supporting bolts, or sharp bends, or wherever moisture may occur. 3. Conductors formed of numerous short pieces of wire should be avoided as far as possible; where they have to be used, the wires should be as long and as straight as possible by stapling, so as to prevent short arcs. 4. A continuous wire should be provided, and no attempt made to cause the current pass back to the machine through the earth. The wire should not be carried over metallic bodies like fans of shafting or gas or water-pipes, since contact with these would be equivalent to a direct ground that part of the wire. Where the wire has to cross metallic bodies, the insulation should be made better than usual. 5. The ready occurrence of cross conductor short circuits must be avoided. Therefore the wires should be of sufficient section to permit the whole current passing without dangerous heating. 6. To avoid danger to life from electrical shocks through the wires, wires should, wherever practicable, be placed out of reach, and, where they have to be touched, should be carefully insulated. 7. Where exposed to accident, they should be covered with a glass globe, and a cap or pan placed below to stop any broken fragments. The committee believe that, if these precautions are taken, electric lighting will be thoroughly safe.

ENGINEERING NEWS.

JAN. 7, 1882.

ELECTRICITY.

Poles for Aerial Telegraph Purposes.—The Elgin (Ill.) Telegraph Company is still furnish the city of Rome (Ga.) gas with four hundred poles for the city with electric light.

Recommended Telegraph and Telephone Wires.—The wires of the National Underground Electric Company, Philadelphia, from the public buildings to the Delaware River, were tested on the 2d, and found satisfactory in every way. On the 3d, they will inform the city council to adopt the underground wire for lighting the city in preference to the present system, which will undoubtedly be discarded. The claim is that city over a fire produced by electric wires will probably result in a renewed effort to bring the telegraph and telephone wires underground. The electrical current over the two-ground Boston, also, has authorized the construction of continuous lines of pipes by private enterprise in a large number of streets, on overhead

over

that all telegraph and telephone companies be allowed to lay their ensemble upon in the pipes at a rental not exceeding the cost of maintaining the wires overhead. In New York our underground wire subscriber has been robbed by the Mayor, pretty much as he would be if he had to pay for water supplied by the full of water, water and gas pipes to give room." It is evident that the time has come for studying and utilizing the whole subsoil of New York. On some definite plan, the entire underground street and park accommodations of the city should be so economized that whether for pipes, sewers, railroads, or other purposes, the least possible interference with the surface and its uses in such a way as to relieve the streets of the needs, cross-pipes, wires, railways and other obstructions, which now help to take away from many carriageways their comfort and size, or clog the feet and ways of the people and obstruct the thoroughfares.

E. G. LOVE, Ph.D., *Gas Examiner.*

* Mosing Grand Street Station.

THE FRANKLIN INSTITUTE AND ELECTRIC LIGHTING.

The *Journal of the Franklin Institute* publishes the report of the committee appointed to consider what precautions are necessary to obviate the dangers likely to arise from electric lighting. At the outset the committee say "that from a careful consideration of the evidence submitted they believe that the use of electricity as an illuminant, as now generally employed, is not attended with any dangers, either to person or property, that cannot be obviated by the adoption of the precautions hereafter set forth."

The report describes the methods of lighting by "incandescence" and the "arc," the construction of the dynamo-electric machine, and the principal points of difference between static and dynamic electricity. That produced by the ordinary frictional machine, or static electricity, has the power of jumping over considerable distances, and as produced in nature is seen in lightning flashes. The electricity produced by dynamo-machines has, on the other hand, no such power of jumping from one conductor to another. Even in the arc light with a powerful electric current, the carbon rods must be brought in contact and afterward separated, the contact serving to form the vapor of carbon between the rods and supply a conducting material. It is therefore a mistake to compare the currents from dynamo-electric machines to modes of lightning. It is important to prevent the formation of any conducting circuits between the regular conductors of the current. If any conducting material be placed in, or form a part of the electrical circuit, or from any cause a momentary break be made between it and the rest of the circuit, an arc of flame may result." "As these arcs of flame are very hot, their occurrence should be carefully prevented in all places except between the carbon electrodes in the lamp." Danger may be avoided by insulating the wires, and there is no necessity for any very high degree of insulation. "Whatever the character of the insulation employed, care should be exercised to insure its being preserved intact on all parts of the wire. The removal of the insulation from but a few points of the wire might cause a dangerous discharge at such points." "Where two different paths are open to the current, it will flow through both such paths." "Suppose, now, that two different portions of an electrical circuit be bridged over by any conducting material: say, for example, that a wire from a line of telegraph or telephone falls across a line of electrical conducting wires, so as to connect the wire carrying the current from the machine with a part of the wire carrying the current back to the machine. If such electrical conducting wire be uninsulated, a series of cross contacts would thus be formed, and two different paths be opened to the current. Since the conducting power of the short wire, forming the cross circuit, would probably be far greater than that of the portion of the circuit with its included lamp, the greater part of the current thus "cut out" or "short circuited" would pass through the cross wire, either fusing it, or drawing dangerous arcs of flame when the contacts were at times but partial."

If the human body accidentally forms a part of the circuit, a painful or even a fatal shock may be received. It is necessary, however, that the current should enter the body at one point and pass out at another. The mere touching of a conducting wire would not place the person in the circuit and no injury would result. It would be different with a frictional machine, in which contact with a charged conductor would discharge it through the body into the ground.

The committee, in conclusion, recommend that the following precautions be taken in all cases where the electric light is employed:

1st. That the conducting wires be suitable insulated.

2d. That frequent inspection be made to insure the insulation intact. Insulation may be impaired by hooks used in fastening the wire, by abrasion with other wires, and by sharp bends in the wires.

3d. That conductors should not be formed by short pieces of wire, or if such are necessary that the joined ends be securely wrapped.

4th. That the wires be not grounded, but that a continuous line of wire be provided, and that the wires be not carried near metallic bodies as gas or water-pipes.

5th. That the occurrence of cross contacts be avoided by keeping the conducting wire as far apart as convenient, that the wires be fixed in position and not allowed to sag, and that in introducing them into a building they be placed in as dry a place as possible.

6th. That the conducting wires be of sufficient size to carry the most powerful current without heating.

7th. That the wires be placed out of reach so far as possible.

8th. That in the use of the arc lights, they be surrounded with a glass globe, and that a cap or gas be provided at the bottom for any falling fragments.

"The committee believe that if these precautions be taken, electric lighting can be thoroughly safe and reliable, and that all dangers attending its use can be entirely obviated.

ELECTRIC LIGHT NOTES.

Water power is to be employed in lighting by electricity the town of Godalming, in Surrey, Eng.

It is acknowledged that one electric light in Boston has the same effect as five policemen "in uplifting the moral condition" of the people.

It is stated that an iron mast 260 feet in height has just been raised in the public square in Cleveland, for the accommodation of the electric light. Two others are to be put up for a similar purpose.

A laborer, while engaged in repairing a telephone wire at the residence of the Marquis of Salisbury, accidentally came in contact with the insulated electric-light wires, and was instantly killed.

The Philadelphia *Times* records another accident caused by electric light and telephone wires coming in contact. It occurred in the telephone department of the Local Telegraph Company. The woodwork was considerably scorched, but no serious damage was done.

The New York *Herald* states that a midshipman has been detailed by the Navy Department to attend the Crystal Palace Electrical Exhibition in London, to gather whatever material may be of value "in the use of electricity for lighting, and other purposes, on shipboard and in torpedo practice."

According to the *Ledger* of Philadelphia, the Superintendent of the Brush Electric Light Co., of that city, is of the opinion that telegraph and telephone wire s should be placed under ground, but he does not think the electric light wires can be similarly placed, on account of the difficulty of insulating them.

The Pullman cars on the Brighton (Eng.) Railway are lighted by electricity supplied by secondary batteries. The lights can be turned out when not needed, and the effect is said to be very fine. Two men are required to look after the batteries, making an item of expense which, of itself, exceeds the cost of lighting the same cars by gas.

The *Railway Age*, quoting from the London *News*, says that the annual cost of lighting a Pullman car by the present methods on English roads is £480, while with an original outlay of £200 for engine, batteries, etc., the same work can be done infinitely better by electricity for £60 per annum. It is considered somewhat singular that American roads have not adopted electricity for railway lighting purposes. There seems to be no good reason for accepting the above figures as representing the comparative cost of the two systems; and Americans are quick enough to grasp anything new which is likely "to pay."

It is known that with electrical machines which furnish a continuous current, the effect of using such a current in producing the arc light is to cause the upper carbon to assume the form of an inverted cup, the inner portion of which is most intensely heated and emits the greatest amount of light. The sides of this cup shut off much of the light which would be emitted horizontally, and tend to throw it downward. M. Deboscq, with the view of correcting this, recommends that the carbons be not placed exactly in line. We do not see that this plan would be any improvement, for the sides of the carbons opposite the arc would cut off the light in two directions, and not afford the reasonably uniform light which, by the present plan, is thrown on all sides of the roadway.

THE ENGINEERING AND MINING JOURNAL.

SEPT. 3, 1881.]

The Electric Light in Mines.—The Swan electric light, which closely resembles the Edison incandescent lamp, is in process of introduction at the Earnock Colliery, near Hamilton, North Britain. There are now sixteen stationary lamps and sixteen "portable." *Engineering*, which gives some details on the subject, does not state to what extent the latter can be carried about, nor is the candle-power of the lamps mentioned.

Inventors appear to be turning much attention to the utilization of electricity for running drills for mining and quarrying. At the Paris Electrical Exhibition, a Tavernlon diamond drill and a percussion drill, by M. Chenot, *fils*, is shown. These can be little doubt that there is much promise of success in this direction, and that, under special circumstances, electricity may prove a welcome substitute for steam or compressed air.

DEC. 16, 1881.

ELECTRIC LIGHTING—ITS FIRE RISKS AND THEIR REMEDIES.*

By HENRY MORTON, Ph.D.

President of the Stevens Institute of Technology.

SOME very lamentable accidents have strongly directed public attention to the question of the safety of electric lighting as compared with the ordinary illuminating agents. Fortunately, in a source of light, such as the actual conditions of this danger, like the true properties of the agency from which it may arise, are few, and a very brief explanation of some simple facts related to the principles of electricity and electric conduction will be needed. I would remark that this whole subject under two general heads, namely: 1st. The source of danger; 2nd. The conditions of their prevention, or of security. The source of danger in the use of electricity is also essentially two; from the conducting wires and from the electric arc. Since, in the use of electricity as an electric energy, is conveyed by a sufficiently good conductor it is perfectly harmless, resembling a water-forcing in its natural channel, and particles to the shores its banks; it is only when some other channel into surrounding objects is offered or some partial obstruction of a certain character is met with that any danger arises. The nature and conditions of these difficulties are, however, very peculiar. Thus, for example, if two electric conducting wires, forming the outgoing and returning parts of a powerful current, are placed near each other, but are separated by a bad conductor, as, for example, when both are buried on the ground, or when they are suspended in the air by wire from end to end, with no development of heat in the same, no tendency to leave the conductor or pass into any adjacent object. If, however, between the two conducting wires we introduce some imperfect conductor, such as a piece of wet, some metallic dust, or a fine thread of carbon, or even a dry piece of wood, there is portion of the current will be diverted into this "short-cut" from wire to wire and may heat the fine wire or the metallic dust or the wood melted with aqueous solution, so as to cause the ignition of inflammable matter. A moment's reflection will show the already concerned. Thus a telegraph or telephone wire may come across a single wire of the conduction used for street lighting purposes has been fused, or, itself escaping, has caused the fusion of their wires connected with it.

Again, two wires being the outgoing and return circuits of a powerful current, may, from any cause, be side by side for some distance, as on the same post or in the floor, partition, or ceiling; and though used safely for a long time, while the woodwork was in its normal state, have developed a very dangerous activity when the wood between them was wet with dirty or impure water. Metal near the water allows a closed circuit which a cross

ELECTRICAL APPARATUS.

American Institute of Mining Engineers.

ANNUAL MEETING, Wednesday, Thursday and Friday, February 15th, 16th and 17th, 1882.

The Institute will meet at the Stevens Institute of Technology, Hoboken, N. J., on Wednesday, February 15th, at 10 A.M., for the reading and discussion of papers, and the election of members.

Thursday, February 16th, at 10 A.M., will be devoted to visiting the Works of the Edison Electric Light Co., the Sprague Electric Railway and Motor Co., the Bergmann Electric Co., and the Electric Tramway Co., in New York City.

Friday, February 17th, at 10 A.M., will be devoted to visiting the Works of the Consolidated Electric Light Co., the Weston Electric Light Co., and the Thomson-Houston Electric Co., in Boston.

Special trains will be provided over the Pennsylvania Railroad, leaving Jersey City at 9 A.M. and Cortlandt Street at 9.30 A.M. on Wednesday, February 15th, and returning from Boston at 5 P.M. on Friday, February 17th.

Members desiring to read papers at the meeting are requested to notify the Secretary at once, and to forward the papers as early as possible.

Members intending to visit the Works of the Companies mentioned above are requested to notify the Secretary at once, in order that arrangements may be made for their reception.

Members intending to be present at the meeting are requested to notify the Secretary, in order that arrangements may be made for their entertainment.

By order of the Council,

ALEX. L. HOLLEY, Secretary.

Stevens Institute of Technology, Hoboken, N. J.

IN VIRGINIA MEETING

of the Virginia Medical Society, to be held in Richmond, Va., on the 17th, 18th and 19th of January, 1882, a paper will be read by Dr. Hunter McGuire, of Richmond, entitled "Electricity in Surgery." Other papers of interest are promised, and the meeting will be a very interesting one.

THE JOURNAL OF GAS LIGHTING,

WATER SUPPLY, & SANITARY IMPROVEMENT.

TUESDAY, JANUARY 10, 1882.

THE TRUE ILLUMINATING VALUE OF COAL GAS.

One of the most striking results of the progress of invention during the last few years, in the matter of the illuminating power of gas for purposes of lighting, is the upsetting of all preconceived ideas respecting the meaning of the term "illuminating power." The principles, indeed, have never been recognised as a description of some fixed property of gas, such as that of bulk or quality; but only as indicating the quality, depending upon some undefined proportions of its complex constituents, which might be found in the flame of gas when burnt under certain conditions. The conditions under which the flame of any class of coal gas is produced have always been regarded as consisting largely in the question of the power of the light afforded thereby; but the true value of this consideration has only recently been acknowledged. It constitutes a most important principle, which controls a number of conclusions of great interest to manufacturers and consumers alike—the principle that, within certain limits, illuminating power depends upon the burner and not upon the gas.

There was a time, in the earlier days of gas lighting, when the illuminating power of the mixture of coal and cannel gases commonly sold by the Companies was regarded from a very different standpoint to that just indicated. The burners then generally used were not such as are most favoured at the present day, and they wasted a great deal of gas—that is, they gave a very low duty for the gas consumed. Yet from these imperfect appliances a man, her of influential personages considered that they could lain all about the illuminating power of gas in relation to its , onstitution; and they consequently preferred to regard the results of photometrical measurement, not as in themselves declaring the value of gas as an illuminant, but as indicative of a value which was to be found in the composition of the gas itself. This habit of thinking led to a partial reversal of the principle now universally followed—and, of course, also known at the time referred to—inasmuch as the proposal to use an improved burner for photometrical measurements of common gas was resisted, on the ground that it would give a fictitious value to the gas by increasing its apparent illuminating power. So long as the composition of the gas remained unaltered, it was believed that the improved result obtainable by the use of a better burner was not a tangible advantage.

This state of feeling fortunately did not prevail in contemporary counsels so far as to prevent common gas from being invested with additional value, by the adoption, as the legal standard burner for official photometrical operations, of an appliance which was a notable advance upon previously existing patterns. From this time the illuminating power of gas became more generally understood, not as a something apart from the actual light of the gas flame, but more definitely as a result of the combined action of gas and burner together. Judged from the common-sense standpoint, it would have been lamentable if another course had been taken, and the manufacturer had been compelled to supply gas of a quality calculated either with reference to its composition alone, or in conjunction with some imperfect mode of burning. As it is, however, the circumstances attending the production of a gas flame are legally held to account for the illuminating power of the light afforded, in even a greater degree than the substance burnt.

Reviewing the present system of gas supply of the United Kingdom, discarding solitary instances when special considerations regarding quality have been allowed to prevail, it may be considered that Parliament has laid no greater obligations on the manufacturers, in this matter of illuminating power, than can very well be complied with in the ordinary course of careful working with common qualities of coal. This reflection is naturally based on the supposition that the most suitable burner is employed in all cases. If the course of invention had stopped with the evolution of the standard burner, its introduction would have to be accepted as showing the absolute illuminating power of gas for practical purposes. But invention has gone far beyond this burner, gas as it normally is, not responding to the older patterns which it supersided. If, as we contend, the true illuminating power of gas is that which it can be made to yield under the best conditions under which it can be burnt, then the results afforded by the best test burner become of formal value only from the moment when it was shown that other appliances rendered an appreciably better duty. As already remarked, there are numerous kinds of burners which cause the development of so much more light than is possible with the test burner, that gas which is legally valued at sixteen-candle power may actually be made to give twice as much light to the consumer. The old truism that much of the bad lighting complained of by consumers is traceable to causes entirely within their own control, receives strong reinforcement and amplification from considerations such as we have advanced. What may not be accomplished respecting the responsibility of gas consumers for the amount of light they obtain in return for the quantity of gas passed through their meters, when it has been shown to be possible, by merely changing the burners, to vary the illuminating power of the same gas through a range of 100 per cent. above the nominal valuation, to say nothing of the depths below this figure? The illuminating power of common gas is now, in fact, just what the consumer wishes to make it. His responsibility is great; but even more pressing is the duty devolving upon gas engineers and gas apparatus manufacturers generally to guard the consumer in the due enjoyment of his rights. Unless there be a radical reform in the present methods of using gas for domestic lighting, whereby the best inventions of the age, in the matter of gas-burners, can be placed at the ready disposal of consumers, as pointed out in the essay which appears in another column, the best results which might be expected of the electric light inventors will be missed. Street lighting is in no danger of falling back into the old groove. When will every on the work of reform, in securing equal benefits on private consumers?

ELECTRIC LIGHTING ON PAPER AND IN REALITY.

THE friends and foes of electric lighting have alike been busy during the past fortnight. To commence with the former, it

THE JOURNAL OF GAS LIGHTING, WATER SUPPLY, & SANITARY IMPROVEMENT.

Electric Lighting.

Jan. 10, 1882.] Professor Young.

THE EDITOR.

At last an expectant world has been informed of what is wanted by electricians to render them masters of the present age. The information is Mr. Jacob Hecse, who, if we are not mistaken, has been heard before as the inventor of a wonderful dise which cuts through iron and steel without touching the metal. Mr. Hecse tells us that electricity is nothing but "dynamic celeric"; which seems very like changing one word for two, and he explains the meaning of this mystic phrase. Celeric, then, is the force of repulsion existing in material substance which prevents the molecules of matter from touching each other. So much of this force as may be in motion is named "dynamic celeric," while the force of mutual attraction keeps another portion of celeric confined in matter, and this part of it is called "static celeric." Mr. Hecse recognizes the fact that where fuel is burnt to produce motion in a steam-engine as a first result, and the engine is made to develop electric energy by means of a dynamo machine as a secondary result, a great deal of the original "celeric" of the fuel expires. Therefore it is argued that if the "celeric" of the fuel could be made to produce the secondary result at once, without the intermediary stages hitherto assumed to be necessary, considerable economy would be secured. The great want of the present age, we are told, is a process by which the "static celeric" of carbon, or a hydrocarbon, may be set free from non-luminous combustion; or, in other words, a process by which coal or oil may be oxidized at a low degree within an insulated vessel. If this can be accomplished there would be realized from 12 to 15 million foot-pounds of energy (electricity) from 1 lb. of petroleum, and from 10 to 12 million foot-pounds from 1 lb. of coal. Quite incidentally Mr. Hecse expresses his belief that before very long all coast cities will be served with electric force obtained from the power of the tides, in which case the "gas companies will suffer." Mr. Hecse's greatest hopes, however, are centred in the notable proposal to obtain "dynamic celeric" by non-luminous combustion, whereby electricity is to be produced at rates so low as to render it the only possible medium for lighting, heating, and driving machinery requiring motive power.

THE INDIANAPOLIS JOURNAL, SATURDAY, FEBRUARY 4, 1882.

ELECTRIC SUCCESSES.

If Edison's electric lighting has not plus forward as rapidly as was at first expected, it has never gone so far a moment back but taken any backward step. Nearly two thousand buildings have been equipped with wires and motors in the

same district shown —some, the mains are laid in more than four miles of streets, and the twelve large steam-engines with [illegible] more are now being put in place in the central station. Edison has contracts with the owners of all the buildings. Most will adopt the whole arrangement will adopt the whole arrangement, but it will not be till everything is ready.

Edison's aim would be in competition with electric lighting being introduced. He is now at Menlo Park lighting up the electric railroad on which trains are to run at forty miles an hour by electricity four years ago and exhibiting another three miles long in Lyttleton, N. J. He thinks that within a year he will have the rails on it at the rate of eighty to one hundred miles an hour.

The chief improvement which prevents steam trains from ruining the track is the [illegible] very slight and practically jerking back and forth. The worst speed is when the wheels of each revolution of the driving-wheel [illegible] at the rate of eighty miles an hour, and no fast passenger train has ever been driven at a speed of 150 miles an hour.

The elevated roads here are ready to substitute electricity for steam on all their lines, and are negotiating with Mr. Edison to this end. Last fall they offered him the Thirty-fourth street track, but he declined to have any experiments here, preferred by a time-table, but he was ready to take the whole job.

The Lowell Daily Courier.

WEDNESDAY, JANUARY 11, 1882.

Corporation Notes—Electric Lights.

The Merrimack company are to make further experiments in the use of electric light. It will be remembered that this corporation given a trial to the Brush system of lighting which resulted, as the use was abandoned after a few weeks for several reasons. One objection was that the light was concentrated in a portion of the mill, and the result, rather than an even distribution of it. The company is to experiment with the Edison incandescent light, and the fancy weaves of Mr. Jas. Hodgkinson, a Westminster-shaders, have had painted in them letters points for improvements in Electric Lamps," which we have received. The invention relates both to the mechanism of the lamps and the carbon [illegible] Fig. 1 and 2 are elevation and plan of the lamp. Fig. 3 shows [illegible] lever gear. The upper carbon C is carried by the holder A, upon which is cut a screw-thread by engaging a similar thread in the bore of the wheel F. D is a key-way or "screw of infinite pitch," which keeps the holder from revolving. In operation, as the upper carbon falls, the wheel F is caused to revolve by the screw A, and retains the piston G and the brake wheel H. The brake-wheel is controlled by an electro-magnet on a shunt circuit acting against a spring, which, when the resistance of the arc increases, is withdrawn from the brake-wheel. In Fig. 3 the toothed wheels are replaced by a brake disc provided with paddles working in fluid.

Daily Evening Traveller.

TUESDAY, JANUARY 31, 1882.

Electric Lighting.

The Edison Company for isolated light of New York [illegible] Engineering for lighting several large mills in New England. The use of which will be lighted during the present season of steam [illegible] Edison's system of electric lighting has [illegible] to ensure absolute safety as to the danger of fire from the light [illegible] to the danger from the current of electricity, and are glad to find the utmost [illegible] practical test.

The [illegible] system of electric lighting [illegible] perfected by Mr. Edison, is to entirely do away with the danger from fire as a [illegible] for which [illegible] are [illegible] The [illegible] system of electric lighting is the first [illegible] safe, as it never conflagrations of Mr. [illegible] are placed among the combustible [illegible] made from the walls, or branch wires [illegible] a tap is [illegible] [illegible] and these is no jerking of metal of ground. Edison's [illegible] the [illegible] construction, so that in case [illegible] that of the copper [illegible] [illegible] [illegible]

somewhat disappointing, on account of the comparatively small area which is illuminated. In clear weather the groups of lamps are very effective at beacons, but if they were separated and placed at different points over the same area, the illumination would be more satisfactory. The following interferes with the efficiency of the lamps, and this objection would be still more noticeable in midsummer.

As to the illuminating power of the electric lamps employed, it should be stated that it is a matter of importance as to how this is measured. In the Brush and other systems in which the lights are fed by continuous current machines, the upper carbon, in the case of the arc light, soon becomes sooty, and in the form of a bulbous, ring-like or deeper part of which emits the greatest amount of light. It is evident, therefore, that in determining the illuminating power of arc lights of this nature by horizontal measurements, a portion of the light will be cut off by the sides of the hollow or ring formed. For a similar reason the greatest amount of light would be thrown downward at an angle of about 60°, and angular measurements would give a result three or four times greater than the horizontal.

The illuminating power of the Brush lamps with ¾ inch carbons is from 300 to 400 candles, horizontal measurement, and from 1,000 to 1,300 candles, angular measurements. There is no reason for the expression "French measurement." It is without any advantage and being unlike the plan customary in expressing photometric results is very misleading. A gas flame of twenty candles would, by French measurement, be rated at eighty candles.

The carbons employed in the groups of electric lights in the Square, are said to be of ¾ inch diameter, and presumably the illuminating power is greater than in the case of the arcs lamps, but the effect produced we are inclined to think that the estimate given (36,000 candles), is rather high, unless expressed as "French measurement."

ELECTRIC LIGHT NOTES.

At the recent exhibition of gas apparatus at Aberdeen, Eng., there was a spirited contest between the Swan incandescent lamps and the gas burners of Mr. Bray. Reports seem to agree in giving the first place to the gas burners.

According to the *Journal of Gas Lighting*, the Directors of the British Museum have decided to again light the reading room by means of the Siemens electric lamps. There will be four arc lights, with a stated candle power of 4,000 candles. In addition it is expected that there will be several of the Swan incandescent lamps.

The *Review of Gas and Water Engineering* mentions the visit of the members of the mining districts of Scotland to the Earnock colliery, near Glasgow, where the Swan incandescent lamps are used for lighting. There were twenty-one lamps, each giving the light of fifteen candles. Two lamps, which were placed at some distance from the rest, were noticeably inferior; the cause for which was subsequently found to be in the higher resistance of those lamps. It appears that there is considerable variation in the Swan lamps in this respect, and the engineer in charge has tried the plan of putting the worst lamps in those branches of the circuit where the resistance was low, and also in regulating the resistance in the different branches. A lamp which is deficient in the nature of gases, showing the necessity for the complete protection against the breakage of these lamps in mines, and the care needed in their use under such circumstances. In lighting the Earnock colliery, the lamps are inclosed in strong protecting cases.

Scientific American.
NOVEMBER 12, 1881.

The Expenditure of Energy in Incandescent Electric Lighting.

At the York meeting of the British Association, Sir W. Thomson and Mr. Bottomley gave the results of some experiments carried out by them in order to determine the illuminants carried out by them in order to determine the illuminating power of incandescent vacuum electric lamps with various strengths of current. Every lamp was tried with lighter and lighter potentials until the carbon broke. The electricity was obtained from a number of Faure's cells, of which 26 were first put in circuit, developing 0 0393 horse power, and others were added until the lamp was destroyed. Three lamps only were tried, the first of which broke down after fourteen experiments; the second lasted through fifteen tests; and the third broke before the third reading could be completed.

With 26 cells the first lamp gave the illuminating power of with 32 cells it showed 42 candle power; and successive additions of cells forced the light up through a very irregular scale until, when giving the maximum of 114 candle power, the carbon gave way. The next lamp was first tried with 40 cells, affording 0·27 horse power, and giving the light of 0 candles; and the lamp broke when connected with 70 cells, when the light would have been over 700 candles. The irregularity of all the records is very striking, the power of the batteries and the light given by the lamps being very uncertain and by no means increasing in any common ratio. For example, the first lamp gave the light of 84 candles, with the expenditure of 0·247 horse-power, from 69 cells. The next lamp, with the same number of cells, gave only 19 candle power in one instance and 35 candle- in another, although the energy of 0·27 horse power was recorded, or nearly the same as before. Again, the second lamp gave 108 candle power with 80 cells, while the addition of 6 more cells, instead of increasing the light, brought it down to 103 candles. Much of this irregularity is said to be caused by the blackening of the interior surface of the globes by the deposition of volatilized carbon, when high powers were applied. The photometric method employed by the authors consisted of directly comparing the light of shadows thrown by a pencil on a piece of white paper, and the candle employed was the usual standard sperm candle, assumed to burn at the normal rate, but not weighed, as the object of the experiments was simply comparative.—*Journal of Gas Lighting.*

Scientific American.
NEW YORK, SATURDAY, NOVEMBER 12, 1881.

Medals for Electric Lights.

The jury of the International Electric Exhibition has awarded gold medals of the highest class to Edison and Brush for dynamo magnetic machines, and a gold medal to Maxim. Also, gold medals to Edison, Brush, and Maxim for arc incandescent lights. Edison takes five gold medals in all, being more than any other exhibitor.

Scientific American.
NEW YORK, SATURDAY, JANUARY 14, 1882.

Electric Lights at Hell Gate.

The dangerous condition at Hell Gate, the eastern entrance to the harbor of New York, causes a nightly blockade of vessels. To obviate this delay to commerce the Light-house Board has believed a proposition to provide Hell Gate with electric lights, and Congress has been asked to authorize the necessary experiments. The plan is unquestionably practical and cannot fail to be beneficial,

wheel mould has been patented by Mr. Grisburg, Pa. This invention relates to its car wheel moulds of that form in sured through a central hole in the core, ized space from the bottom; and it consider ours with an annular re-enforcing , perforated to permit the passage of air and combining this with the drag-sand, h a circular recess to receive the lower d rollating channels that connect the the wheel spaces.

In common use are moles of links strength of the chain being determined ze of the rivets and their resistance to or pull of the links, and when a link nks have to be cut out and a new link ew sides, which latter must be upset, of repairing a flat link chain of ordi- slow and expensive. Mr. James W. ille, Fla., has patented an improvement to the repairing and lengthening and ink chains. The improvement consists having the thick or double link made vened and socketed at each end, the it, and in forming each single link with ojecting at right angles from one face ain is made by coupling the double and r by means of the engagement of the the undercut sockets of the former. ocates for the water packing of screw- and durable. The invention consists in a coarse cloth, such as a burlap, which is covered on one or both sides with a mixture of clay and tar.

Mr. John J. Tierney, of New York city, has patented an improved door scanner, consisting in the combination with a screw, for securing a door, of a post socket having on its forward end the right angled plate fitting into a notch of door post and secured by screws, so that a scanner cannot remove the socket, even after he has withdrawn the bolt.

Mr. John B. Bennett, of San Luis Obispo, Cal., has patented an aromatic or mechanical lubricator, which consists of a compression gauge, a measurement, and a valve, for giving a lasting and uniform flow of oil, and which is adjustable to suit any consistency of oil of such construction that it can be placed in almost any place or position required.

THE GASTROSCOPE.—AN ELECTRIC LIGHT FOR THE HUMAN STOMACH.

The application of electricity in ways the most varied, and, perhaps, we might add, unexpected, has, within the last few years, developed with almost bewildering rapidity. As in so many other things, it has its applications also in medicine; perhaps one of the most novel and ingenious of these, as well as the least generally known, is the employment of the electric light to illuminate various parts of the body which are only obscurely visible, if they can be seen at all, under ordinary circumstances. There have been many instruments, says Mr. H. Wilson in the *English Mechanic*, designed to facilitate in this way the diagnosis of the less accessible cavities of the human frame. The oesil-

FIG. 2.

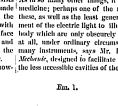

FIG. 3.

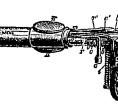

FIG. 4.

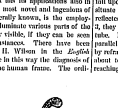

FIG. 5.

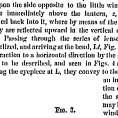

FIG. 6.

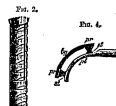

FIG. 7.

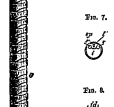

FIG. 8.

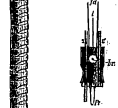

FIG. 9.

THE GASTROSCOPE—AN ELECTRIC LIGHT FOR THE HUMAN STOMACH.

nary instruments are constructed to reflect the light either of day or of some artificial source upon the part to be examined. The bright oil-lamp which a medical man will often use to help him to see a sore throat more clearly by reflecting additional light upon it, is of course a primitive form of such instrument. In some of the most recently perfected of these appliances a small piece of platinum foil is the electrode from a source of electricity, is placed in the focus of a small mirror. By allowing a carefully regulated electric current to circulate through this, when the platinum is, of course, reduced to a white heat and emits a brilliant light. This is reflected upon the part to be diagnosed, which is then made clearly visible to the operator. Instruments for viewing the interior of the bladder, the œsophagus, or the stomach (for obvious reasons the examination of bowels is no longer to escape the scorching gaze of science), are necessarily more complicated than those for diagnosing, for instance, the mouth or the ear.

We select the gastroscope for viewing the interior of the stomach, as the most ingenious and remarkable of all these instruments which have recently been brought to great perfection in Vienna, and also as showing to what a point of delicacy the executive scientific instruments has been carried in our day. We add that the gastroscope is not a mere model or plaything, but has been in actual use. A figure of the complete instrument is shown in the first block, Figs. 1 and 2, and references to it and to the smaller cuts will enable us to explain the principal features, which will, we think, interest all lovers of ingenious mechanical appliances.

The gastroscope consists mainly of a right horizontal tube, Fig. 1, *a*, terminating in one direction in the eyepiece, *b*, Fig. 1, *c*, terminating in one direction in the eyepiece, *b*, and in the other prolonged into a partially flexible tube, and which can be passed down the œsophagus until its end reaches the stomach. This flexible metal tube, Fig. 2, is is formed of 40 annular pieces, united by lateral joints, and thus forming a completely closed tube, whether it be disposed in a straight line or in a curve, without any chinks or openings, in which, did they exist, the folds of the mucous membrane might easily be caught and lacerated. This closefitting arrangement is effected by making the inside of the guide-tube without this plate.) The most ingenious feature of this arrangement is that it allows the guide-tube to move freely backward and forward through the curved outer tube or guide, Fig. 2, and yet at the same time maintains the guide-tube in a constant position. This is effected thus: The guide-tube, Fig. 3, has a small oblong aperture, *Or*, on the under side, which is of just sufficient size to allow the insertion of the prisms one after another. The aperture *k-k'* is prolonged into a slit for some little distance in the direction of the lower end of the tube. A corresponding slit in the tube, *a*, Fig. 1, slides along the prism supports, which thus offer no obstacle to the motion of the guide tube, which in this manner is movable within the outer tube, while the latter and its inclosed prisms retain a constant position. This arrangement will be better understood by a reference to the sectional drawing of the two tubes and prism plate, Fig. 4.

To obviate the inconvenience which might arise from any elevation of temperature in the stomach, the space between the two sheets of the *hastere* is kept filled with water, and communicates with two diminutive caoutchouc pipes, *rr*, conveyed down the side tube, as seen in the sectional drawing, Fig. 7, and terminating in the bent nozzles, *c-c'*, Fig. 1. To these further India-rubber tubes are adapted, one to supply, and the other to lead off the water which is thus kept in perpetual circulation, and the temperature of which has of course to be regulated so as to obviate any inconvenient degree of heat produced in the stomach.

The ensuing pieces of confirmed and delicate workmanship in the instrument is an equal significance, by which the extremity of the guide-tube, *a*, its little window, may be made to revolve. The eyepiece has merely to turn the little milled wheel, *Ii*, Fig. 1, round which is stretched the silk cord, *fd*. The latter passes from the tube and round the tiny wheel, *Ir*, shown in the section of the tube, Figs. 8 and 9. This tiny wheel, which, it will be observed, is toothed, plays into an indented ring and the interior of the lower rotatory portion of the tube, *Pi*, *Ir*, which it can by its means cause to revolve whenever motion is imparted to itself by the agency of the silk cord which communicates with the milled wheel, *Ii*, placed conveniently near the eyepiece. This ingenious and delicate motion gives the necessary

THE DAILY GRAPHIC.
NOVEMBER 1, 1881.

ELECTRICITY meets with great opposition from the great monopolists of Europe. M. Gaulard, a French chief of staff, has only just set in motion dynamo-engine for generating electricity into working order. The gloom and the dwarfs that he had to stay were infinite. He blamed more than they deserved the mechanics and laborers employed to raise it, for the needless delay there was in getting through their task. The Messrs. Siemens' patience has been severely taxed by the obstructive course shown in regard to their transversity the Board of Works and the police, at the instigation of two great companies, to whom, it is given, but enough, as astonishing, to have the Siemens' system of electric lighting thrown known-in Cabbs the Vienna, the advantages of electricity over steam as a locomotive power for tramways, but the remarkable was hampered with so many conditions as to be practically of very little use. There were men with low-pressure boxes which were not to be interfered with, the members were not to be disturbed, the waterior service was not to be impeded, and many other things which stood in the way were to be experienced upon. The six company really threw every obstacle in the way of the new invention which threatens to supersede its own, and the omnibus company is not less decided in its opposition; and now that it has been demonstrated that the electric light can easily be transformed into heat and motive power, the companies are against it. Just as they were against the use of steam in the early part of the century.

ECONOMY OF THE ELECTRIC LIGHT.

Some figures are given showing that the cost of the electric light may be about one-third that of gas under favorable conditions. This is encouraging, but it is evident that the electric light has not yet been so far perfected that it can be employed safely. The one serious danger is that arising from the breach of insulation of the conducting wires. Hitherto these wires have been wound with thread for the most part, but it is evident that a current so anxious as we think to impress which might bring the metal wire into contact with woodwork, in which case a conflagration would infallibly ensue, or with human beings, in which case somebody would probably be killed. Of course it must be possible so to insulate the wires that they cannot be exposed, but this has not been done yet, and it will have to be done before the electric light can be introduced on a large scale.

THE CHICAGO HERALD.
FRIDAY, MARCH 3, 1882.

The Opposition It Does Not and the Success It Has Accomplished.

It is reputed that at the close of the first day's fighting in the Wilderness, General Grant summoned his Division Commanders together for counsel.

Unanimously they expressed their conviction in the necessity for retreat.

To each General Grant gave written instructions, to be opened on arriving at quarters.

To orders were: "Attack at day-break, burying the enemy's flank."

The result of this, judging by former experience, stood in the way of such disposition, but when the forward movement dawned upon them an immense clear accepted was the Union lines, and like a flash of lightning the spirit was changed to confidence of victory.

That magnificent Army of the Potomac had

at last found a chieftain worthy of its heroism and patriotism.

Whether or not the foregoing is historically accurate, it is certain that General Grant possessed those rare qualities of soul which inspire others on the battle-field and hasten success.

In other realms of human activity circumstances frequently arise which call into action prophetic and heroic qualities which demand our admiration. The storm of adverse criticism from the scientific world, which fell like shot in the Titan, failed to overwhelm the practicability of the substitution of the electric light, as still the electric light burns.

A plentiful harvest fall in of wealthy genius, and wise not slow to avail itself of such instrumentalities as are proved. Messrs. Gilliland, of Montreal, in the United States; William Henry Preece, of Dolgelly, in Wales; Messrs. Siemens, of Berlin, and Gaulard and Gibbard, of Paris, and Professor Jamin, of the French Academy, in adapting the force of their scientific.

These years of persistent and courageous labor followed, during which the public, losing confidence, withdrew their support, and the inventors themselves were disheartened with so many conditions as to be practically of very little use. There were men with low-pressure boxes which were not to be interfered with, the members were not to be disturbed, the waterior service was not to be impeded, and many other things which stood in the way were to be experienced upon. The six company really threw every obstacle in the way of the new invention which threatens to supersede its own, and the omnibus company is not less decided in its opposition; and now that it has been demonstrated that the electric light can easily be transformed into heat and motive power, the companies are against it. Just as they were against the use of steam in the early part of the century.

ECONOMY OF THE ELECTRIC LIGHT.

Some figures are given showing that the cost of the electric light may be about one-third that of gas under favorable conditions. This is encouraging, but it is evident that the electric light has not yet been so far perfected that it can be employed safely. The one serious danger is that arising from the breach of insulation of the conducting wires. Hitherto these wires have been wound with thread for the most part, but it is evident that a current so anxious as we think to impress which might bring the metal wire into contact with woodwork, in which case a conflagration would infallibly ensue, or with human beings, in which case somebody would probably be killed. Of course it must be possible so to insulate the wires that they cannot be exposed, but this has not been done yet, and it will have to be done before the electric light can be introduced on a large scale.

MECHANICAL ACTION OF HEAT AND ELECTRICITY.

The difference between heat and electricity in their modes of mechanical action is very wide. Heat acts by expansion of volume which we know to be a necessarily wasteful principle, while electricity operates by attraction not repulsion, and thus produces motion in a manner which is subject to no greater loss of effect than attends the motive action of gravity as exemplified in the pondera bleapplication of falling water in hydraulic machines. If then we could produce electricity with the same facility and economy as heat, the gain would be enormous, but this, as yet at least, we cannot do. At present by far the cheapest method of generating electricity is by the dynamic process. Instead of beginning with electricity to produce power, we begin with power to produce electricity. As a secondary motor an electric engine may, and assuredly will, play an important part in future applications of po_____ but our present inquiry relates to a primary, and not a secondary, employment of electricity. Thus we are brought to the question, From what source, other than mechanical action, can we hope to obtain a supply of electricity sufficiently cheap and abundant to enable it to take the place of heat as a motive energy? It is commonly said that we know so little of the nature of electricity that it is impossible to set bounds to the means of obtaining it; but ignorance is at least as liable to mislead in the direction of exaggerated expectation as in that of incredulity. It may be freely admitted that the nature of electricity is much less understood than that of heat, but we know that the two are very nearly allied. The doctrine that heat consists of internal motion of molecules may be accepted with almost absolute certainty of its truth. The old idea of heat being a separate entity is no longer held except by those who prefer the fallacious evidence of their senses to the demonstrations of science. So also the old idea of electricity having a separate existence from ponderable matter must be discarded, and we are justified in concluding that it is merely a strained or tensional condition of the molecules of matter. Although electricity is more prone to pass into heat than heat into electricity, yet we know that they are mutually convertible. In short, I need scarcely remind you, that according to that magnificent generalization of modern times, so pregnant with great consequences, and for which we are indebted to many illustrious investigators, we now know that heat, electricity and mechanical action, are all equivalent and transposable forms of energy, of which motion is the essence.

To take a cursory view of our available sources of energy, we have, firstly, the direct heating power of the sun's rays, which as yet we have not succeeded in applying to motive purposes. Secondly, we have water power, wind power and tidal power, all depending upon influence lying outside of our planet. And, thirdly, we have chemical attraction or affinity. Beyond these there is nothing worth naming. Of the radiant heat of the sun I shall have to speak hereafter, and bearing in mind that we are in search of electricity as a cause, and not an effect, of motive power, we may pass over the dynamical agencies comprised under the second head, and direct our attention to chemical affinity as the sole remaining source of energy available for our purpose. At present we derive motive power from chemical attraction through the medium of heat only, and the question is, can we with advantage draw upon the same source through the medium of electricity. The process by which we obtain our supply of heat from the exercise of affinity is that of combustion, in which the substances most consist, on the one hand, of those we call fuel, of which coal is the most important, and on the other, of oxygen, which we derive from the atmosphere. The oxygen has an immense advantage over every other available substance in being omnipresent and costless. The only money value involved

at once in the fuel, and in being cast we employ the cheapest available substances to be found in nature. Moreover, the weight of coal used in the combustion is only about one-third of the weight of oxygen, so that we only pay upon one-fourth of the whole material consumed. Then we have conditions of the most favorable description for the production of energy, in the form of heat, and if we could only use the affinities of the same substances with equal facility to evolve electric energy instead of heat energy, there would be nothing more to desire; but as yet there is no appearance of our being able to do this. According to our present practice we consume coke, instead of coal, in the volatile production of electricity, and not only is zinc thirty or forty times dearer than coal, but it requires to be used in about six-fold larger quantity in order to develop an equal amount of energy. Some people are bold enough to say that with our present imperfect knowledge of electricity we have no right to condemn all plausible theories, other than coal, as impracticable substitutes for metallic zinc, but it is manifest that we cannot get energy from affinity, when affinity has already been satisfied. The numerous bodies which constitute the mass of our globe, and which we call earths, are bodies in this inert condition. They have already, by the union of the two elements composing them, evolved the energy due to their combination, and that energy has ages ago been dissipated in space in the form of heat, never again to be available to us. As well might we try to make the ash ashes, as to use such bodies over again as sources of either heat or electricity. To make them fit for our purposes we should first have to annul their state of combination, and this would require the expenditure of more energy upon them than we could derive from their recombination. Water, being oxidized hydrogen, must be placed in the same category as the earths. In short, the only abundant substances in nature possessing strong unsatisfied affinities are those of organic origin, and in the absence of coal, which is the accumulated product of a past vegetation, our supply of such substances would be insignificant. This being the case, until a means be found of making the combination of coal with oxygen directly available for the development of electric energy, as it now is of heat energy, there seems to be no probability of our obtaining electricity from chemical action at such a cost as to supplant heat as a motive agent.

But while still looking to heat as the fountain-head of our power, we may very possibly learn to transmute it, economically, into the more available form of electricity. One method of transformation we already possess, and we have every reason to believe there are others yet to be discovered. We know that when dissimilar metals are joined at opposite ends, and heated at one set of junctions while they are cooled at the other, part of the heat applied disappears in the process and assumes the form of an electric current. Each couple of metals may be treated as the cell of a voltaic battery, and we may multiply them to any extent and group them in series or in parallels with the same results as are obtained by similar combinations of voltaic cells. The electricity so produced we term Thermo-electricity, and the apparatus by which the current is evolved is the thermo-electric battery. At present this apparatus is even more wasteful of heat than the steam-engine, but considering the very recent origin of this branch of electrical science and our extremely imperfect knowledge of the actions involved, we may reasonably regard the present thermo-electric battery as the infant condition of a discovery, which, if it follow the rule of all previous discoveries in electricity, only requires time to develop into great practical importance. Now, if we possessed an efficient apparatus of this description we could at once apply it to the steam-engine for the purpose of converting into electric energy the heat which now escapes with the rejected steam and the gases from the fire. The vice of the steam-engine lies in its inability to utilize heat of comparatively low grade, but if we could use up the leavings of the steam-engine by a supplemental machine acting on

thermo-electric principles, the present excessive waste would be avoided. We may even anticipate that in the distant future a thermo-electric engine may not only be used as an auxiliary, but in complete substitution of the steam-engine. Such an expectation certainly seems to be commanded by what we may observe in animated nature. An animal is a living machine dependent upon food both for its formation and its action. That portion of the food which is not used for growth or structural repair, acts strictly as fuel in the production of heat. Part of that heat goes to the maintenance of the animal temperature, and the remainder gives rise to mechanical action. The only an logy between the steam-engine and this living engine is that both are dependent upon the combustion of fuel, the combustion in the one case being extremely slow, and in the other very rapid. In the steam-engine the motive [illegible] produced by pressure, but in the animal machine it [illegible] fected by muscular contraction. The energy which [illegible] t not purely electrical, but it is so similar [illegible] of produce the same effect by electricity. A scientific system of the nerves is also [illegible] with our conception of an electrical arrangem[illegible]s. In a description of the animal machine [illegible]body exhibits that of an electrodynamic machine actuated by thermo-electricity, that we may sometimes have to be substantially the same thing. At all events, the animal process begins with combustion and ends with electrical action, or something so nearly allied to it as differ only in kind. And now observe how superior the result is in nature's engine to what it is in ours. Nature only uses heat of low grade, such as we find wholly unavailable. We reject as worthless, as useless, at a temperature that would cook the animal substance, while nature works with a heat we unite as not to hurt the most delicate tissue. And yet, notwithstanding the greater availability of high-grade temperature, the quantity of work performed by the living engine relatively to the fuel consumed, puts the steam-engine to shame. How all this is done in the animal organism we do not yet understand, but the result points to the attainability of an efficient means of converting low-grade heat into electricity, and in striving after a method of accomplishing that object we shall do well to study nature, and profit by the excellence which is there displayed.

But it is not alone in connection with a better utilization of the heat of combustion that thermo-electricity bears so important an aspect, for it is only the want of an efficient apparatus for converting heat into electricity, that prevents our using the direct heating action of the sun's rays for motive power. In our climate, it is true, we shall never be able to depend upon sunshine for power, nor need we regret that our ground is so far away as we have the perennial mines which we possess in the condensed and portable form of coal, but in regions more favored with sun and less provided with coal the case would be different. The actual power of the sun's rays is enormous, being computed to be equal to melting a crust of ice 100 feet thick over the whole earth in a year. Within the tropics it would be a great deal more, but a large deduction would everywhere have to be made for absorption of heat by the atmosphere. Taking all things into account, however, we shall not be far from the truth in assuming the solar heat, in the part of the world, to be capable of melting annually, at the surface of the ground, a layer of ice eighty-five feet thick. Now let us see what this means in mechanical effect. To melt one pound of ice requires 142.4 English units of heat, which, multiplied by 772, gives us 109,932 foot pounds as the number of foot pounds of the heat consumed in melting a pound of ice. Hence we find that the solar heat, operating upon an area of one acre, in the tropics, and competent to melt a layer of ice eighty-five feet thick in a year, would, if fully utilized, exert the smarting power of 4,000 horses acting for nearly nine hours every day. In dealing with the sun's energy we could afford to be wasteful. Waste of coal means waste of money and premature exhaustion of coal-beds. But the sun's heat is poured upon the earth in endless profusion—useless at all events in a practical sense, for whatever anxiety we may feel as to the duration of coal, we need have none as to the duration of the sun. We have therefore only to consider whether we can divert to our use so much of the sun's motive energy as will repay the cost of the necessary apparatus, and whenever such an apparatus is forthcoming we may expect to bring into subjection a very considerable proportion of the 4,000 invisible horses which science tells us are to be found within every acre of tropical ground.

But whatever may be the future of electricity as a prime mover, either in a dominant or subordinate relation to heat, it is certain to be largely used for mechanical purposes in a secondary capacity, that is to say, as the offspring instead of the parent of motive power. The most distinctive characteristic of electricity is that which we express by the word "current," and this gives it great value in cases where power is required in a transmissible form. The term may be objected to as implying a motion of translation analogous to the flow of a liquid through a pipe, whereas the passage of electricity through a conductor must be regarded as a wave-like action communicated from particle to particle. In the case of a fluid current through a pipe, the resistance to the flow increases as the square of the velocity, while in the case of an electric current the resistance through a given conductor is a constant proportion of the energy transmitted. So far, therefore, as resistance is concerned, electricity has a great advantage over water for the transmission of power. The cost of the conductor will however be a grave consideration where the length is great, because its section must be increased in proportion to the length to keep the resistance the same. It must also be large enough in section to prevent heating, which not only represents loss but impairs conductivity. To work advantageously on this system, a high electromotive force must be used, and this will involve loss by imperfect insulation, increasing in amount with the length of the line. For these reasons there will be a limit to the distance to which electricity may be profitably conveyed, but within that limit there will be wide scope for its employment transmissively. Whenever the time arrives for utilizing the power of great waterfalls, the transmission of power by electricity will become a system of vast importance. Even now small streams of water inconveniently situated for direct application may, by the adoption of this principle, be brought into useful operation.

For locomotive purposes also we find the dynamo-electric principle to be available, as instanced in the very interesting example presented by the Siemens electric railway, which has already attained that degree of success which generally precludes even an important future. It forms a combined fixed engine and locomotive system of traction, the fixed engine being the generator of the power and the electric engine representing the locomotive.

Steam power may both be transmitted and distributed, by the intervention of electricity, but it will labor under great disadvantage when thus applied, until a thoroughly effective electric accumulator be provided, capable of giving out electric energy with almost unlimited rapidity. How for the secondary battery of M. Faure will fulfill the necessary conditions remains to be seen, and it is to be hoped that the dilations which may be expected to take place at this meeting of the British Association will enable the jury of its capabilities to be formed. The introduction of the Faure battery is at any rate a very important step in electrical progress. It will enable motors of small power, whether their nature may be, to accomplish, by uninterrupted action, the effect of much larger machines acting for short periods, and by this means the value of very small streams of water will be greatly enhanced. This will be for electric lighting, which, in summer, when the springs are low, will only be required during the brief hours of darkness, while in winter the longer nights will be met by a more abundant supply of water. Even the fitful power of wind, now so little used, will probably acquire new life when aided by a system which will not only collect, but equalize, the variable and uncertain power exerted by the air.

It would greatly add to the utility of the Faure battery if its weight and size could be considerably reduced, for in that case it might be applicable to many purposes of locomotion. We may easily conceive its becoming available in a lighter form for all sorts of carriages on common roads, thereby saving to a vast extent the labor of horses. Even the nobler animal that strides a bicycle, or the one of inferior courage that prefers the safer seat of a tricycle, may ere long be spared the labor of propulsion, and the time may not be distant when an electric horse, far more amenable to discipline than the living one, may be added to the businesses gifts which science has bestowed on civilized man.

In conclusion I may observe that we can scarcely sufficiently admire the profound investigations which have revested to us the actual dynamical relation of heat and electricity to outward mechanical motion. It would be a deliberate task to apportion praise amongst those whose labors have contributed, in various degrees, to our present knowledge; but I shall do no injustice in saying that of those who have expounded the modern doctrine of energy, in special relation to mechanical practice, the names of Joule, Clausius, Rankine, and William Thomson, will always be conspicuous. But up to the time our knowledge of energy is almost confined to its inorganic aspect. Of its physiological action we remain in deep ignorance, and as we may expect to derive much valuable guidance from a knowledge of Nature's methods of dealing with energy in her wondrous mechanisms, it is to be hoped that future research will be directed to the elucidation of that branch of science which as yet has not even a name, but which I may provisionally term "Animal Energetics."—*Sir William Armstrong, Section G, British Association.*

Electricity and Chemistry.

The Electro-Technical Society of Berlin (*Elektrotechnischer Verein*) offers a prize of a thousand marks (shillings) for the best essay on the transmission of power by electrical and mechanical means, which must be sent in before the 1st of October, 1882.

The galvanic current has for many years been applied successfully in quantitative determinations of copper, lead, cobalt, nickel and manganese. The case of zinc presents peculiar difficulties, however, and none of the series of methods proposed for its determination has proved satisfactory. From a paper in the *Journal für Praktische Chemie*, it appears that Herr Hampel and Dr. Ilin have succeeded, even with a weak current, in getting zinc, in a form well suited for weighing, from an oxalate solution. They chose oxalic acid, as being an acid easily removed by the current, and not formed again by secondary action. Since, however, oxalate of zinc could not be used because of its insolubility in water, they had recourse to the soluble ammonium double salt.

Use of Magneto- and Dynamo-Electric Machines for Electric Lighting.—The fundamental principles which underlie all magneto-electric machines are the four great principles discovered by Oersted in 1819, by Ampère and Arago in 1820, and by Faraday in 1831. In 1820 Oersted discovered the action of a current of electricity on a magnet. In 1820 Ampère discovered the action of magnets and currents on currents of electricity in their neighborhood, and in the same year Arago showed that currents of electricity produced magnetization, thus laying the foundations of electro-magnetism; and in 1831 Faraday showed that induced currents were produced by the motion of magnets. All machines for the conversion of work into electricity are founded on Faraday's great discovery of the induced current, derived from the relative motion of a magnet and a coil of wire.

Magneto-electric machines are divided into two great classes, according as they furnish continuous currents or alternate currents. All such machines are alternate, in so far as regards the currents in the coil; but these currents are made to flow always in the same direction in the external circuit, in continuous-current machines, by means of a commutator, which reverses the contact at every half-turn.

The machines of Pixii, in 1832, followed by those of Saxton and, Clarke, were the first continuous-current machines. From these we may pass to Wheatstone's introduction, in 1845, of electro-magnets in place of permanent magnets, to produce a magnetic field. In 1854, Messrs. Wertner, Siemens, and Halske introduced the Siemens armature, in which the coil is wound longitudinally in a groove. The strength of the contiguous-current depends on the velocity of rotation, on the length of the wire, and the power of the magnetic field form[illegible] the magnets.

It is remarkable that, [illegible] which was some thirty-[illegible] big[illegible] patented an improved ma[illegible] in which the currents induced in the revolving [illegible] 388 round the electro-magnets, and increase their [illegible] s and so increase the induced currents at a compound [illegible]. This was the celebrated principle afterwards rediscovered by Siemens and by Wheatstone simultaneously in 1867, which has formed the basis of all dynamo-electric machines, and which, for equal power, are cheaper and more compact than all other multiple guidance from a knowledge of Nature's methods of dealing with energy in her wondrous mechanisms, it is to be hoped that future research will be directed to the elucidation of that branch of science which as yet has not even a name, but which I may provisionally term "Animal Energetics."—*Sir William Armstrong, Section G, British Association.*

Dynamo-Electric Machines.—In February, 1867, Dr. Siemens and Sir Charles Wheatstone, on the same evening, presented to the Royal Society their two papers, "On the Augmentation of the Power of a Magnet by the Reaction thereon of Currents induced by the magnet itself." According to the principle then put forward by Dr. Siemens, the sphering armature, the electro-magnet and the external resistance, such as an electric lamp, are joined up so as to form one simple circuit. A small amount of magnetism is communicated to the electro-magnet, so that, on rotating a coil, a current is induced alternately in opposite directions, and after being reduced to the same direction by a commutator, this current passes through the coils of the electro-magnet, in such a direction as to make it stronger, so enabling it to rend in the armature. Thus the magnet and the armature act and react on one another, strengthening the magnetic field and continually energizing the induced currents. Sir Charles Wheatstone put forward the same principle, and called attention to the fact that at the first moment of completing the combined circuit, the effects are stronger than they are permanently.

He also pointed out that a very remarkable increase of all the effects is observed when a shunt is employed to divert a great portion of the current from the electro-magnet. By that means 4 in. of platinum wire, .0007 in. diameter, was made to glow. A certain resistance in the shunt was found to be necessary to produce best effects, so as neither to weaken the magnetism too much, nor to give the current too much work to do in heating a high resistance.

In addition to this, Sir Charles Wheatstone showed that the effects above described are far inferior to the effects obtained by placing the work to be done in the shunt circuit. Three series coaches of wire were made to glow in the shunt, when *only four* inches of the same wire would glow in the original circuit. There is thus a double advantage for there is no loss of resistance by introducing the shunt, the resistance of the shunt being the resistance on which the useful work is done.

This improvement was suggested by Sir Charles Wheatstone in 1851, and is now being adopted by Dr. C. W. Siemens in his latest dynamo-electric machine.

Wheatstone also showed that the effects are much less influenced by a resistance in the electro-magnet branch than by either of the other branches. Thus, with about four inches of glowing platinum wire in circuit, the addi-

tion of about five inches of platinum wire in the armature
branch, or in the shunt, produced a three-quarter-inch
glow, whilst four feet of the same wire was required in the
electro-magnet branch to reduce t
of an inch. Dr. Siemens has shar
efficiency, the resistance of the ro
but the resistance of the electro-m
and that in both cases the wires al

one half of which has been treated. Although there is scarcely any difference as regards the appearance of the two halves, you see that water is readily absorbed by the untreated half, but not by the portion which has been rendered impervious by the solutions of Messrs. Ransome and Co.

The dephosphorising properties of lime have been rendered available in obtaining compact masses of the refractory metal, iridium; the spongy metal being first fused with a moderate proportion of phosphorus, after which the comparatively fusible phosphide is located in powdered lime, until all the phosphorus becomes removed.

As an indirect measure, lime possesses some value, decomposing silicates, disintegrating organic matter, and destroying insects. As an agent in various chemical industries, lime holds an important position; its uses in tanning, the preparation of the caustic alkalies, the liberation of ammonia, and other processes, being very considerable. With respect to its bearing on the iron industry, my remarks must be deferred until the utilisation of the furnace slag is considered. Some kinds of glass, as for example the hard Bohemian varieties contain a considerable proportion of lime; and powdered lime is often used in packing [illegible] to prevent [illegible] during annealing.

READ

JUVENILE LECTURES.

RECENT WONDERS OF ELECTRICITY.

By W. H. PREECE, F.R.S.

Lecture II.—Delivered on Wednesday, 4th January, 1875.

Last week, when we had the pleasure of meeting, I endeavoured to disclose your minds of any such idea as that electricity was a fluid, or, in fact, any kind of matter. I pointed out to you that every electric phenomenon really was a form of that curious, mysterious agency that exists throughout nature, that produces all the work done on the face of the earth, that probably is at the root of life itself, called energy. Nevertheless, we can speak of electricity as though it were a distinct entity; precisely in the same way that we speak of sound, of light, and of heat. We know that sound and heat are not sensible to the touch, or taste, or sight; so electricity is of the same character, and is invisible and intensible in every shape or form. Moreover, we cannot either create or produce energy; there is only a certain fixed quantity of energy in the universe, and all that we can do is simply to transform it into its different shapes, such as I illustrated to you last week. All physical phenomena, without a single exception, may be traced to the mere transformation of this energy. I showed you on the last occasion how, by simply winding a wire round a mass of iron, and sending a current of electricity through the wire, we could produce that form of energy called electro-magnetism. To-night I have to speak of one or two other forms in which this energy does its work, forms in which, when electricity is transferred through matter, it does work in some shape or another. The operation of the electric current, when passed through chemical compounds in solution or liquid, is to tear asunder the constituents of the compound, and to arrange them on different sides. A simple means of illustrating this is a glass jar, like the one before you, containing water and two glass tubes, each fitted with a stop cock. When an electric current is passed through the water, the elements of water, oxygen, and hydrogen, are driven asunder, and take refuge, as it were, in the right or left-hand tube respectively. To prove that these gases have been collected, if a lighted match be placed over the hydrogen tap, the hydrogen will give evidence of its presence by inflammability; but if the match be blown out and immediately presented to the tap of the tube containing the oxygen, that gas will make its presence evident by relighting the match. [Experiment shown.] The effect of the passage of electricity through water is something like the effect which would be produced by a storm, or other agency, in this room, which caused all the boys of this audience to go to one side, and all the girls to go to the other—excepting that in water there are always two parts of hydrogen to one part or volume of oxygen. Not only does the current tear asunder the oxygen and hydrogen of water, but it also breaks up the constituents of most of the chemical compounds, and the weight of material decomposed per second is an exact measure of the work done, and of the current flowing. For instance, if we take a solution of sulphate of copper and pass electricity through it, the solution is broken up into copper and sulphuric acid, and if a bunch of keys were put into the solution while the electricity was passing through it, the keys would receive a deposit of copper. If nitrate of silver solution were used instead of the sulphate of copper solution, silver would be

deposited upon the keys or piece of metal inserted. Through the kindness of Mr. Boles, I am able to show you an experiment of this kind, which will enable me to give you a record of this evening's entertainment. I have here, a large glass dish containing a liquid, which, no doubt appears to you like water, but, which is really a solution of the double salt of cyanide of silver and potassium. In this solution, I now place a piece of sheet copper, which you see has the usual appearance of copper all over it. Now, while that plate of copper is inserted to one half its extent in water, we will pass electric currents through the liquid from the hand-dynamo machine on the table [experiment proceeding], which cause the cyanide of silver to break up into cyanogen on one side, and silver on the other, and if I take out the plate of copper, you see there has been deposited upon its immersed surface a coating of silver. Silver spoons and all the various kinds of electro-plate wares receive their silver deposit in the manner I have just shown you. Now, we will set this small dynamo-machine in action by turning its handle, thus converting the energy of the human body into electric energy; and we will immerse a quantity of brass bottom in the liquid, which, when they have received their coating of silver, will be laid aside, ready for distribution as a memento at the close of the lecture. Through the kindness of Messrs. Elkington, I am able to show you the handsome specimens of electro-plating which hang on the walls of the room, and which were plated at their works at Birmingham, by a process exactly similar in character to that I have described, excepting that steam-power is substituted for the manual labour you just saw for producing the electric currents.

We next come to the work performed by electricity in passing through solids. The result of this work is simply the production of heat. Before me you will notice two brass stands, and between them I will suspend a piece of fine platinum wire. I now join up one of my battery wires (the same that I used last week) to one of the brass stands, and touch the other brass stand with the other battery wire; the effect appears as a red glow in the platinum wire. If I bring one of my battery wires from the bottom of the brass stand to the end of the platinum wire, the colour of the glow becomes brighter; and as I move my battery wire along the platinum wire the glow or light produced by the high temperature to the platinum becomes more and more intense, until finally, when it reaches a certain temperature (about 3,000° Fahr.) the wire is ruptured, and falls to the ground. That is evidence that the passage of electricity, through solid conductors, produces heat, and the amount of heat produced is proportioned to the work done in the battery. Energy expended in one part of a circuit must be given out at another. If zinc is consumed in a battery, it generates a certain amount of energy, that energy must be evident in some other part of the circuit, and the best you saw in the platinum was really the heat that would have appeared in the battery itself if we had not caused the current to flow through a solid conductor which offered a considerable amount of resistance to its progress, as compared with the resistance in the battery itself. This power of producing heat has been utilised in various ways, such as for firing fuses. [An Abel fuse was exploded.] At many places throughout the country, time guns are fired by such an electric fuse to announce the Greenwich time current at a certain hour. Mines and torpedoes are exploded in a similar manner; quarries are blasted, and many other results are brought about by passing electricity through platinum wire placed in explosive substances, or by special fuses. I do not intend to frighten or alarm you, but for your amusement, and through the kindness of Professor Abel, I have had fuses fixed out of harm's way at various points round the room, and when a small current is passed through them you will hear the explosion produced. [Experiment carried out.] Those fuses might have been fixed miles away, and the same effect would have been produced, and from it you will understand how a number of charges can be fired, or a number of guns can be discharged simultaneously on board our large men-of-war.

The next branch of the subject is the work done by electricity in its passage through air and gases. I have shown you that, in its passage through liquids, it tears the constituents of the solution asunder; in its passage through solids heat is produced; and in its passage through air, it not only produces heat, but violent projection of material particles as well, which it renders incandescent, producing sparks, heat, and other disruptive effects. To illustrate this, I have provided an Apps' induction coil, to which can be joined up vacuum tubes of various kinds, and through which the currents produced by the hand-dynamo machine will be passed. [A beautiful collection of vacuum tubes, fitted with various rarefied gases, was then shown, while the lights

tion of about two inches of platinum wire in the armature
branch, or in the shunt, produced a three-quarter-inch
glow, whilst four feet of the same wire was sufficient to the
electro-magnet branch to reduce

were turned down.] In those effects we have the result of electricity passing through air, and gases of extreme tenuity, and also an indication of the way in which electricity produces heat—and, therefore, light—in gaseous matter. All instances of artificial lighting or heating are simply due to the fact that we are able to produce heat, and heat of a very high temperature. It is a curious fact that all matter, whether metal or porcelain, carbon or lime, begins to emit light at precisely the same temperature, which closely approaches 1,000° Fahr., or, to be accurate, I believe it is 980° Fahr., so that, whenever it is possible by any means to raise any material to that temperature, light is emitted, and the intensity of light increases, until, in the case of carbon, when about 4,000° Fahr. is reached, the material is destroyed. In platinum a lower figure (3,080°) represents the point of fusion. To obtain this very high temperature by electric currents, we must utilise higher means of producing the electricity than I have hitherto shown you. In the battery I have just used, the electric current was produced by the combustion of zinc, but now I want to explain to you how, as I said, muscular power was converted into electric energy. The reason is simply due to the fact discovered by Faraday, that whenever a wire or conductor moved through the sphere or field of a magnet it became electrified. I take up the brass rod before me and move it rapidly, and by doing so have to a certain extent electrified it by causing it to pass through the magnetic field of the earth. The earth is an enormous magnet, a fact which we know, because our compasses guide the mariners across the deep. The air in this room is under the influence of the earth's magnetism, and if I move a wire or rod within that influence, at right angles to the lines of magnetic force, I cause it to be electrified, but only to an excessively small extent. The strength of the current produced, depends upon the strength of the magnetic field, and upon the velocity with which the conductor moves across the field. Instead of having only one rod, or one wire, we have in this hand machine, an arrangement of a thousand turns of wire, instead of having the weak magnetism of the earth, we have the powerful field of permanent magnet, and instead of causing it to move through the air by the velocity of my arm, we apply multiplying gear, which, as you see, imparts velocity to it of great rapidity. Thus motion, through a magnetic field, produces an electromotive force. There never can be a continuous electromotive force without some source of energy. Here we have mechanical energy expended, and all the conditions for the production and maintenance of a current. Energy expended in one point must be found in some form in another point. If it is not utilised, it is wasted. Some of it must always be wasted, and the true economist will try and waste the least possible quantity. If I place a piece of platinum wire between the two wires connected with the hand dynamo-machine, you see that the muscular energy of my assistant, by turning the handle, generates currents of electricity, which give a red heat to the platinum wire. The energy of the body is thrown into the machine, the machine converts it into electricity, the electricity passes through the wire, which, by having work done upon it is rendered incandescent, and, in consequence, becomes luminous. I have here a lamp containing a piece of platinum wire, and if I connect it to the wires of the dynamo-machine [this was done], the platinum glows and gives us light. It is a machine precisely similar in principle to the one now before you, fixed under the arches on the Thames-embankment, and worked by a steam-engine (sent for the purpose by Messrs. Robey), that is supplying currents of electricity to the lamps now lighting this room. There is an occasional break in the light; this is produced by the unsteadiness of the engine, which was not specially prepared for the purpose, but was the best available. It is, in fact, an agricultural machine. There are two kinds of electric machines of this class. One is called the magneto-machine, like the one before you, because the magnetic field is produced by the presence of a powerful permanent magnet, which I think is visible to most of you, and which consists of several pieces of steel that have been magnetised. The other kind of machine is called the dynamo-machine, in which the magnetic field is produced by an electro-magnet, which is itself excited by the currents it generates, so that there is a kind of accumulative action, one current piles up the agency on the other current, and all of them together, acting on the electro-magnet, increase the total effects until the iron is saturated with magnetism. So much as regards the production of currents for electric lighting purposes. The motion of the conductor through the magnetic field may be caused by the energy of coal, which is consumed to generate heat and steam for working a steam-engine; or, as at Godalming, by the energy of water on a

water-wheel; and it is very probable that where water is available, it will be the most economical source of energy for electric lighting purposes. Sir William Armstrong, at his seat at Cragside, near Newcastle-on-Tyne, has illuminated his house for some time by currents of electricity, produced by a waterfall in his grounds, so that, he says, his library and his drawing-room are lit by the river flowing through his grounds. As regards the light itself, there are two kinds of lamps. I have already explained and illustrated to you the fact, that electricity in its passage through air produces sparks. I have here what is called an arc lamp; in it two rods of carbon are held by two brass clips (not in metallic connection with each other), and the ends of the carbon are, when in action, a short distance apart. On joining up the wires to the brass clips the current flows, a bright light is instantly set up in the air between the carbon points, and the arc is formed. This light is due to the passage of an infinitely rapid succession of particles of carbon which are projected across the air space, which, in their high state of incandescence, produce light, and which in brilliancy would not compare unfavourably with that of the sun. The light from a larger arc lamp would be far more brilliant than this, but I do not want to damage your eyes or my own. I have experimented on the electric light so much, that I have suffered great tortures from the irritating and exciting influence of its bright rays upon the retina of the eyes, and I advise all people who have no opportunity of examining the arc light, not to look at it too much, or the eyesight may be unfavourably affected. The arc light is used principally for lighting large areas, for instance, Charing-cross Station is lit by one form of arc light, called the Brush; Cannon-street Station is lit by what is known as the Brockie lamp; the space in front of the Royal Exchange is lit up by the Siemens arc lamp; King's-cross Station is lit up by the Crompton plan; and so on. A very brilliant arc lamp at Paris, which attracted a great deal of attention, was called the Jasper light. But all arc lamps play upon one string, similar to the plan I have just shown, viz., that when two pieces of carbon are maintained at a certain distance from each other, and electricity passed between them, great heat and brilliant light is the result. There are certain difficulties in arc lamps which militate against their employment for domestic and internal use generally. The light is very intense; the effect is irritating; the ladies do not like it (and they are a powerful influence in this country), because it does not suit their complexion, nor their style of costume for evening wear: they have not their faces against it for internal illumination, and that being so, it is all up with it. Now, the light that is going to supplant the arc light for domestic purposes, is the incandescent light. The principle of the incandescent lamp is exactly the same as that I showed you in Mr. Becker's lamp, viz., that a suitable substance is enclosed in a glass bulb, from which the air has been extracted, and is brought to a high state of temperature by the passage through it of currents of electricity. The lamps illuminating this room are Mr. Edison's incandescent lamps, whose representative, Mr. Johnson, has been most indefatigable in his assistance for these lectures. The Edison lamp consists of a single curl, or loop, of a fine carbon filament (instead of platinum wire) placed in an exhausted glass bulb. The carbon is extremely thin—as thin as a human hair—but, in spite of its extreme tenuity, you see [knocking a lamp on the table] that concussion or shaking does not cause it to break, but it possesses great resilience, and vibrates like a steel spring; and it is so refractory that it will stand electric currents of enormous strength. As I have said, the lamps before you are worked by electric currents generated by an Edison dynamo-machine on the Thames-embankment, but each lamp is self-regulating and (you see) can be turned on and off by turning a top way like those used on gas-brackets. The stronger the current supplied to the lamp, the greater its heat and brilliancy, and when, by turning a handle in the instrument I have for the purpose, the strength of the current is increased, it forms a brilliant light in the glass tube, until the amount of current is greater than the carbon can stand, when it emits a beautiful blue haze, which indicates that its end is near, and then it is broken (as you see), and the lamp goes out. I can easily replace the broken lamp by unscrewing it out of its socket, and placing a fresh one in its place, when at once all is in good order, and the light resumed. These lamps are water-tight as well as air-tight, and to prove this, I will insert a lighted lamp into the little aquarium on the table, when you see that the globe is brilliantly lit up, and that the fish it contains show rather a sign of curiosity than discomfiture, and seem rather proud of their colours which are so distinctly brought out by the brilliancy of the light. Here I have a globe

tion of about five inches of platinum wire in the armature
branch, or in the shunt, produced a three-quarter-inch
glow, whilst four feet of the same
electro-magnet branch to reduce
of an inch. Dr. Siemens has sho
efficiency, the resistance of the b
but the resistance of the electro-

of coloured water to show what brilliant effects
can be produced. A good deal has been said
about the dangers of electric lighting, and how
careful we ought to be in its use, and there is
no doubt that electricity is a very dangerous
agent if you do not know how to use it. We
have heard of the danger from fire through its
use in theatres and houses, but I want to show
you that, when I place a cambric pocket-
handkerchief round a lamp, which I then break
while electricity is going through it, no spark
or fire of any kind occurs, but the lamp in-
stantly goes out. [Experiment shown.] There
is also danger from wires coming in contact
with each other, and in that case they short
circuit the machine; they cause an increased
strength of current to flow, producing heat, and
in that manner setting fire to houses. To obviate
this danger "safety-catches" have been intro-
duced by Mr. Edison. These safety-catches con-
sist in the insertion of a very small piece of lead
wire in the circuit, which is readily fusible, so
that if the current becomes unnecessarily
powerful, it passes through the lead wire, heats
it to fusing point, and so breaks down the
section on which the "safety-catch" is placed,
eliminating at once all danger. [Illustrated.]
It does not affect any other lamps, as you see.
When the fused safety-catch is replaced by a
good one, the lamps which were broken down
by its rupture become lighted up again. We
have the means of regulating the lights now
burning in the room. Here is an apparatus in
connection with the machine at the engine-
station, and by moving the handle and inserting
in the circuit a certain amount of resistance,
I am able so to reduce the current flowing
from the machine that a considerable lowering
of the light takes place. On turning the
handle back again, the former brilliancy re-
turns. That shows the electric light in
the latest stage of its perfection. We have
a bright light now in this room, but no impure
gases are given off by the electric light and
the air is not vitiated by it. The room is warm,
but that warmth is due to the number of people
present, and not to the heat produced by the
electric light; though the electric light does,
as I have said, generate heat to produce its
effulgence. Many people talk of the electric
light as being "cold" and cheerless. The
light produced by the arc lamp does look cold
and cheerless; but the soft, delicious, incan-
descent lamp before you has just as soothing
an effect upon the eye as the prettiest lamps,
or the pleasantest candle; and it has certainly
removed all the objections that were previously
raised to the electric light for internal illumina-
ting purposes.

The next and last branch of my subject is
the transmission of motive power to a distance.
I have shown you how currents of electricity
are produced; also how they do work; how
they produce electro-magnetism; how they
generate heat; how they produce light; and
now I want to show you that the whole thing
is reversible. If, by the exertion of mechanical
power, currents of electricity can be produced,
those very same currents of electricity can in
their turn produce mechanical power. If
instead of receiving currents of electricity from
the dynamo-machine on the Thames-embank-
ment, we transmitted currents of electricity to
it, we should cause it to rotate, but in the
reverse direction. I have here a small
machine for the purpose of illustrating this
to you, it is the invention of Mr. Griscom,
who has supplied it to a large extent in
America for turning sewing-machines. The
wires from the hand dynamo-machine are now
attached to the Griscom machine, and when
currents of electricity are generated by turning
the handle of the dynamo, they are conveyed
to the motor, and cause it to revolve with the
high rapidity you see. It is surprising that
such a tremendous momentum should be pro-
duced by so small a strength of electric current.
The wires connecting the two machines in this
instance are short, but the effect would have
been practically the same had the machines
been miles apart. By changing the wires, the
direction in which the motor rotates is reversed,
so that I not only get power transmitted, but
can reverse its direction. In this case, as the
electricity is generated by hand, its power
is small; and, therefore, with my strength
(which is only about one-twelfth of a horse-
power), I can stop the rotation of the motor;
but if steam-power were employed to generate
the electricity, the power transmitted would be
beyond my control, in that sense. This
motive-power was illustrated, in many dif-
ferent forms, at the Paris Exhibition;
for instance, from the commencement of the
Champs Elysées to the Exhibition building, a
tram-car was propelled (sometimes at the rate
of 25 miles an hour) upon rails laid down for
the purpose, and during the time that the
Exhibition was open, that car carried 25,000 to
30,000 people, who were conveyed to or from
the building by motive power, generated by
steam in the Exhibition, and conveyed by
wires to the further extremity of the track.
An electric railway will form part of the

Electric Exhibition at the Crystal Palace,
and among the proposals to be laid before Par-
liament next Session is a project for constructing
an electric railway between Northumberland-
avenue and Waterloo Station. Again, at the
Paris Exhibition, an enterprising firm of agri-
culturists showed land-ploughing by electricity,
and in fact, the application of electricity to
innumerable useful purposes was illustrated;
rock boring, newspaper printing, driving of
sewing-machines, embroidery, leather work,
glass-cutting, wood-carving, lifts raised, ven-
tilation assisted, &c. I am looking forward to
the Crystal Palace Exhibition with great interest,
to see how far these exhibits will be repeated.
The Exhibition will be well worth a visit; in
fact, all Exhibitions are worth visiting, for
they excite interest, they induce everyone,
more or less, by generating curiosity, to add to
his knowledge, they honestly stimulate national
as well as individual competition, and they
always result in the enlargement of the useful
application of a power like that of electricity,
because a man of one trade who sees electricity
used in another trade cannot resist think-
ing out whether it cannot also be usefully
applied to his own purposes. We sometimes
hear electricity spoken of as a mysterious
agency, and sometimes as a wild, untamed
beast. It is only mysterious to the ignorant,
and it is only untamed to the unskilled. I
hope that the promise I made to you at first
starting, that you would leave this room with
a fair knowledge of how the electric light is
produced, has been fulfilled, and I can only
add that electricity will always prove an
obedient slave to those who take the trouble
to understand it; but it may, and it has, proved
a very dangerous ally to the ignorant and the
unskilled.

A hearty vote of thanks was accorded to Mr.
Preece for his two lectures.

SIXTH ORDINARY MEETING

On Monday, January 16th, 1882, ANDREW CASSELS, Member of the Council, in the chair.

The following Candidates were proposed for election as Members of the Society:—

Ainslie, Oliver Alexander, F.R.Hist.Soc., 48, Lincoln's-inn-fields, W.C.
Birkbeck, Edward, M.P., Henstead-hall, Norwich.
Brereton, Cuthbert Arthur, M.I.C.E., 23, Delahay-street, S.W.
Brind, Alfred Walter, M.I.C.E., East Preston, near Worthing.
Burch, Nathaniel Geach, Bromwich-house, Dartmouth-park, Forest-hill, S.E.
Carmichael, David, Ward Foundry, Dundee.
Carter, E. Harold, F.S.S., 33, Waterloo-street, Birmingham.
Cook, Arthur Stanton, 14, Furnival's-inn, E.C.
Cooke, William Henry, Lea Bank, Coppice, Oldham.
Common, Andrew Ainslie, F.R.A.S., 65, Eaton-rise, Ealing, W.
Cropper, Samuel, 48, Budge-row, Cannon-street, E.C.
Crossley, Richard, Beckliffe-house, Accrington.
Cust, Robert Needham, F.R.G.S., 64, St. George's-square, S.W.
Dodsen, Albert William, 6, Raymond-buildings, Gray's-inn, W.C.
Dawson, Joseph Emerson, A.M.I.C.E., M.I.M.E., 3, Great Queen-street, Westminster, S.W.
Fell, John, Augusta-place, Leamington.
Fyfe, John, 9, Grosvenor-terrace, Glasgow, and Young's Paraffin Light and Mineral Oil Company, 7, West George-street, Glasgow.
Henderson, Kirkby, 9, Bush-lane, Cannon-street, E.C.
Holthouse, Carsten, 15, Penpont, Bedford-sq., W.C.
Jones, Thomas John, 12, Princes-street, Hanover-square, W.
Kingzett, Charles T., F.C.S., F.I.C., 17, Lansdowne-road, Tottenham.
Ladd, John Haskins, 116, Queen Victoria-street, E.C.
Leonard, Hugh, 7, Hanover-square, W.
Lloyd, Robert Samuel, 82, Upper Whitecross-st., E.C.
Macdonald, Colonel R. M., 80, Oxford-gardens, North Kensington, W.
Moll, Frederick Henry Ludwig Raphael, 18, Old Broad-street, E.C.
Radford, Frances, 56, Pembridge-gardens, W.
Russell, Joseph, Glenclune, Port Glasgow.
Schrane, Otto, 29, Wood-street, Woolwich, S.E.
Scott, Edward Lionel, Salters'-hall, St. Swithin's-lane, E.C.
Simpson, James Carrington, M.I.C.E., Broadway-chambers, Westminster, S.W.
Speck, Thomas Samuel, M.I.C.E., 8, Eaton-rise, Ealing, W.
Wallis, George Ambrose, M.I.C.E., 14, Sea-side-road, Eastbourne.
Watson, John William Milton, M.I.C.E., Claremont, Silverhill, St. Leonards-on-Sea.
Williamson, George Charles, The Institute, Guildford.

The following Candidates were balloted for and duly elected Members of the Society:—

Allfrey, Edward Richard, South Eden-park, Beckenham, Kent.
Asselin, Josiah, Nechells-house, Nechells, Birmingham.
Ayrton, William, Wigton-road, Ormskirk.
Clark, John Somervail, 29, Peter's-square, W.
Colvin, Clement S., India-office, S.W.
Glover, Walter T., Moorhouse, Kendal, Manchester.
Hallett, Holt Samuel, M.I.C.E., F.R.G.S., 37, Edgware-road, W.
Hawksley, Thomas, 97, Adelaide-road, N.W.
Hill, James Woodward, A.M.I.C.E. (Mayor of Bedford), Kimbolton-road, Bedford.

HEDGES' ELECTRIC LAMPS.

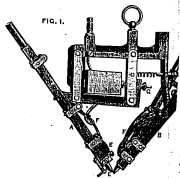
We reproduce from Engineering, illustrations of two new forms of Electric Lamps, belonging to that class in which the position of the ends of the carbons is not determined by clock-work or similar controlling mechanism, but by the position of the geometrical intersection of the axes of the carbon rods, which is determined by mechanical means.

Referring to Fig. 1, *A* and *B* are two troughs recta-

THE MECHANICAL NEWS.

SPRINGFIELD, OHIO, JANUARY 15, 1882.

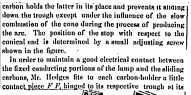
FIG. 1.



HEDGES' ELECTRIC LAMP.

gular in cross section attached to the supports in such positions that their axes are inclined to one another so as to form the letter V as shown in the figure. Within these troughs slide freely the two carbon pencils, which are of circular cross section, meeting, when no current is passing, at the lower point *E*. The carbon-holder *B*, to the right of the figure, is rigidly attached to the framing of the lamp, but the trough *A*, which carries the negative carbon, is attached to the framing by a pivot shown in the figure, and on this pivot the carbon-holder can rock, its motion being controlled by the position of the armature of an electro-magnet *M*, the coils of which are included in the circuit of the apparatus. By this means, the moment the current is established through the lamp, the armature is attached, and the points of the two carbons are separated, thus forming the arc. The positive carbon *H* is held firm sliding and dropping through the trough by the gentle pressure against it of the smaller carbon rod *C*, which also slides in a trough or tube fixed in such a position that the point of contact between the two rods is sufficiently near the arc for the smaller rod to be entirely consumed as the other is burnt away; the latter in that way is permitted to slide gradually down the trough as long as the lamp is in action. The negative carbon-holder *A* is provided with a little adjustable platinum stop *K*, which by pressing against the side of the conical end of the negative carbon holds the latter in its place and prevents it sinking down the trough except under the influence of the slow combustion of the cone during the process of producing the arc. The position of the stop with respect to the conical end is determined by a small adjusting screw shown in the figure.

In order to maintain a good electrical contact between the fixed conducting portions of the lamp and the sliding carbons, Mr. Hedges fits to each carbon-holder a little contact piece *F F*, hinged to its respective trough at its



Claims:—1. The method of demagnetizing watches or other similar articles of or containing steel, which consists in subjecting the same to rapid reversals of polarity in a gradually weakened magnetic field.

2. The method of demagnetizing watches or other articles of or containing steel, which consists in gradually withdrawing them from the influence of a rapidly-alternating magnetic attraction.

3. In an apparatus for the demagnetization of watches or other articles, the combination, with an electro-magnet and means for revolving the same, of a rotary holder for presenting the articles under treatment to the influence of said magnets, and mechanism, as described, for withdrawing them from the magnets.

4. In an apparatus for the demagnetization of watches or other articles, as described, the combination, with the revolving magnet, of a movable frame or carriage, a holder for the watch mounted thereon, and means for rotating the holder simultaneously in horizontal and vertical planes, substantially as set forth.

completed with the electric generator the carbons are drawn apart by the action of the solenoid on the plunger, and the distance to which they are separated is determined by the diffusion of attractive force exercised upon the armature by the solenoid and the magnet.

Eng. News. March 11, 1882

ELECTRICITY.

BALTIMORE WILL USE ELECTRICITY.—The Mayor will sign the electric light contract which was recently passed by the council, authorizing the Mayor, Comptroller and City Register to contract with the Brush Company to light the business portion of the city. The Mayor said that the contract would provide that although the annual cost would be $50,000, which is $30,000 more than is now paid for the same area roads, the new light would be worth the difference.

ELECTRIC LIGHT PROPOSITION.—St. Louis has received a proposition from the Brush Company to light Union Market with 20 electric lamps of 2,000 candle-power each, at a cost of $5,000 per annum. It now costs $2,000 per annum for gas.

Scientific American Sept 1881.

A Fatal Electric Shock.

A strange and terrible accident occurred last evening at the generating rooms of the Brush Electric Light Company on Geneva street. About 9 o'clock two young men named George Leonard Smith and Henry Rinkhall, in company with another young man and two girls, stepped into the station and stood looking at the machinery in motion. Smith was very inquisitive and wanted to experiment. The manager, Mr. G. Chaffe, allowed him to try a harmless experiment, which consisted in taking hold of one of the brushes attached to the commutator, in which the electricity is held until carried away over the wires, and then, taking hold of the hands of his companions, a gentle current of electricity was passed through their bodies. Smith wanted to take hold of two of the brushes, but Mr. Chaffe grabbed his arm and held him back, telling him it was sure death to touch them. The party shortly afterwards left, Mr. Chaffe telling them to get out. About a quarter past ten o'clock Smith suddenly came into the building, seemingly under the influence of liquor. He leaned over the railing which keeps outsiders at a distance from the machinery, and, before a warning word could be said, he had grabbed the first and third brushes. Mr. Chaffe saw what he was about to do and made a jump for him. His hand stuck fast to the brushes, and, giving the engineer the word to stop the engine, he took hold of Smith and endeavored to pull him from his hold. This he was unable to do, but as soon as the engine stopped Smith raised himself to his feet, and, throwing up his arms, gave a loud gasp and expired instantly.

The thing was done so quickly that those who witnessed it could scarcely believe their eyes. Smith's face had a pale bluish tint and was drawn out of shape. His hands were badly burned, and on several of the fingers the flesh was burned to the bone. Of the unfortunate man but little could be learned, save that he was formerly a sweeper at the Wheeler elevator, but for the past week had been handling lumber in various yards on the island. He was about twenty-eight years of age, and is the neighborhood of five feet eight inches in height. He is stated that he has a wife and child living in the city, but where the writer was unable to ascertain. Mr. Chaffe says the generator is one of tremendous power, and would kill fifty thousand men as easily as one.—*Buffalo Courier, August* 8.

Eng. News. March 11. 1882.

ELECTRICITY.

OPPOSED TO THE ELECTRIC LIGHT.—Jackson, Miss., has refused to appropriate fifty-thousand for electric light purposes.

ELECTRIC LIGHT IN BOSTON.—The Board of Aldermen, of Boston, gave a hearing Monday to electric lighting companies. The proposition of the Brush Company said that the electric light could be furnished for $80,000 a year by its self-extinguishing properties. Its thirteen 1,500 lights would suffice for the city, and possess twice the candle power of the present 10,291 gas lamps. The Common and public Garden, he said, might be lighted at a yearly expense of $10,000.

LARGER BY ELECTRICITY.—San Antonio, Tex., has introduced the electric lights in its streets.

ELECTRICITY FOR DEPOT ILLUMINATION. —The depot at Springfield, Mass., will be lighted by electricity.

TELEGRAPH PIONEER.—The Texas-Mexican line has been finished to Laredo.

PANAMA MINES, will have a telephone exchange.

ELECTRIC LIGHT FOR READING.

A Number of Business Firms of the City Contemplating its Use in Their Stores.

H. F. Card, representing the Edison Company for Isolated Lighting, New York, who has been in Reading for about two days calling upon manufacturers and business men with a view of introducing the electric light in their places, left last evening for Philadelphia. He met many others in various parts of the city in the interest of the Eastern Pennsylvania Telephone Co., meeting with flattering success. While in Reading he called upon a number of firms, and in some states that they looked upon his proposition in a very favorable light. Among those whom he has seen may be mentioned the Reading Hardware Co., Wm. Bertolet, Jr., Jacob J. Wilson, T. A. Wilson, Hess, Pancoast & Stewart and others. The latter firm have under consideration the introduction of the electric light in their new four-story building on Penn street, above Sixth. The manager plans to Reading which uses the electric light. The Reading Hardware Co. Union Mill has its factory and office fit up with it. The firm which Mr. Card represents manufactures two electric lamps—arcs of 8 and the other of 16 candle power. Mr. Card explains very advantages for the electric light, and believes that it will eventually take the place of gas and oil. The cost of running the electric light in a central station is about $1.85, which covers the cost of a generator, lamps already piped into position, and everything for their proper lighting. This figure is for from 70 lamps of 16 candle power, each equal to a 10 foot gas burner, to 150 lamps of 8 candle power, each equal to a 5 foot gas burner. Mr. Card has made these figures with him to show that the electric light is 50 per cent cheaper than gas. In regard to lighting the city with the electric light, he hopes that would have to be done by the Board of Trade and as to the cost he could not definitely enquire into it, but thought that the cost would be less than that of the number of lamps we had. There are a number of other parties in Reading besides those called upon by Mr. Card, who, it is understood, talk of introducing the light into their business places. The lamps are very solid, and it is claimed that they can last a long time. The electric light can be stored in such a manner that when not in use the cost of the same as gas. It is conducted through the streets in small pipe made for the purpose, and in this way the horses of consumers can be supplied the same as with gas.

H. W. Spence, of this city, has purchased the right to manufacture in Berks county the Edison electric light generator and lamps in Delaware and forty-one counties in Eastern Pennsylvania, including that portion east of the Susquehanna, and will make arrange for their manufacture and introduction. Mr. Spence states that the firm adding from the electric light current are owned principally by some of the wealthiest men in Philadelphia, and the quality of electricity required for lighting from twenty to fifty arc lights on one circuit. Regular safety less wear and tear of machinery and the last results can be obtained by employing generators adapted for ten or a less number of arc lights. Incandescent lamps, capable of subdivision, and so far as can judge from the electric light will eventually be fully overcome. Where the arc light would be too bright, the incandescent light can be employed, for lighting residences, offices, &c., although its expense, as far as the quantity of light furnished is concerned, is much greater than the arc light.

PROPOSED ELECTRIC LIGHT TOWER AT NEW ORLEANS.

The convenience and economy of electric illumination for harbors and water fronts, particularly when it is desirable to handle freight by night as well as by day, have been amply demonstrated in this country and in Europe. The experience of Liverpool on this point has been especially valuable, both in showing the economy of the electric light for docks and shipping, and the very satisfactory working of lights raised high in the air.

The crescent shape of the river front at New Orleans, the massing of the shipping business along a comparatively short reach of shore, and the broad open space along the levee, to

ELECTRICITY.

RAILROAD LINE TO BE LIGHTED BY ELECTRICITY.—The tracks of the Union Railway Company through Indianapolis will be lighted by electricity.

ELECTRIC LIGHTS FOR STREETS.—A committee is now selecting certain streets in Baltimore, Md., upon which to place electric lights.

ELECTRIC LIGHTS are being put in the House of Representatives at Boston.

NO DANGER FROM FIRE.—A new electric light company is being chartered at Minneapolis upon a system designed to meet the objection urged in Mayor Ames's veto. The wires are to be placed under ground.

PROPOSAL TO LIGHT BY ELECTRICITY.—The Fuller Electric Light Company offers to light the streets of Lynn with 100 arc lamps till midnight every night in the year for 50 cents per light.

ELECTRICITY IN CINCINNATI.—The method by which the Brush Electric Light Company proposes to illuminate the city of Cincinnati, if the Board of Public Works accepts the offer, is to erect towers 200 feet high, at places on hexagonal figures, with a capacity of 30,000 to 70,000 candle power, and on 70 ft. posts lamps of 2,000 to 5,000 candle power. A central station has been established. Five machines, with a total capacity of 268,000 candle power, are now being manufactured, and more machines will be ordered as necessity requires within a year from this date. According to the contract, the cost is to be 25 per cent. less than the price now paid for gas.

THE electrical apparatus for the new City Hall at Delaware, O., cost $250.

XENIA, O., is talking of lighting the town by electricity.

Am. Gas Light Journal, March 2nd 1882.

Paddington Vestry—Electric Lighting.

At the last meeting of the Paddington Vestry a report was presented by the General Purposes Committee upon the comparative cost of the electric light and gas in a certain main thoroughfare of the parish. The report stated that owing to the large outlay which would have to be incurred for the purchase of plant, etc., the committee were of opinion that the time had not yet arrived for inviting tenders for lighting the parish by means of the electric light, and further that it would neither be advisable nor economical for the Vestry to enter into arrangements of the kind. The committee called attention to the experiments now being made in the city, where three rival systems were at work for twelve months, the several contracts being with the Anglo-American Brush Company, £1,410, or £44 per lamp; the Loutin System, £2,220, or £31 per lamp; and Messrs. Siemens system, £3,720, or £116 per lamp, exclusive of plant, each lighting equal areas.

Of the three methods, the first, which was the lowest in price, was considered the best light and the simplest in its action. The committee had ascertained that the cost of displacing 76 public lamps and four Bray's lamps, between Edgware-road and the eastern end of Westbourne-grove, would, as an instance, be very great. These lamps at present cost £276 6s. 8d. per annum, including salaries and everything, whilst the cost under the electric system would be £788 10s. The first outlay would be £1,863 8s., or a gross sum for the first year of £2,702 1s. for the sixteen necessary electric lamps. There would have to be duplicate engines, boilers, etc., in case of breakdown, or the streets might be left in darkness.

Mr. J. P. Anderson said this was a very large question and should be very carefully considered, and he would move that it be taken into consideration at the next meeting of the Vestry. The motion was seconded and carried.—London *Metropolitan*.

Killed by Electricity.

A singular and fatal accident occurred at Carnegie & Co.'s Union Iron Mills, on Thirty-third street, Pittsburg, Pa., Tuesday, Feb. 21st, at about half-past one o'clock in the morning. In the mill there is an electric machine of sufficient power to run the sixteen lights necessary to illuminate the premises. Some trouble has been experienced in the past with boys working in the mill who persisted in making dangerous experiments with the generating machine. In order to stop this practice a fence about four feet high had been built completely around the engine and a special watchman employed to keep the boys away from it. At the time mentioned Henry Balzer, a workman employed in the plate mill, took a lantern in his hand and went over to a clock hanging near the electric machine to see what time it was. After ascertaining the hour he walked to the machine and stood leaning upon the fence around it. The facts just at this point could not be clearly learned, but from the statements made by persons connected with the mill, it appears that Robert Lyon, the engineer, in connection with some experiments he had been making, had stretched a wire from the machine to one of the other wires and along the top of the fence. While Balzer was leaning upon this fence he suddenly turned around, smiled, and gesticulating "Oh," dropped into the arms of Lyon, who was directly behind him, expiring immediately.

It is supposed that while leaning upon the fence he had touched the wire with his lamp and empty hand, thus forming a circuit, the current passing completely through his body and into the ground. A livid mark around the throat and a long furrow running from the thigh of the left limb to the ankle showed the course taken by the electricity. Otherwise Balzer looked as if he had fallen into a deep sleep.—New York *Herald*.

Fire Protection Against Electric Lighting.

In our last issue we published some extracts from a preliminary report of Mr. Edward Atkinson, President of the Boston Manufacturers Mutual Fire Insurance Co., on danger of fire from electric lighting. Another brief report has followed and still more specific information is to appear later. We give some further extracts from the two reports:

"It may be added that we have not yet found any cause of danger of fire, from the use of the electric method of lighting, which may not be avoided, if the right method and proper care be used in putting up and operating the apparatus; but electricity is a force which cannot be too carefully controlled, directed, and watched, if generated in currents of considerable intensity.

"We add also one word of caution. Our members should be careful with whom they deal, and be perfectly sure not only of good and safe work, but also of the responsibility of the contracting parties, both with respect to the character of the work and of indemnity from loss, in view of the fact that the whole subject may be said to be shingled over with patents.

"The frequent manifestation of danger caused by the contact of what may be called the public electric arc-light wires with the public telegraph and telephone wires call for attention and care on the part of members of this company. These accidents do not impair our confidence in the safe use of the arc-light rightly put up and adjusted within the limits of a well ordered city under the control of the manager; they only mark the danger of permitting these various public wires to be carried over or between buildings without any general system or supervision, and without being subjected to a single or central authority with powers competent to regulate and control the matter.

"It is alleged that the difficulties in the way of carrying the arc-light wire under ground are considerable, but it is hoped and expected that they will be overcome.

"We therefore now advise all members whose risks are in places where there is any probability, or even possibility, of contact of public arc-light wires in the manner described, to not to permit any public telegraph, telephone, or electric light wires, to be attached to their buildings, or to be so placed in or across their salt yards as to expose their property to the possible danger of the diversion of the current of a public electric arc-light wire out-

ELECTRIC LIGHTING BY INCANDESCENCE.

ON Friday last Mr. Swan lectured at the Royal Institution on the incandescent system of electric lighting, and, in the course of his remarks, gave the following interesting details:—He thought he could fairly say that the difficulties encountered in the construction of incandescent electric lamps had been completely overcome, and that they were now commercially practicable. They knew, in actual experiments, that continuous fusing to a fairly high degree of incandescence through 1,200 hours did not destroy a well-made lamp. What the utmost limit of a lamp's life might be they did not know. Probably it would be never-increasing space; as, with increasing incandescence, the carbon became more perfectly homogeneous and more perfect. Taking it, therefore, as fully established that a cheap and durable lamp could now be made, the further question was as to the cost of the means of its illumination. The cost of producing light by means of electric incandescence might be compared with the cost of producing gas-light in this way: that, of coal produced by the labor of a man for a day, a certain portion of the quality called 16-candle gas, would produce 3,000 candle-light for one hour. But besides the product of gas, the coal yielded certain by-products of almost equal value. He would, therefore, take it that they had in effect 1,000 feet of gas from one cwt. of coal, instead of from two, as was actually the case. For the electric light, the dynamo-machine which he now used produced 1,000 candle-light per horse-power. Repeated and reliable experiments showed that they could obtain through the medium of incandescent lamps of 100 candle-power each one horse-power per hour. But as there was waste in the conversion of motive-power into electricity, and also in the conducting-wires, he made a liberal allowance, and assumed that they had 500 candle-light as the net available product of one horse-power. For fifty horse-power, the products of one cwt. of coal, they had then 7,500 candle-light, as against 3,000 candle-light from 1,000 feet of gas. That was to say, two-and-a-half times the amount of light which the gas from the same quantity of coal was capable of producing. The question, therefore, was reduced to the basis to cover the cost of the renewal of lamps. Whether by the method of multiple arc, which necessitated the multiplication of electrical stations, or by means of the simple series or of secondary batteries connected with each other from house to house in single series, the large lessening of candle-light in the last

New England Association of Gas Engineers.

The Annual Meeting of the Association will be held at Young's Hotel, Boston, on the 16th, 17th and 18th days of February next, commencing at 11 o'clock on Wednesday morning, Feb. 16th.

Members intending to propose to the Association the names of applicants for membership are requested to send them to the Secretary at least one day before the meeting. The Directors will meet, at the same place, on the evening of February 16th, at eight o'clock. Papers to be read should be forwarded to the Secretary in season to be presented by him to the Directors, at that meeting, for their approval.

BOSTON, Jan. 10, 1881. GEO. H. NEAL, *Secretary.*

ILLUMINATION BY ELECTRICITY IN NEW YORK CITY.

For the past six or eight weeks there has been quite an extensive demonstration going on in this city as to the results obtainable, in a practical way, with electric lights for thoroughfares.

Upon each block, at one of the street corners, posts of iron about thirty feet high, were erected from 14th to 24th streets, on Broadway, upon which electric lamps were placed; and in the open space in front of the Fifth avenue Hotel a lamp was placed on the top of the two mansard-like gas posts which are placed there. The electricity is generated in 20th street, between Sixth and Seventh avenues. A complete circuit of large insulated wire is made from the source of supply through the different lamps, the wires being carried upon the posts of the city's fire alarm system. Other wires are also used to supply private consumers.

It is said that wires are also to be suspended from the elevated railroad structure to reach some points where the light is desired. The total number supplied at the present time from this source is said to be about eighty, of which twenty-three or twenty-four are especially street lights. All of these street lights are furnished, free, for, to the city free of cost, so that a direct statement of cost, as compared with gas, cannot be arrived at as yet.

Of course the company supplying the light will be able to arrive at a tolerably accurate estimate of the running expenses after so long a practical experiment. The number of gas lamps which have been in use on that part of Broadway where the electric lights are located is about seventy-five. These cost the city $16 per annum, including cleaning, lighting, painting, etc., which would make a total annual cost of $1125.

Where the electric lights are supplied to "private consumers" the charge is one dollar per lamp per night up to 12 o'clock. The street lamps burn all night; but if it be assumed that the company would be willing to furnish the light to the city for all night at the same price as they supply private consumers up to midnight, viz., one dollar per lamp per night, the cost of lighting the one mile of Broadway by electricity would be, for twenty-three lamps, $8395. Of course, this is "supposing a case," and, in the absence of actual data, is only given as a supposable case. As to the character of the light it has been very aptly described by a French writer as "illumination but not lighting." It is true that there is much more light in some places than by the gas system; but the object of street lighting is to light the roadways and sidewalks, and for this purpose all the light that is sent off in the upper air is wasted.

Around each of the posts of the electric lights there is a very dark shadow for a space of twenty feet radius. There is more or less unsteadiness to the light of necessity although those above referred to are the steadiest we have ever seen when taken on the average. The average candle power of these electric lights, so far as can be judged from casual observation, will probably not exceed 250 candles; but in this judgment we may be in error, and no doubt, at times, the candle power is higher than that, but, on the other hand, there are times when it is less. There have been but few extinctions, and during the recent heavy sleet storms, the comparatively limited extent of wire enabled the company to so watch and attend to their lines as not to have an interruption when the hour of lighting arrived. In one or two instances this is said to have been done by cutting the wires during the worst of the storm, which was in the daytime, and thus relieving them from the strain of the heavy weight of ice, which demolished the various telegraph

IL FUNICOLO
Milano, 23 Marzo

Per la patriottica emorranea il Municipio avora fatto lo sforzo di far illuminare straordinariamente anche la Galleria Vittorio Emanuele, dove poi passavano tutti i reduci da Porta Vittoria; per cui anche la Galleria si animatissima fino ad ora tarda.

Un altro richiamo di gente fu per la Galleria la illuminazione elettrica che l'ingegnere Shephort del Ridotto della Scala ha portato al Caffè Biffi, dove ieri sera assolutamente non era possibile di trovar posto.

Così l'esperimento di luce elettrica fa'o con tanto successo al Ridotto, può esse o giudicato da tutta la cittadinanza, ed è certo che i giudizi emessi ieri sera sono favorevolissimi al sistema Edison, e danno come risolto il problema.

Questo pubblico esperimento ha persuaso la Società del gas a migliorare l'illuminazione della città, per cui ieri sera si trovavano, specialmente nelle località centrali, le fiamme dei lampioni più vivaci e luminose del solito — la qual cosa tuttavia non impedirà alla luce elettrica — in un'epoca più o meno lontana — di impadronirsi del campo, perchè il progresso della scienza non può essere fermato. Intanto ieri sera fra gli altri vantaggi della luce elettrica si è notata che l'aria del caffè non era più viziata ed afosa.

L'as sesore Ostuni, che si interessa vivamente a questa questione della luce elettrica si è trattenuto ieri sera molto tempo al Caffè Biffi in compagnia di alcuni capi servizio del Municipio, volendo studiare qua'o su sia l'effetto e con quale risultato può a ale luce venire applicata su larga scala.

LA LOMBARDIA 23 Marzo 1882

Scienza ed industria. — Il trionfo della luce elettrica è assicurato, grazie all'invenzione del genio di Edison e della cura diligentissima del valente ingegnere Shepherd.

Ieri sera il caffè Biffi era illuminato da seicento lampade *Edison*, che diffondevano una bellissima luce, simile assai a quella del sole, perchè conserva l'intonazione dei colori, ed è sempre eguale, chiara, simpatica.

Nessuna oscillazione, nessuna diminuzione d'intensità, nessuna intermittenza; la luce elettrica è dunque un fatto compiuto.

L'ingegnere Shepherd è il primo che è riuscito ad applicare con successo e praticamente il sistema Edison.

La luce elettrica dallo studio scientifico è passata allo studio industriale e qualunque piccola città, qualunque opificio può ottenere con minor spesa e senza alcun pericolo un'illuminazione più bella di quella del gas.

Noi che abbiamo applaudito il Shepherd quando faceva i primi sforzi per introdurre tra noi la luce elettrica, non possiamo trattenere di lodarlo ora che, associato alla potenza del genio di Edison è riuscito a darci così splendidi risultati.

IL SECOLO
23-24 Marzo
Milano 1882

La luce Edison al Caffè Biffi. — Ieri sera si inaugurò al caffè Biffi in Galleria Vittorio Emanuele l'illuminazione elettrica colle lampade ad incandescenza sistema Edison. L'effetto corrispose pienamente all'aspettazione generale, la luce fu brillante, ma moderata, eguale, stabile, gradevole alla vista anche pel suo colore. In prima ora il pubblico si accalcava dinanzi e dentro al caffè per ammirarla dando non dubbi segni di soddisfazione. Ecco un'altra passo verso la meta che a quanto dicesi verrà in breve raggiunta per opera d'una Società che in questi giorni sta costituendosi sotto la direzione dell'ingegnere Shepherd.

Le nostre congratulazioni all'intraprendente proprietario del caffè Biffi.

LA PERSEVERANZA DI GIOVEDI'
Giovedì, 23 Marzo 1882.

Illuminazione elettrica. — Ieri, a cura del signor Shepherd, s'è fatto al Caffè Biffi, nella Galleria Vittorio Emanuele, un esperimento di illuminazione a luce elettrica col sistema Edison. L'esperimento è riuscito ottimamente.

SCIENTIFIC AMERICAN

A WEEKLY JOURNAL OF PRACTICAL

Vol. XLVI.—No. 13. [New Series.]

ELECTRIC LIGHTING FOR SIEGE PURPOSES.

It is extremely useful for the defenders of besieged places to be able at night to illuminate the accesses to the place the enemy generally profits by darkness to make his sapping operations and to effect those movements of troops that are necessary to make an assault or attempt a surprise. So, from all epochs, the endeavor has been to illuminate the country by throwing projectiles composed of materials that are inflammable but of slow combustion. Sometimes these projectiles were held aloft by means of parachute with which they were provided, and while folded itself after a certain length of time; and, sometimes they were allowed simply to drop on the ground. But the latter case, the combustants among whom they fell mutually hastened to extinguish them or to null them into ashes. This is the reason that the fire bombs employed at the present day by the artillery are provided internally with a grenade designed to explode at the moment contact with the ground.

The latter is not fastened to the carriage, and can be removed by a couple of men and carried to any culminating point in the vicinity, while the vehicle remains where it is. The projecting apparatus is set up on a folding support which opens and closes in the form of a sort of lattice work. The engraving gives herewith represents the type adopted for the French army, which at present possesses light apparatus of the kind. One of the apparatus was shown at the recent exhibition of electricity by the Minister of War, and another by the house of Sautter & Lemonnier.

The projector, which was devised by Colonel Mangin of the French army, is 40 centimeters in diameter. The Gramme machine gives a light equal to 600 Carcel burners. The apparatus thus arranged permits of the exploration of the country to a distance of 2,400 meters, and even of three kilometers if the weather is sufficiently clear.

There was also exhibited at the Palais de l'Industrie another type designed for forts of the first category, but on the same system. This was experimented with for a long time at Mont-Valerien, and it was found that an observer standing alongside of the apparatus could recognize a soldier at a distance of more than six kilometers, and distinguish details of construction at five kilometers. With so great a power as this, it is naturally necessary to employ low-power able machines than those above mentioned, and the projecting apparatus and the generator of electricity have to be carried on separate carriages.

We shall now briefly point out the peculiarities of these two essential parts.

What constitutes the originality of the Mangin projector is the form of the mirror. It is well known that in order to reflect the rays diverging from a lamp into a fascicle of parallel rays, it is only necessary to place the lamp in the focus of a parabolic mirror. Now the construction of parabolic curves is difficult and expensive, so Col. Mangin conceived the idea of employing glass cut with two spherical surfaces, thus facilitating the labor. These two surfaces must not be concentric; and calculation permits of finding the degree of excentricity with which the ray, emanating from one of the centers, is sufficiently parallel in practice (though not geometrically so) with the diameter which joins the two centers to give the fascicle all the power desirable. It is easy to verify the fact that the convex surface has a greater radius than the internal concave one, in other terms, that the thickness of the metal in the center is less than at the edges.

A biconvex lens, interposed between the luminous focus and the reflector, diminishes the focal distance, and, consequently, permits of reducing the dimensions of the projector.

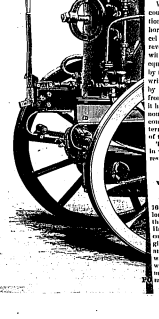
Col. Mangin likewise employs a *diaphragm*, the object of which is to spread out horizontally the fascicle obtained, a height being of slight importance. It appears that this arrangement has been somewhat criticised, as it diminishes the intensity of the light produced. "The projection is demountable," say the adversaries of this system, "their field may be extended, without any loss of illuminating power, by a simple displacement."

Let us now pass on to the source of electricity.

The Gramme machine, adopted in France, Russia, and Norway, is actuated by a three-cylinder engine on the Brotherhood system. The electro-magnets are flat and very wide, and the bobbins have two current collectors. The elements may be coupled for tension or quantity by means of a commutator mounted on the machine, and the changes may be effected instantaneously.

When the electro-magnetic parts of the machine are coupled for quantity, it revolves at the rate of 800 revolutions per minute, with an expenditure of a power of four horses, the light produced varying from 1,200 to 1,300 Carcel burners. When coupled for tension, the machine revolves with a velocity of 1,200 revolutions per minute, with an expenditure of eight horse-power, and gives a light equal to 2,000 to 2,200 burners. With such a power, and by the use of projectors 40 centimeters in diameter, ordinary writing may be read at a mile distant, as has been shown by experiments made at Berlin in 1875. By placing in front of the regulator a mirror inclined toward the horizon it has been found possible to project on the clouds a luminous band which, from a distance, looked like the tail of a comet, and on which (as on the screen exposed before a lantern) exhibited themselves such signals as were made in front of the mirror.

There is thus realized, then, a system of optical telegraphy in which the Morse alphabet is employed as a means of correspondence.—*Revue Industrielle.*



Verdict of the Coroner's Jury.

sion, Monday, Feb. 25, 1878.

We find that Levi J. Bircher came to his death on the 16th day of February, 1878, by the explosion of the boiler belonging to the Jewell Milling Company. We believe and find that the sole responsibility for said explosion rests upon the Hartford Boiler Insurance Company; and we hold said company responsible for the death of Levi J. Bircher, in giving permission to the Milling Company to carry an amount of steam which the age of the said boilers did not warrant, and which, in the jury's estimation, said boilers were unable to carry. We are of the opinion, and recommend, that boilers be tested in the future by both the hammer and hydrostatic test."

THE METROPOLITAN.

APRIL 1, 1882.

Improved Street Lighting.—The employment of Messrs. Siemens's new regenerative gas-burner for the lighting of Holborn and other central spots affords a further illustration of the marked improvements that have taken place in the appliances available for lighting our public thoroughfares since the advent of the electric light. When the use of the Jablochkoff candle, on the Victoria Embankment, and elsewhere, first suggested to the gas companies that if gas was to hold its own for street lighting a vast improvement would have to be made on the system which had hitherto prevailed, large Argand burners and a very much better form of lantern were tried for a time in Queen Victoria-street and Waterloo-place, and although for the purposes of this demonstration three or four times as much gas was used as formerly, the fact that the Argand system has since been discarded for public lighting would seem to indicate that the experiment did not prove in every respect the satisfactory success that was anticipated by the companies. Flat-flame burners were then brought prominently under the notice of the public as being specially applicable to the purposes of public lighting, and there can be no doubt that, as arranged by Mr. Sugg and Messrs. G. Bray and Co., they were so employed as to produce a high illuminating power for the quantity of gas consumed; Messrs. Bray, according to the latest trials, showing, perhaps, the best results in this respect. The new burner of Messrs. Siemens, however, yields a light in excess of that obtainable by the use of any improved form of flat flame burners. Going into figures—we quote from the results of some recent tests by Mr. Vernon Harcourt—we find that while the best light produced by flat flame burners, however governed and combined, is something like 978 candles per cubic foot of 16 candle gas consumed, the Siemens burner for the consumption of a similar quantity of gas gives a light equal to 4,731 candles. Hence in Holborn the Siemens burner has even thus early made its appearance as so many centres of traffic in the metropolis, and its value is evinced in its practical working is fully explained. True the first cost is in advance of that of the better known and more simple form of lamp; but, on the other hand, it gives the same light for about 25 per cent. less gas. Concerning the installation in Holborn, it may be added that Messrs. Siemens are lighting that portion of the thoroughfare between Holborn-circus and Gray's-inn-road, and altogether 26 lamps have been put up. The burners in which the lights are inclosed cannot lay claim to much beauty, judged from an artistic standpoint, but they have the advantage of being constructed on sound scientific lines with a view to making the most and the best of the lighting power available.

Crystal Palace Electric Exhibition.—The directors of the Crystal Palace, acting on the recommendation of the Honorary Council of Advice in connection with the Electric Exhibition, have appointed the following twenty-one British jurymen:—Captain F. W. Abney, R.E., F.R.S., Professor W. Grylls Adams, F.R.S., Major R. F. Ansonyge, R.E., Professor W. E. Ayrton, F.R.S., Sheffield Bidwell, Esq., Sir S. Canning, Professor Fleeming, M.A., F.R.S., T. H. Compton, Esq., C.E., Horace Darwin, Esq., Professor G. Carey Foster, F.R.S., Professor E. Frankland, F.R.S., Captain Douglas Galton, C.B., F.R.S., F.R.G.S., F.G.S., F.L.S., D.C.L., Lieut.-Colonel W. Haywood, Dr. Hopkinson, F.R.S., Professor D. E. Hughes, F.R.S., Professor Fleeming Jenkin, F.R.S., S.L. and E., M.I.C.E., Professor J. W. Langley, W. H. Preece, Esq., F.R.S., Professor Silvanus Thompson, B.A., D.Sc., C. E. Spagnoletti, Esq., C.E., Lieut.-Colonel Webber, R.E., President Society of Telegraph Engineers. The first meeting of the British section of the jury was held at the Crystal Palace on Tuesday evening, when nearly all the jurymen were present. Some of the foreigners who have been asked to act on the jury have already accepted, and the names of the foreign jurymen will be announced as soon as the list is complete.

The Edison Electric Light Company, Limited.—This company was registered on the 15th ult., with a capital of £1,000,000, divided into 200,000 shares of £10 each. The £ shares will be entitled to a preferential accumulative dividend of £5 per cent. per annum on the amount paid up. The company proposes to acquire the whole of the patents taken out for the United Kingdom by Mr. Edison in relation to the application of electricity or magnetism as a lighting, heating, and motive agent. The purchase includes the electric lamps, dynamo machines, and other plant of the vendor now in Great Britain, and, when capable of being used, for the exhibitions of the patents or the production of the electric light. The consideration is a payment not exceeding £50,000 in cash, and further, the allotment to Mr. Edison of one fully paid £ share for every £10 capital paid up, or credited as paid up, in respect of the A shares. The first subscribers include the Right Hon. E. P. Bouverie, Sir J. Lubbock, Bart., M.P., Mr. W. Fowler, M.P., Mr. F. J. Bramwell, C.E., Mr. W. Pilkington, M.P., &c. It is proposed that the first directors are Viscount Anson, Mr. Sheffield Bidwell, Mr. E. B. Wade, and two first-mentioned subscribers.

The Electrical Power Storage Company, Limited, is another new undertaking. It was registered on the 21st ult. with a capital of £200,000, in £10 shares, to carry on the business of electricians and electrical, mechanical, and chemical engineers, and of workers and dealers in electricity, motive power, and light. The first subscribers include Mr. Daniel Spence, Hon. Lieut. C. P. Stuart, Mr. William Ladd, Mr. W. M. Rollivant, Mr. C. Dorman, and Mr. F. Dean.

THE METROPOLITAN.

APRIL 1, 1881.

The Cost of Electric Lighting.—The following communication is from the pen of a gentleman practically acquainted with the subject on which he writes :—

TO THE EDITOR OF THE METROPOLITAN.

SIR,—Considerable interest is now being displayed by the public as to the cost of the electric light as compared with that of gas; but up to the present time we have not any reliable estimate by the electric companies to answer the question. The electric light is not generally given a central station in the same manner as gas, so as to make a comparison, but is from time to time hoisted in the daylight period—and what it would cost if a separate electric apparatus, with generator and engine, were erected for every house, will also give an exact idea of its cost then if you were to calculate the cost of gas on the supposition that every householder had his own gasometer.

Now, to fully analyse this question, we must divide the electric light into its sections, viz., the arc light and the incandescent light. The former is the large light now so extensively used in streets, railway-stations, philanthropic-gas, iron-works, and factories, and is generally of 2,000 candle-power per lamp. These are the lights which have been used in the streets of the city of London and Chesterfield, and the cost of which, including interest on capital, depreciation, repairs, wear and tear, and all other items, does not exceed 2d. an hour; and I am credibly informed by a gentleman who was there the other night that at a distance of 175 yards from one of these lamps a newspaper may be easily read, and the time by the watch told at even 230 yards so that if one of these lamps be erected where four streets meet, you would light four times 175 yards, or 700 feet long. Now, it would take 9,000 lights of equal distance to light those streets, and these at 4d. per hour, would cost £37 10s.

I have given the greatest distance at which gas lamps are ever placed even in badly-lighted districts; but to give an illuminative equal to that of the electric light they would need to be only 30 yards apart, which would take 21 gas lamps = 42d. per hour.

For such quarters the saving is still greater, as the electric light gives a light equal to 100 gas jets, while the cost is 2d. per hour, as compared with 2s. 6d. The cost of the small incandescent light, which is the only one suitable for domestic purposes, I have ascertained by to be as follows :—Electric generator and steam engine to run 2000 of the 16 candle-power each, main leads for say 20 houses, &c., &c., £1,500.

I do not calculate the cost of the gas, because the fittings and lamps for electric light would cost very considerably less than gas fittings. The annual cost would be :—

Fuel for 2,000 hours per annum @ 20 infl.
- extra hour-power engine, with coals, at 20s. per ton £466 13 6
- Cost of screening the carbons of 400 lamps twice yearly, at 3s. 300 0 0
- Wages, engineer, &c. 150 0 0
- Interest and redemption, 10 per cent. 150 0 0

£1066 13 6

Now the cost of lighting 20 houses with 20 gas jets, 365 days, 6,000 hours per annum, at 5d. per hour per light, would be £1,825 0s. 0d., or a saving of £758 6s. 6d. per annum; and I am assured that no house would be taxed by not having the yearly whitewashing.

The electric light, however, would be comparatively cheapest if a whole town were thus lighted, and electric mains and accessories—fitting at each house; and I am assured that such would be practical men, that the latter improvements will shortly be brought out, and, indeed, are likely to be ready before the British public is educated up to electric lighting, and so that to give it a fair chance, it must be supplied in large quantities like gas; and that no practical benefit can be obtained if every one is to have his own electric light generating machinery, any more than if every one had his own private gasometer.

What we want to know is, how it will work out if a whole town were supplied with the electric light, and our municipal authorities would confer an immense boon upon the public if they would make the trial for themselves, or allow some enterprising firm of electrical engineers to make it for them; and I believe there are some who would be willing to make the experiment without any cost or risk to the ratepayers if they were asked to do so.—Yours truly,

P. C. BARKER.

THE METROPOLITAN.

NOVEMBER 5, 1881.

£3,889 15s. 5d. under the scale system, the saving effected being as stated above.—The report was approved and adopted, and ordered to be entered on the minutes.

Electric Lighting at Chesterfield.—The trials of the Brush Electric Light at Chesterfield have been so successful that the Corporation have decided to dispense with gas entirely as far as public lighting is concerned, and to replace it with the electric light. The contract has been secured by Messrs. Hammond and Co., of 110, Cannon-street, London, the general agents of the Brush Co. The lighting will be done by means of about 22 brush arc lamps and about 70 Lane-Fox incandescent lamps. The annual lamps and about 70 Lane-Fox incandescent lamps. The annual cost is guaranteed by the contractors not to exceed the present gas cost in quantity, and it is claimed that the light will be three times as efficient, and it is claimed that the light will be three times as efficient, and it is claimed that the highly improved illumination can be obtained at a less cost. Once in public lighting, the example of Chesterfield will be speedily followed by other towns—in fact we understand field will be speedily followed by other towns—in fact we understand that deputations have already visited Chesterfield from Derby, Nottingham, Barnsley, Sheffield, and other towns who are now in active negotiation with the contractors for the trial of the Brush in other towns.

Electric Lighting at the British Museum.—On the 26th ult. the arrangements were completed for placing the electric light in the hitherto dark places of the British Museum, such as the lavatories, cloak-rooms, passages, &c. Swan's incadescent lamps are now used in these parts yielding a bright light which makes the room as clear and bright as noonday. This principle, it is believed, will be extended to the MS. departments, and eventually the old and large rooms behind the reading-room, and the galleries, which will enable the attendants to supply books to readers in the evening, instead of limiting the time in November and the winter months to 3 or 4 hours—a great inconvenience to library students.

NATURE

August 25, 1881]

ELECTRIC LIGHT IN COLLIERIES

AUGUST 9, 1881, witnessed the first practical application in the United Kingdom of the electric light to the illuminating of coal-mines. The Earnock Colliery, near Hamilton, Lanarkshire, belonging to Mr. J. Watson, has been fitted with Swan's incandescent lamps specially arranged with outer lanterns of stout glass, air-tight, and provided with steel guards. The workings in which the lamps were fixed are 118 fathoms, or 708 feet below the surface. Twenty-one brilliant little lights placed at the pit-bottom, in the roads, and at the actual face of the seam where active operations were in process, supply an illumination of a very different character from the dismal glimmer of an occasional Davy. The electricity was generated by a dynamo-electric machine at the surface worked by a special 12 horse-power engine, and conveyed by two cables, first along telegraph poles to the pit mouth, then down the shaft to the workings, in one section to a distance of half a mile. The overhead wires are naked copper wires of 3 inch diameter, while those below ground are carefully insulated, and in the shaft are protected with an outer tube of galvanised iron. At suitable points of the circuit safety air-tight switches, the invention of Messrs. Graham of Glasgow, are inserted to afford control over individual lamps. The mine was visited two days after the installation of the light by members of the Mining Institute of Scotland, with whom was Mr. W. Galloway, whose remarkable experiments on the explosive effects of coal-dust will be remembered in connection with the more recent report of Prof. Abel. The party were photographed in the workings. An experiment was made with a lamp to test whether in the event of its being broken by accident a surrounding atmosphere of explosive gas would or would not be kindled by the strip of red-hot carbon before it had had time to cool. Into a box containing about three cubic feet of explosive gas a single lamp, removed from its outer protecting case of stout glass, was placed, and the c[illegible]as turned on. The fragile bulb including the incand[illegible]at carbon thread was then purposely broken, when the [illegible]ook inclosed in the box immediately exploded. No such occurrence could possibly happen if the protecting case of stout glass is properly constructed. The risk of accident must be considered as immensely less than that of the ordinary Davy lamp, especially when it is remembered that with the brilliant light of the electric lamps they need no longer be carried in the hand or set down upon the floor near the actual spot where the coal is being got, but will be fixed overhead at a safe distance against the wall of the mine. The ease with which the light can be turned out during the firing of a blast is another point in their favour. The proprietor of the Earnock Colliery is greatly to be congratulated on the step he has taken. In 1880 the death-roll of the shale by explosions of fire-damp in Great Britain reached the figure of 499 persons. We venture to predict that the universal adoption of electric lighting in fiery mines would reduce this figure to one-tenth of its terrible proportions. How many years will it be, we wonder, before the adoption of electric lighting will be made compulsory by Act of Parliament? And how many colliery owners will discover, we would ask, when driven to this course by compulsion, that in the long run they effect an economy by discarding the clumsy and unsafe "safety"-lamp, which will so soon be numbered with the "flint mill" amongst the relics of the past?

American Gas Light Journal.

Sept. 2, 1881.

Mr. B. F. Spice on Electric Light.

The following letter, written to the Directors of the Dublin Gas Company, gives the views of one of the leading gas men of England on the electric light. An effort is being made to induce the Dublin authorities to grant permission to an electric light company to lay wires, etc., the real object of which is to give the shares a good send-off and establish the electric light company in Dublin on a luminous basis without the trouble of going to Parliament for powers, as gas companies are obliged to do.

21 PARLIAMENT STREET, WESTMINSTER, S. W.,
12th July, 1881.

To the Chairman and Directors of the Alliance Gas Co., Dublin:

Gentlemen:—I have not been unobservant of the attention paid and the encouragement afforded to the efforts made for the introduction of electric lighting in your city.

Nor have I been surprised at the effect produced thereby on the market value of the property of your company, experience having proved that public opinion is easily affected, adversely to the interests of the holders of property in gas undertakings, by the highly colored statements of the numerous advocates of the "light of the future," as it is fondly called by its patrons, which, they say, is to supersede gas as a lighting power.

But, while it is to be deplored that the holders of shares in a perfectly sound and stable undertaking, such as yours, should be deluded into parting with their interest in it at a price or prices far below its intrinsic value, no consolation remains to you, and those of your shareholders who know better than so to sacrifice their property, that, as a prosperous and good paying concern, it is worth as much as it ever has been.

I make this statement to you in all seriousness, with an full and intimate an acquaintance with the facts as regards the surroundings of the two systems of lighting as almost anyone can obtain, and without an atom of prejudice against the electric light; regarding it, indeed, with great favor, my opinion being that it is proving to be, to gas companies, a blessing in disguise.

For the past two years I have been proclaiming the doctrine, that, as people became accustomed to a light of great intensity, such as the electric light, they will find it extremely inconvenient to put up with the less powerful gas burners, such as those which the parsimony of local authorities have hitherto commonly insisted on as being sufficient for lighting the streets of cities and towns; and the truth of this doctrine has been abundantly proved by the brilliant specimens of gas lamps which have been set up in London and in the cities and large towns of the provinces.

Perhaps the best known specimens of public lighting by electricity are to be seen in the metropolis; and respecting its cleanness and durability, it is not too much to say, public opinion is divided. Some admire it, some accord to it qualified praise, and others object that it is cold and disagreeable in character, while the intensity interferes disagreeably with the vision in passing from one intense light to another, through the comparatively obscure spaces which intervenes.

Then, again, another objection with which observers in general cannot fail to sympathize is the vital defect of its uncertainty. This has very often been proved most inconveniently, all the lights on a circuit having gone out again and again through some undiscovered defect by which the flow of the current has been stopped, the effect being to leave the district in total darkness. This has occurred several times on the Thames Embankment, on the Holborn Viaduct, and in some of the most important streets of the city of London.

A popular fallacy has lately been widely and industriously propagated, that this may be overcome by the "storage of electricity," Sir William Thomson having had a box of it sent over to him at Glasgow all the way from Paris! Wonderful, certainly, but worth nothing practically, except for scientific purposes. Who would think of sending a box of gas from Paris to Glasgow, except to show that it could be done? And who d[illegible] know that either the one or the other, gas or electricity, can be made and economically produced where it is wanted than it can be made and sent in a package from one place to another, the two places being some hundreds of miles apart?

And then, again, as to the quantity of "electric energy" sent to Glasgow being stated as amounting to "one million foot-pounds," this appears to

me to be studiously defensive. The box containing this energy is said to have weighed 72 lbs., and this weight of coal is capable of giving out 12 million foot-pounds, and the boasted one million foot-pounds of electric energy means about the same quantity as is contained in two cubic feet of compressed gas.

The whole thing, indeed, practically considered, is a delusion, and has not advanced the storage of electricity one single step. We are just where we were, and nowhere else, as concerns the question of "storage."

Electricity has to be produced as it is wanted, and conducted to where it is wanted, and any trifling hitch in the combined operation will prove fatal to the continuity of the current and extinguish the lights depending upon it.

So much for the application of electricity to public lighting.

The most important experiments and display of its adaptability to the lighting of interiors have recently been made in the House of Commons; and the result, after several trials, was a failure. The diameter of the light was objectionable; its uncertainty was more than once made disagreeably manifest, and the old system of lighting by gas was decided to be preferable.

While these experiments were going on, another practical application of it was sought to be effected by an old established firm, having large business premises in Westminster, to which they have recently added a carpenters' shop, adapted to the requirements of sixty workmen; however, as the sum required by the Company for the requisite fittings and dynamo-electric machine was £700, the luxury of the light was abandoned, for the simple reason that the cost of driving the machine to produce the light, the expense of attendance upon its working, and wear and tear, added to the interest on the first cost of fittings, would greatly exceed the cost of gas.

This may serve just as a gauge to enable you to measure pretty accurately the chances of your business of gas supply being interfered with by electric lighting during the twenty generally-due interims. And it may well encourage and resolve confidence to shareholders, whose faith in the continued prosperity of gas undertakings may have been shaken by the assertions of electricians and others that "the days of gas lighting are numbered."

Possibly there days may be numbered, but no one has yet ventured to predict the number, nor can anyone determine it within a century or two. The prediction was made more than thirty years ago, when a great step in advance was effected, and the light was exhibited at the Polytechnic Institution; but although a generation has passed away since then, the prophecy remains unfulfilled, and just about as far from fulfillment as ever." Side by side with modern electric lighting in its most improved forms, the use of coal gas has gone steadily on at an accelerated rate.

It would be difficult indeed, to point to any business which has prospered so steadily through long continued seasons of depression and convulsions, which have shaken the very foundations of commerce, and never has the prosperity of gas undertakings been more solid and assured than at the present time. Nor could a better incentive be increased means of economy in production, and consequent widening of the base of this prosperity be devised than the electric light, and this will be proved as certainly in Dublin as in London.

It is cheering to know that while the zest of some prominent electricians palpably exceeds their common sense, and has led them to make ridiculous assertions, there are others, such as Dr. Siemens and Mr. Preece whose statements in this special branch of science are of the highest order and second to none, who have over and over again publicly declared their convictions that the use of gas will not be prejudicially interfered with by electric lighting. These foremost electrical authorities are content with widening the field of their operations, well knowing there is ample room for both; and we gas men know equally well that the more electric lighting prospers in its acknowledged proper sphere, the better it will be for that interest for the prosperity of which we are more particularly concerned.

My advice to your shareholders, therefore, is that those of them whose main object is a sound investment, steadily yielding a satisfactory income, *stick to their property*, which will certainly continue to flourish, and let those of their fellow citizens who are so minded, manifest their patriotism by taking shares in the projected "Dublin Electric Light Company," and wait patiently for the result of its operations, which may possibly teach a much needed lesson, calculated to enlighten us respecting the actual cost of the luxury, concerning which a great amount of ignorance prevails.

I am, gentlemen,
Yours faithfully,
R. P. Spice,
M.Inst. C.E., M.I.M.E., F.R.G.S.

astened, should be indicated. The ordinary method of representing the common wound-armature is shown in Fig. 13, and a complete representation by Fig. 14. Here the coils are wound on a bar of iron of T-square, it is not necessary to point out a place if the work in appearances, so as to get the important parts on a large scale of full size, and yet not to take up the necessary paper to show the whole or disjointed coil.

If the T-square is of the steel kind, Fig. 6, refer to the "Hints to Inventors," page 305, vol. xiii. A form of hand will no doubt suggest itself to many. Especially those who have had free-hand, or ordinarily angle, will want to bench off into an elaborate display of scroll work, bolstering such pretensions approximate. But the moment the draughtsman begins to conceive forms of his own he will find that he has got into a mess. A well-wood himself, if he is not careful to do it as well as he advances, he will find less to unlearn in after years, and par be back upon with great benefit if he permits fancy to take the place of reason. Tools and machines are not for mere ornament. Neither should they be made ornamental, when they are, they are not what they should be. Just as soldiers, they are, so with the fashion, with which they can be cured for, or kept clean. A strict adherence to these principles does not in the least prevent tools from possessing elegant forms, and the construction of machines possessing grace and beauty in the extreme.

The T-square cannot give grounded forms to which it is adapted, and not likely to depart very much from the original dimensions. If he keeps within these prescribed limits, though he may not produce any very brilliant results, he is sure not to produce any ridiculous ones. Mistake are straight lines, are not least resisted, when possible, by straight bodies, with lines of strain, meeting at least at right angles. In this case, the wire, when pressed on to armature in the direction of the T-square bar, is in a position to resist the tendency to fracture. The tendency to natural strain on the T-square head is at the ends, and must be resisted by the screws. Remembering from the end to the screws, pass an near through the centre of the screw as it passes, and the tendency to fracture, which, in the case, as it is, is the most likely to occur, is resisted by the screw, and prevented from dropping the square on the floor. The worst place for it to strike would be on one end, and here the screw would be resisted in the best possible way. The arms are made widest at the centre, to resist vibration.

To determine the size of T-square, as in the case of the bobbin, the wire to go over the head, I have found that the method here given looks well. Let the altitude of all the curves be equal. That is, the distance from *a* to *b* and from *c* to *d* are the same. Any perfecting arm should be the strongest, and finished with a pad or curved piece, as *a*, to join the body of the work, so that the arm may be made thinner, and the appearance of a tree with curves at the junction. In the designing of the T-square head no thought was taken of this principle, but the pattern was whittled out until it appeared to satisfy the designer, and it was afterwards found that the area of the brass was on a line from the centre of the screw, and so it will be found with any good form of T-square. The T-square head is a good architectural style. They have been made by hand right at first, and the laws of right have been discovered afterwards.

Do not attempt to find out the right and wrong ways in repeated attempts, for there is no such thing as right and wrong about it. Just as you have got a thing to look right in one way you make your drawings. You will be a good deal bespoke behind them. If your view of the drawing-board looks better to you with the lower and left hand and lines made twice as large as the others, make them so, since there is some practical work in designing afterwards. Do not try to draw "nearly" work by the eye, for it is worth no more worth of time and thought and bother-putting times or four times, are over the other, on the same paper, in broken parts, dotted lines and the like.

THE SCIENTIFIC PRINCIPLES INVOLVED IN ELECTRIC LIGHTING.—V.*

By Professor W. Grylls Adams, F.R.S.

(*Continued from p. 6.*)

Magnetic Machines.

THIS same reasoning will apply to the case where a transmitting coil is used in place of the original battery current, a closed circuit armature, as the magnetic field, or a magnet moved in the neighborhood of a fixed coil. In fact, the theory of Ampère requires that a small closed current should be equivalent to a magnetic molecule, and so a collection of equal small closed currents, all going the same way, and occupying a given area, is equivalent to a collection of equal magnetic molecules with their poles in the same direction, and of the same magnet. But a collection of equal small closed currents all going the same way, and occupying a given area, is equivalent to a current round that area.

We may usefully express the efficiency of magneto-electric machines by a formula. Taking C to be the effective work done by a unit current in one second, and R the resistance, the number of turns in a circuit, and O the amount of resistance, the total effective work is $C\nu\delta$; and the work expended in overcoming the resistance, in the circuit is $C^2\delta$; hence, by Joule's and Ohm's laws, if E be the electromotive force,

$$EC = C\nu\delta + C^2R.$$

Hence the efficiency $= \frac{C\nu\delta}{C\nu\delta + C^2R} = \frac{1}{1 + \frac{R}{\nu\delta}}$.

Thus, for a given resistance, the greater the number of turns of the machine, the greater is the efficiency, and the higher the resistance, the less the efficiency. This formula shows that machines and lamps of high resistance can only be efficient when the machines are revolving at high speed.

We may represent the efficiency of batteries or magneto-electric machines in connection with lamps, electromotors, such as a dynamo-electric machine, by a diagram from *La Lumière Électrique*, in which the electromotive force of the battery or excited machine is measured on a horizontal line, and either the current or the energy expended is represented by vertical lines, the total electric energy by the area of the rectangle (vi.), as the sum of the effective work (iv.), and the loss of energy by heating, &c. (v.).

FIG. 3.

i. Electromotive forces.
ii. Strength of current.
iii. Energy converted into electricity.
iv. Effective work in the external circuit.
v. The efficiency.
vi. Energy set converted into useful work.

It will be seen that when the efficiency is $\frac{1}{2}$, the greatest amount of effective work is produced, and this amount of work is $\frac{1}{4}$ the total electrical energy. Since the electromotive force is proportional to the current, the greatest effective work is produced when given the effective work and efficiency at different speeds.

In the case where the fixed and the movable parts of the machine are electro - magnets, the following laws are found to hold, which we have—

I. The action of the currents on one another.

(1.) The action of the fixed magnetic core on the movable coil, and of the movable magnetic core on the fixed coil.

(2.) The action of the two magnetic cores on one another.

Here the values of *a* *b* of the form $a + bn + \frac{c}{n}$ are constants, and depend on the magnetic properties of the cores.

Each of these actions arises from the influences of the equal currents on one another, and, therefore, will be proportional to the square of the current, and to the number of turns of the coil in a unit area, so that—

If n proportional to n C^2 $(a + bn + cn^2)$

and the efficiency—

$$P = \frac{1}{1 + \frac{S.R}{C^2}} = \frac{1}{1 + \frac{R}{n\,(a + bn + cn^2)}}.$$

The most important part of the action is such machines depends on the action of the two magnetic cores one upon another. The reactions between the fixed and the movable cores produce great disturbance, in consequence of the cores not taking up their full magnetism instantly, but requiring time for their full magnetisation. In consequence of this, in all dynamo-electric machines, it is necessary to allow the rotation to go on through an angle determined by the retardation of the magnetism of the cores, before the reversal of the current from the coils is to take place, and, moreover, in order to get the greatest current, the springs for making contact with it coils came to be shifted round in the direction in which the rotation is taking place. Faraday attributed this retardation to the time required to develop the molecular currents in the magnetic cores.

Alternate Current Magneto-Machines.

Alternate-current machines, there is no commutator for making the current continuous; but the current from the coil are collected and sent through the external resistance in opposite directions, as in Fig. 4. In the Siemens' machine, a section of these was the "Alliance" magneto-electric machine, which has been adopted by the French Government for lighthouse illumination. Holmes converted this into a continuous current machine, by means of a commutator, which is, in fact, a divided ring, on a portion of which the lighting, like armature. He subsequently removed this commutator, and again converted it into an alternate-current machine.

The four methods of placing the coils on the revolving wheel, in machines for electric lighting, which have been adopted by Siemens, Wallmark, have been named by Mr. Hedges—

1. In Siemens' magneto-electric machine, the coils are wound transversely, with their axes parallel to the axis of rotation around the circumference of the wheel.

2. In Siemens' machine, the wires are longitudinal, and remain about the long axis of the piece on which they are wound.

3. In Siemens' machine, the wires form a belt round a drum.

4. In the De Meritens machine, the wires are wound as in the Siemens, but are divided into separate parts, which are insulated from one another, and passing in succession in front of opposite poles of magnets, give off alternate currents.

The Siemens' Alternate-Current Machine.

A cast-iron disc-ring bobbin is set at right angles to a shaft, and revolves between two sets of electro-magnets, which are set at right angles to the disc, having their axes parallel to the shaft. The bobbins have no iron cores, and so the heating caused by magnetisation and demagnetisation of the iron is avoided. The electro-magnets are excited by a small Siemens continuous-current machine.

This is similar to Wilde's dynamo-electric machine, which he produced in 1866, except that in the coils on his cast-iron disc Wilde placed soft iron cores, and arranged them so as to form eight groups of four each. The current from one of these groups reacted on the succeeding group, and the other groups strengthened or set the current for each group. In Wilde's more recent alternate-current machines, arranged so as to be excited by a separate continuous current machine, there is one which has lately been invented by M. Gramme, in which the bobbin of the continuous-current machine is replaced by a ring, which is wound in two sets with the relative armature which have the alternate currents, so that the two turn with the same velocity, and the continual machine run at the same rate. This is much simpler than having two machines, and it is called a self-acting machine.

In the machine which I have already explained, the greatest amount of effective work or yield obtained from an alternate-current machine, when the lamps are in series, is no more than 50 per cent. of the electrical work given out by the first machine.

Result of M. Mascart and M. Jamin's Experiments.

M. Jamin has found that, in the Alliance machine for electric light and giving alternate currents, the strength of current can be calculated from the law, established for electromotive force, as proportional to the velocity, but replacing the resistance of the coils by the total resistance of eight times as great. The resistance to be added is proportional to the velocity of the machine.

M. Mascart determinations of the efficiency of machines are complicated by the retardation of magnetisation of the magnets, which accounts for the change of position of the commutator for the direction of the current in the armature. If this change be not made, then it would be possible, as in the bobbin in which the wire resistance was high, to get currents in opposite directions when the coil is rotated at different rates. For slow rotation, the galvanometer reading is nearly proportional to the velocity of rotation, but reaches a maximum, and beyond that diminishes rapidly to

THE ELECTRIC LIGHT.

HOW SHALL THE WIRES BE TAKEN CARE OF?

The Question Discussed before the Senate Judiciary Committee—An Interesting Report from Experiments with an Underground Current.

The Senate Judiciary Committee gave a hearing, yesterday afternoon, upon the bill declaring that wires through which dangerous currents of electricity are conducted shall not be maintained above the surface of the ground, and upon that with the written consent of the owners of the land over which the wires are erected. There were about twenty-five gentlemen present, including representatives of at least four of the leading systems of electric lighting, viz. the Edison, the Westen, the Brush and the Ansonia. The proceedings developed some interesting information in relation to the subject of electric lighting.

Hosmer Jordan, Esq., of Fall River, spoke for the Edison light, first addressed the committee. After the introduction of the bill, he said:

The following article from an address of Sir William Thompson, as President of the Physical Society of London, on the subject of lighting alone, will be found quite explicit as to the conditions to be asserted into a house or shop or other place where safeguards against accident cannot be made absolutely and forever certain, and which I think will be found to be the most reliable and safe guide for an expert to meet such by Mr. Clarke, electrical engineer:

"It is, therefore, the duty of every engineer who undertakes the distribution of electricity for any purpose to make it his study to use the electricity at the disposal of wires in be used for electric lighting.

"Let it be known that no one may use the first heating better coal connection, or transformer, or lamp, or other apparatus, or method of application of electricity, without first submitting it to a skilled electrical engineer. The engineer should be required to report in writing that the electricity used at the time of said testing was safe, and that the apparatus and method of using it were such as to render accidents unlikely to happen, and that proper precautions, by means of fuses or otherwise, were taken to prevent danger. A brief description of the apparatus, the precautions taken, and the conditions of the test should be recorded in writing. The engineer should be required to certify that the apparatus was constructed and the wires laid down in accordance with the rules of the Board, and every facility be properly conducting the test. The engineer will continue to be responsible.

Two Brush dynamos each running a circuit of 50 lights, and a Thomson-Houston dynamo of 100 lights, are now contained in the same vessel. There are six fuses were therefore in the circuit, and the current was about 10 amperes. The maximum electrical pressure developed between the terminals of the dynamos was 1,000 volts. The electrical pressure between the terminals of the lamps was about 100 volts. The electrical pressure between the terminals of the lamps was about 100 volts. The electrical pressure between the terminals of the lamps was about 100

THE METROPOLITAN.

MARCH 25, 1882.

Gas, Water, and Electricity.

Domestic Electric Lighting.—It has always been fully accepted by us as a condition of the success of the electric light for ordinary domestic purposes that it must be brought to our houses in the same way as gas is now supplied, and further, we have at all times conceded that the cost of the light must not materially exceed that which the public have hitherto been accustomed to pay for other artificial illumination. That these facilities for obtaining the light would sooner or later be afforded the public has been only too plainly evident for some three or four years past, and even their parties are prepared to undertake the supply of the electric light on the conditions above specified as indispensable. A very practical illustration of what is now being actually done in this respect is afforded by the installation nearly completed by Mr. Edison's representative on the Holborn Viaduct, where a central station has been established, and arrangements completed for lighting therefrom the public roadway, the City Temple, the Viaduct Hotel Restaurant, a portion of the General Post Office, and a number of shops and warehouses in the immediate vicinity. The electric current is supplied to all these places in a manner exactly analogous to the mode of gas supply, and possibly by the time these lines appear in print the installation will will prove of even greater interest to ordinary householders is that issued by the Domestic Electric Lighting Company whose exhibit at the Crystal Palace, consisting of a very handsome suite of rooms lighted electrically, has been so universally admired. The company is prepared to give estimates for and to undertake the supply of the whole of the machinery, lamps, and connections necessary for the complete installation and working of the electric light for domestic and practical uses. The directors do not bind themselves to any particular system, but only undertake that everything requisite for the successful and economical production of light and power in the simplest, safest, and best manner shall be installed. The installation of the electric light in private houses, and for domestic and practical purposes, forms indeed the chief objects of the company. Whenever sufficient subscribers are found a lighting-station will be set up, and the price to be charged will be at the same, or nearly the same, rate as gas. Therefore any ten or twenty persons who are neighbours can shortly leave the electric light substituted for gas or oil with a much greater illumination, and without those discomforts and inconveniences so frequently experienced where gas is used. The application of incandescent lamps and electric motive power to public streets, clubs, hotels, theatres, concert rooms, workshops, and other public and semi-public places; and the erection and supply of arc-lights for streets, squares, docks, and all open-air positions form a separate branch of the undertaking. As stated above, the directors do not bind themselves to any particular system, but the installation at the Palace (which has already been fully described in these columns) is based upon that of Mr. Edison's, by which not only is there absolute security against risk of fire, but the utmost simplicity and economy are attained. Indeed the entire absence of any danger from fire is a feature of this system, and it is accompanied by an exceedingly simple means of detection, which consists in a piece of lead wire that is included in every branch or circuit is what is termed a protector block, which contains a piece of lead wire that is comparatively easily fused. The current traverses this wire, and if, from any cause, the current becomes too strong, and likely to create heat to an undesirable or dangerous extent, the small piece of wire is fused, the circuit is broken, and the lamps are extinguished.—attention being thereby called, in a very practical manner, to the fact that something is wrong. A new block or plug can be at once screwed in, and the cause of the undue heat having been ascertained, the lamp may be immediately lighted again. It need scarcely be pointed out, however, that after the first day or two of the introduction of the lights into a house, the utility of this system of protection would be very rarely demonstrated in so practical a manner. The current would be adjusted to the requirements of the household, and any "short circuiting" of the wires would be provided against, but the inhabitants would derive confidence from the fact that the in the event of anything unforseen occurring. Most unquestionably the electric light has been brought within the region of practical domestics, and we need scarcely add that we shall watch with considerable interest the progress of any organisation established to promote its use for domestic purposes.

Rogers's Electric Light.—A number of gentlemen interested in the subject of electric lighting assembled on Wednesday afternoon at the works of Mr. J. B. Rogers on the Holborn Viaduct to witness a further series of experiments with that gentleman's system of dividing and subdividing the electric current. In February last Mr. Rogers explained to a somewhat similar company the main features of his system demonstrating its utility for ordinary interior lighting in a very practical manner, and on that occasion we described the principle by which the division of the current is secured. On Wednesday, however, the arrangements were of a much more extensive character, over a hundred incandescent lamps being shown in various parts of the buildings, and in place of the Otto gas engine formerly employed a 7 horse power of Easton's improved horizontal engines has been provided, and appeared to work admirable. In the course of the past few weeks Mr. Rogers has also invented a lamp of his own, which was the only kind used for the purposes of the recent display. The application of the light to ordinary indoor purposes was very satisfactorily shown, and in respect of the distribution of the current Mr. Rogers's method undoubtedly possesses several distinctive features. Of his lamps we shall probably have occasion to speak at greater length on another occasion.

The Electric Light at the City Temple.—The City Temple was lighted throughout by Edison's electric light for the first time on Sunday evening. During the whole service the lights were perfectly clear and steady, and the result of the lighting was regarded as entirely satisfactory. The sermon was preached to a congregation that crowded every available inch of room, and the temperature was ten degrees lower than that registered the previous Sunday. The lighting of this large building, we may remind our readers, forms part of a very much larger installation, now nearly completed, on the Holborn Viaduct, a full description of which will appear in these columns, probably next week.

Engineer, Mechanic & World of Science. Mar 24/82.

DOMESTIC ELECTRIC LIGHTING.

A LECTURE on electric incandescent lamps suitable for domestic lighting was delivered on the 20th inst. at the Crystal Palace, by Professor Silvanus P. Thompson, of the University College, Bristol. So far back as 1841 the principal had been made to construct little electric lamps, in which platinum wire was the thin wire of resistance or thin strip of carbon, which on the passage of an electric current became incandescent. This method of obtaining light from electricity by incandescence was revived in 1878 by Mr. Edison, who at first attempted to construct platinum lamps, which, however, in spite of many ingenious contrivances for preventing the burnt wire overheating, could not be kept from fusing etc. Eventually Edison settled upon a filament of carbon. The carbon filament was prepared and has made by Mr. Swan, of Newcastle. Edison prepared his filaments of cotton thread, Swan from cotton thread. In each case the carbonised fibre was fixed in a small platinum holder, and exhausted as perfectly by mercurial air by a mercurial air-pump. A filament of carbon, however, is very brittle and elastic as steel. Such a fibre had been constructed by Lane-Fox and Sir Henry Bessemer, the difference of detail in the manufacture. These little lamps gave a light of about equal brightness to a candle-light gas-jet. They were described as a revolution in domestic lighting, since, when supplied by means from a central station, they would not only be cheaper than gas, but would be far more readily controlled and regulated. There was no inflammable or noxious products of combustion produced, very little heat, and there was no risk of explosion. The incandescent lamp lent itself to use with extraordinary facility to the requirements of rooms, and would shortly, he believed, become the fashionable mode of lighting. The experience of the working of the system showed that it was practicable to apply them to a large building. The public safety depended that no lamp should be used making electric lighting inoperative in all public buildings. It might also be made compulsory to use electric lamps in coal mines. In a few days the experiment would be tried of lighting the Holborn Viaduct and surrounding houses by Edison's lamps from a central station. This would be but a small sample of the manner in which domestic electric lighting could be carried out on a large scale. The lecturer predicted for this method of lighting results far more important and widereaching than those which any other kind of electric lighting could possibly attain.

Nature May 27th 1884

THE MAXIM SYSTEM OF ELECTRIC LIGHTING BY INCANDESCENCE.

LAST night an interesting demonstration of the Maxim System of Electric Lighting by incandescence took place before a crowded meeting of political, financial, and scientific gentlemen, at the Albany Works, 374, Euston-road, under the auspices of Mr. St. de Rakuch, of New York.

The premises, which are very spacious, consist of two houses of four and six stories respectively.

At the back of the ground floor a 20-horse power nominal engine, supplied by the firm of Messrs. Ransomes, Head, and Jefferies, of the Orwell Works, Ipswich, and exactly similar to the engine which has been driving the electric lights on the Thames Embankment for the last two and a half years past, and of the same firm, was driving, directly and by means of intermediate shafting, a group of three machines.

The arrangements were at first pleasant only for the two machines which are driven direct from the engine, and it is only recently that, a second large machine having just arrived from the United States, it has been decided to add it to the one already working during the interval of the present month, and drive it from a countershaft; the number of lights having, at the same time, been correspondingly increased.

It is, however, contemplated before this Exhibition is over (and the whole of the plant is intended for the Electrical Exhibition which is to be held in Paris at the beginning of August) to still add more machinery and electric plant. Some forty are light regulators, and the machines for working them, both on the Maxim and Weston systems, being on their way from New York for that purpose.

The Maxim system of incandescent lighting which is now successfully and very extensively adopted in the United States of America, and which was exhibited on the occasion referred to as follows :—

A small dynamo-electric machine running at about 800 revolutions per minute, generates a current of electricity, which is caused to circulate in the electro-magnets of a large similar machine, exciting therefore the magnetic field of the latter with which it is thus connected.

The small machine is provided with an extremely ingenious device for controlling the supply of electricity, and regulating the current in order to suit, and accordingly to the number of lights which may be burning. This machine is called the Maxim regulator, and it gives a current of it, it may be said that the brushes collecting the current, generated by the exciter, together with the brush holders, are made to swing round the axis of the machine, and are automatically set to any position between the maximum and the neutral points.

Two pairs of electro-magnets at the top receive a proportion of the currents of the large and small machines respectively, one pair operating the regulating movement, and the other a shunt which will be hereafter described. The regulator is operated by means of an armature attracted with forces varying according to the number of lights in circuit. When the supply of current becomes insufficient by more lamps being turned on, the armature being released in one direction, and attracted in the opposite one by means of an antagonistic spring, a pawl which is suspended from this armature, causes the brush holders to revolve through an intermediate system of gearing being brought into play, thus supplying a greater volume of current.

The opposite phenomenon takes place when the current becomes too great owing to the removal of a certain number of lamps from the circuit.

The delicacy of the working of this regulator is such that—as was illustrated by Mr. Lockwood —the current supply is automatically, immediately, and effectively controlled, either when a large number of lights are in circuit or whe there only remains one.

The other pair of electro-magnets are so connected and adjusted that they only act upon their armature when a large increase of the current passing through them takes place, such as would be the case should a main wire happen to accidentally break, or any other accident occur; in such a case this armature is strongly attracted, and overcoming the tension of its antagonistic spring, brings its free end in contact with a platinum point, thereby cutting out of circuit the field magnets of the exciting machine, and completely stopping the generation of current until the accident shall have been remedied. This forms a perfect safeguard against any possible injury being done either to the machine or lamps.

The large machine is composed of two distinct parts built into one on the same frame and spindle; they are coupled together, and an ingenious and simple contrivance is provided at the top of the machine, and by means of which the currents supplied by each of the two distinct machines can instantly be disconnected or coupled either in quantity or tension, according to the requirements of the case.

The machine runs at about 900 revolutions per minute. The regulator can be used to regulate and control from one to six of the large machines.

Both machines are of a very highly finished workmanship, and resemble in their external appearance Siemens's dynamo machine.

They have been very carefully studied in all their details, and many of their parts, such as the commutators, the sections of which are made out in the shape of a very elongated or widely open letter V, instead of being in a straight line

DAILY NEWS.

Mr. J. W. Swan, the well-known electrician, lectured on the above subject last evening at the Royal Institution, directing his remarks chiefly to the mode of lighting known as the "incandescent." He said that the first step in the practical realization of the incandescence of incandescent electric lamps had been accidental, and that their use was commercially possible only after they had experienced that continuous heating to a fairly high degree of incandescence during 1,000 hours did not destroy a well-made lamp. What the utmost limit of a lamp's life might be they had not yet found out. They had, however, obtained by means of long experience, processes of manufacture by which they were to believe more and more perfect. Turning to theories, as fully established fact a change and durable lamp could now be made, the further question was as to the cost of the means of its illumination. The cost of producing light by means of electricity was made up of the cost of the steam power and producing machinery in the way: 2 cwt. of coal produced 1,000 cubic feet of gas, and this quantity of gas of the quality called fifteen-candle gas, would produce 8,000 candle light for one hour. But besides the product of gas, the coal yielded certain by-products of almost equal value with the gas itself. Example, 2 cwt. of coal had, in effect, 1,000 cubic feet of gas, one cwt. of tar instead of two, as erroneously the case. The one cwt. of coal would give fifty ounces power for one hour. Dowsell and Siddons experiments showed that they would obtain through the medium of formaldehyde 1,000 candle-light for one hour from one penny's worth. But to those who thought the system practicable however into electricity, and also to the consulting users, to make a fixed allowance of 10 per cent., and took only 750 candle-light as the unit available product of one horse power. For fifty horse power, the produce of 2 cwt. of coal, they had then 7,500 candle-light. Now, 7,500 candle-light for one hour, 1,000 feet of gas would be required, and, instead of the illuminant of light which the gas from the same quantity of coal was capable of producing. There remained, however, an allowance to be made to cover the cost of the interest of capital. There was a parallel expense in connection with gas lighting in the cost of the maintenance of burners, globes, chimneys, &c. But it would be seen that even if the cost for renewal of lamps should prove somewhat more than the corresponding expense in the case of gas, there was a wide margin to meet it. In short, they had reached the limit of the cost of gas lighting, as he thought, too, it might be fairly placed to the credit of electric lighting that the cost of the renewal of lamps would be no evidence for finality in the hand distribution of lessons, to books, pictures, and to speak. In short, without the least trouble, and by the use of coal which entailed a large expenditure for repair, and things almost out of the question impossible. In comparison with a penetrating light by gas and by electricity, he had no hesitation in saying that the latter was as well cheap. Gas lighting was certainly cheaper than coal—electric lighting was not; but in all probability coal would be used in the same sense of energy in the case of electric lighting also. When, however, water power was available, electric lighting was in a position of still greater economy, and on this point of coal altogether formed competition with electric lighting. Even with water power, the cost of plant, there would be a very even balance in the two cases. In a hamerick they had patents and furnace, providing cleaning and engineers, engine, boilers, and appliances for distilling and condensing purposes. That for generating electricity as much as it would consist principally of boilers, steam engines, and dynamo machines, and storage batteries for example. Dowsell electrical station, on the scale he was supposing, had yet been put into actual operation, but seven small stations for the manufacture of coal—lighty already existed in England, and those large in America. They were therefore even on the point of nevertheless by actual experience what was the cost of plant for generating electricity would be. Meanwhile there would necessary the cost of boilers and engines, and what ought to be the cost of dynamo-electric machines of suitable large size. There was consequently sufficient data for a reasonable estimate to be made of the probability of light electrically the cost of plant would not exceed greatly, if at all, the cost of gas-making plant. Then remained the cost of distributing electric

Scientific Am. April 15. 1882.

Electrical Capacities of Heated Bodies.

It is well known that a burning match or a gas flame acts as a discharger of electricity, and the fact has been applied by Sir William Thomson in his proximable electrometer in observing the potential of the atmosphere at any point Recent experiments of Professor Guthrie, F.R.S., have shown that an incandescent platinum wire also acts as a discharger of electricity, and displays a preference for discharging a negative rather than positive charge. If a platinum wire, made incandescent by an electric current, is placed between two gold leaf electroscopes, one charged with positive and the other with negative electricity, it will be found that the negative charge is rapidly drawn off, while the positive charge remains almost unaffected. The wire in this experiment was at a dull red heat; and it is probable that a higher temperature would also have affected the discharge of the positive electricity. Professor Guthrie further shows that a red-hot metal ball at certain high temperatures will not accept a charge of positive or negative electricity from the conductors of a glass electrical machine; while at certain lower temperatures it will accept a negative charge, but not a positive one, and at still lower temperatures it will take both a positive and negative charge.

SUNDAY HERALD
FEBRUARY 26, 1882.

To the Editor of the Herald: In the leading editorials published in to-day's issue of your paper, under the head of "Electric Dangers," you have made the subject of danger likely to arise to lives and property by the running of electric light wires over the roofs of houses or on poles along the streets. This is certainly true in all are systems, as has been demonstrated in a number of occasions in different parts of the city. But there is one system of overhead

106

American Mechanic April 8, 1882.

Regulations for the Use of Electric Lighting Apparatus.

The following specific regulations have been prepared for the use of the Boston Manufacturers' Mutual Fire Insurance Company by the Inspectors of that company, C. J. H. Woodbury and W. H. H. Whiting:

DYNAMO MACHINES.

Dynamo machines should be located in dry places, not exposed to dyings or easily combustible material, and insulated upon wood foundations. They must be provided with devices capable of controlling any changes in the quantity of the current; and, if these governors are not automatic, a competent person must be in attendance near the machine whenever it is in operation.

Each machine should be used with complete wire circuit, and connection of wires with pipes, or the use of ground circuits in any other method is absolutely prohibited.

The whole system should be kept insulated, and tested every day for ground connections at ample time before lighting, so to remedy faults of insulation, if any are discovered.

Preference is given for switches constructed with a lapping connection, so that no electric arc can be formed at the switch when it is changed; otherwise the stands of switches, where powerful currents are used, should be made of stoneware, glass, slate, or some incombustible substance, which will withstand the heat of the arc when the switch is changed.

WIRES.

Any conducting wire which is warm to the touch, in comparison with another wire, is liable to become a source of danger, and should be replaced by a larger wire. Conducting wires should be secured to insulating fastenings, and covered by an insulation which is waterproof on the outside. Wires—or wires pass through walls, roof, floors or partitions, or where there is a liability to abrasion, or exposure to rats or mice, the insulation should be protected with lead, hard rubber, stoneware, or some other satisfactory material.

Joints in wires should be securely made and wrapped; soldered joints are desirable, but not essential.

Wires should not approach each other nearer than one foot, and twice that distance is preferable in conducting electricity of high tension. Care should be taken that wires are not placed above each other in such a manner that water would be liable to make a cross connection.

The ends of a broken wire should be everywhere provided against by securing the wires on suitable insulators; avoiding danger from an accumulation of lint, by placing them one-eighth to one-quarter of an inch from the walls, ceilings or beams, except where necessary to lead to the lamps, and in all cases avoiding loops of wire, or leading it across the space from beam to beam.*

A cut-out should be placed in the circuit outside of each building, in a well-protected and accessible place.

ARC LAMPS.

The lamp frames and other exposed parts of lamps should be insulated from the cir

*It is important that wires parallel to each other, one above another, upon the same surface of wood, should be avoided in buildings constructed like those insured by this Company, for the reason that water used in washing floors, and water condensing upon walls in blasteries, dye works, paper mills, or petst works, may trickle down from one wire to another, thus making the conditions upon which a cross are may be formed. This danger would be greater from acid or alkaline water decomposing the insulating covering. It would therefore be preferable that all wires to arc lamps should be carried on one surface, and the wires from the lamps upon another; this mode may require a little more wire.

Perhaps the best method would be to keep the main wires upon the walls of the mill, and where they are carried to and from lamps, to place the wire to the lamp upon one beam, and the wire from the lamp upon the next one.

These suggestions are put in the form of a note to the Regulations, because the circumstances vary in different mills, or works, but managers can apply the reasoning on which these suggestions are based, to their respective conditions.

cuit. Each lamp should be provided with a separate hand switch, and also with an automatic switch, which will close the circuit, and put the lamp out whenever the carbons do not approach each other, or the resistance of the lamp becomes excessive from any cause.

The light should be surrounded by a globe, and, when near combustible material, this globe should be protected by a wire netting. The globe should rest on a tight shoal, so that no particles of melted copper or unconsumed carbon can escape. Broken or cracked globes should be replaced immediately. Unless the globe is very high, and closes in as far as possible at the top, it should be covered by some protector, reaching to a safe distance above the light. Flat sheets of metal or wire gauze should not be used for this purpose, because filings will collect upon such places when the lamps are not in use.

The lamps should be provided with some arrangement or device to prevent the incandescens from falling out, in case the clamp should not hold them securely.

INCANDESCENT LAMPS.

The small wires leading to each lamp from the main wires should be very perfectly insulated, and, if separated or broken, no attempt should be made to join them while the current is in the main wires.

The conducting wires leading to each building should be provided with an automatic switch or cut-out, or its equivalent, capable of protecting the system from an excessive current of electricity.

Evening Post, Saturday, 7.11.81.

WHAT ELECTRIC LIGHT COSTS.

Statistics and Comparisons Regarding the Arc Lights and Incandescent Lamps Prepared by Prof. R. P. Thompson.

In view of the recent competitive bidcasts by the gas and electric light companies for lighting certain streets in the city below Thirty-fourth street, the following extracts from a paper recently prepared by Professor Thompson, professor of experimental physics in University College, London, on the comparative cost of arc and incandescent electric with gas lighting will be found of unusual importance and interest. The practical business man, says Professor Thompson, sees that the light is a good one for himself, but the question always recurs, What does it cost? Will it pay? The questions, he says, are difficult ones to answer accurately, as data, especially regarding incandescent lighting, are yet meagre, and the improvements being made daily make the cost for to-morrow less than it is to-day, but how much less cannot be stated immediately. Lighting by the arc, he says, is undoubtedly much cheaper than gas, although the difference is not very apparent in some of the bids now under consideration of the city authorities. The following shows the relative cost of gas and the Lieb light in London, with Brockie-Pell Regulators, which the British light has been in use for two years.

Allowing 5 per cent. for interest on the plant and another 5 per cent. for wear and tear, the cost per hour per lamp is 2.08. The cost of running the lights, including coal, carbons, oil, cotton, labor, and incidentals, is 1.25 per hour. Cost per hour, 27.33 the light. A good deal depends on the price of gas, as per cubic foot. The total cost of gas lights consumed in this same room were as follows, allowing a saving of, approximately, 25 per cent. for interest, wear and tear, and depreciation of fittings, which is the usual allowance made for the latter item in estimating a saving of approximately 25 per cent., or 10 per cent. of the former 2.08 per hour, 1.25 per hour, 27.33 per hour. The cost of the regular candle per hour of the incandescent system is 1.66, or 10 per cent. of the former 2.08 per hour, 1.25 per hour, 27.33 per hour. The cost of mechanical power differs enormously, according to individual circumstances and the scale on which the power is used. Under the best conditions 1 pounds of coal are consumed per horse-power per hour. Under this rule 6 pounds of coal will produce a light of 1,374 candles per pound of coal per hour. Mr. Thompson continues:

Compare this with gas. Since a ton of coal yields 10,000 cubic feet of gas, and since 1 pound of coal produces 1,374 candles per hour of gas; and supposing that with a good burner 5 cubic feet of gas are used per hour, it follows that 5 pounds of coal are used per hour, which is equivalent to 6.41 of gas, and gives a light of 1,374 candles per hour. The latter is equivalent to 274 candles per cubic foot of gas; but since only one foot of gas is exchanged for one candle in the case of the Sugg burner, which is a very good burner, it follows that the economy represented by the usual 16 candles as the light of a burner using 5 cubic feet per hour is equivalent to a consumption of only 80 candles per cubic foot of gas. Hence, 480 lights as cheap as by gas. The items of capital and current, apart from the steam engine, are: Electrical machinery, renews this immense margin to the benefit we have assumed in the previous minutes.

In regard to the Edison, Maxim, Swan and Lane-Fox incandescent lamps, Mr. Thompson says each lamp gives a light of from 16 to 20 candles, and for purposes of comparison he supposes that it replaces gas, light for light. The Edison lamp furnishes 125 candles (20 lamps) per horse-power, "much less than the arc lamp, but still a good result." The same number of gas-jets would consume 4,000 cubic feet, costing twenty-one cents per hour. The same amount of gas in a gas-engine would supply power for 20 lamps at a cost of 2.5 cents's light as it would give of gas-light. By steam the same light would be produced at one-sixth of a penny instead of twopence.

107

THE JOURNAL OF GAS LIGHTING, WATER-SUPPLY, & SANITARY IMPROVEMENT. (Feb. 14, 1882.

THE VALUE OF ELECTRIC LIGHTS.

There is so much uncertainty about the illuminating power of electric lights, and the methods by which this power is to be ascertained is so undetermined, that some interest has been excited in a paper on these subjects by Dr. Ingal Higgs, which was read at the Institution of Civil Engineers on Tuesday last. The writer endeavoured to prove the existence of a relation between the illuminating power of an electric light and the heat developed by the resistance of the carbon or other electrodes which are used for the purpose. He stated that with different types of arc lights this ratio might be expressed as about 0·12 heat unit per candle power. A Maxim lamp gave 0·62 heat unit per candle power; and an Edison lamp, giving 11-candle power, developed 0·70 heat unit per candle. The author concluded that theoretically the incandescent was more costly than the arc lighting, in the proportion of 6 : 1. It was also assumed in the course of the paper that the average amount of light required for domestic purposes was equivalent to that of a standard candle at 1 foot distance. Assuming an average distance of 8 feet for domestic lighting, the electric shandelier would have to be of 64-candle power to give the same surface intensity of light in a room 16 feet square, and of slightly more than this ordinary height. The incandescent lamp would give this light at an expenditure of 0·6 unit per candle power, or 38·4 heat units per light-centre, or about four shandaliers of this size per horse power. Dr. Higgs values the equivalent light from a 4-light gas chandelier burning 20 cubic feet per hour of New York gas, costing 10s. per 1000 cubic feet, and calculates that the cost of a horse power of energy would be 0·45 cents per hour in the electric chandelier, while the gas as above would cost 5 cents. It would perhaps have been better, considering that the paper was intended for an English audience, if the author had taken, as his unit of photometric measurement, the light of the standard candle, instead of the foot candle, which is almost unknown in London instead of in New York. In this event the comparison works out differently.

New Electrical Regulator.

M. Saligney, one of the most active electricians of Paris, has discovered a new regulator which will be one of the curiosities of the next electrical soirée given at the Observatoire on March 18th. Each of the two carbons is supplied with a parallel rod of glass, to which it is attached in a solid manner. These two rods being placed horizontally, are pushed by a spring, and the spark is lighted between them. But between the two glass rods there is a glass stopper which is warmed by the light in such proportion that the rods yield gradually to the pressure of the springs, and the carbons can approach each other as is required for the consumpt of the combustion. A correspondent of *Nature* witnessed preliminary experiments which he states have been a wonderful success.

Electric Light in Hall Cars.

Recently the Brighton (Eng.) Railway Company introduced the electric light on a special train of Pullman cars. Thirty-two Faure secondary batteries were employed to the car, to operate a dozen 8-candle lamps. The illumination was said to have been satisfactory.

The regular meeting of the Association was held Thursday evening, Dec. 15, Mr. Stetson presiding.

LIABILITY OF FIRE FROM ELECTRIC LIGHT.

Mr. Keith read the rules lately put in force by the Board of Underwriters of New York City, in regard to the manner of putting in electric light apparatus to buildings in that city, to avoid danger from fire. The rules go to an extreme of caution. Mr. Keith explained that the electric light companies already largely exceed the required conductivity, 98 per cent. excess. The smallest, even with the arc system, is No. 8 wire. It conducts the current without being appreciably raised in temperature. Heat is generated in a conductor when it is too small to carry the current freely. No. 16 is large enough; it will only raise the temperature to about 118° Fah. With the incandescent system most companies use larger wire, up to No. 3. These wires are a fourth of a square inch in section. The electric resistance of a small wire absorbs and wastes power which otherwise would drive rapid as light at the lamps.

The case was analogous to passing water through pipes; a small pipe requires more head, or force, to cause the passage of a given quantity of steam, or any fluid, in a given time, and the working pressure at the delivery end is reduced by the wire-drawing.

Mr. Keith averred that the brick, or plaster walls and ceilings of a building are not conditions as regards insulating substance which can be put around the wires. Dry wood is nearly as quite as good.

He thought there was no advantage worth considering in an insulating covering for wires on the ceilings; but such was important in places upon the floors or walls where there is a liability of some conducting substance touching both the inlet and outlet wires.

Where the positive and negative wires run near together they should be well covered by some non-conducting substance, which will absolutely prevent accidental contact with both at one time. The rules were aimed on that.

There is not a particle of danger in touching one wire with any substance or any place. All thought the practice of returning the current by the earth, or connections to water or gas pipes, should be absolutely prohibited. Doing so makes all conducting substances in connection with the earth a return conductor.

A MINIATURE ELECTRIC LAMP.

Five-Hundred-Candle Power in the Area of a Half Dime.

Mr. Edison has just completed and transmitted to Prof. F. G. Fairfield of the New York College of Veterinary Surgeons a new electric lamp which is the smallest and most powerful ever made. The cylinder, or carbon pencil, we only one-tenth of an inch in diameter, the object being to obtain the highest attainable incandescence within the smallest possible space. It requires a battery of about forty cells. The flame will not exceed the dimensions of a silver five-cent piece, but it will give a light of 500 candles, or about the power of 100 candles. The resistance was relatively higher than a 1000, and the electricity was allowed to flow through the lamp with a pressure of 100 volts. Another fine element of their subtle force each object possessed was made to disappear as a substance when incandescent, such the heavy elements that of course a power of 50,000 diameters. At such a power only a few molecules of platinum would be visible, and they appeared as a cloud. Certainly the invention of Edison matter to be called a vacuum of an inch in diameter, and the lamp is a success with the help of the Sprengel pump. Mr. Edison will have a private exhibition of his new lamp at his laboratory in Menlo Park, and by this afternoon showing the molecular condition of platinum before the camera.

Mr. Thompson says that details as to the working of the electric lighting system are still wanting, and that his experience in lighting 800 houses in this city with the Sawyer-Man lamp will be watched with deep interest. Mr. Thompson concludes:

For the present it is safe to assert that even a country house to be lit up by incandescent electric lamps supplied by currents generated on the spot, as gas is now so commonly generated, in a little building in the yard, will be lighted at a cost, in most towns, less than the existing rental given for current gas lighting. And if domestic electric lighting can be made cheaper than gas lighting, public gas lighting on the small scale, there remains to be proven why on the large scale, with a vitrea tion of the expensive gas-manufacturing establishment, lighting should not be accomplished more cheaply by electricity than by gas.

Menlo Park Scrapbook, Cat. 1038

No. 24. "Thermo Electricity"

This scrapbook covers the years 1875-1881 and 1887-1889 and contains clippings about thermoelectricity. On pages 8-61 are clippings from technical journals, covering the years 1875-1881. Pages 63-77 contain clippings from newspapers (1887-1889), describing Edison's pyromagnetic generator for producing electricity directly from coal. Page 62 contains a copy of Edison's paper on this device, which was read before the American Association for the Advancement of Science and published in the Telegraphic Journal and Electrical Review, September 9, 1887. There are 140 numbered pages.

Blank pages not filmed: 2-7, 58-59, 78-140.

On the Thermo-Electric Properties of Lime Spar, Beryl, Idocrase, and Apophyllite. By M. HANKEL.

When a heated crystal is cooled, it presents at its surface an electric distribution variable with the form of crystal. When it has the hemihedry of tourmaline, the two ends of the same axis are charged with different electricities. Apart from this case, the two ends of the same axis have identical properties, but the ends of different axes may be charged with opposite electricities. In particular, in crystals belonging to the system of prism with square base, the faces parallel to the axis of symmetry are not charged with the same electricity as normal or inclined faces limiting the crystal. Two classes of these crystals may be distinguished, according as the positive electricity is carried to the extremities of the axis or to its lateral faces. To the first class belong:—1. Spars of Scheeberg and Fryberg, formed of a hexagonal prism limited by the primitive rhombohedron or one more obtuse. 2. The majority of emeralds. 3. Idocrases of Wilui (Siberia). 4. Apophyllite. On the other hand, very elongated scalenohedra of Derbyshire spar, emeralds of Elba, and idocrases of Alta, belong to the second.

MIC JOURNAL. [APRIL 1, 1876.

ON THE ALTERATION OF THE THERMAL CONDUCTIVITY OF IRON AND STEEL CAUSED BY MAGNETISM.

By HERBERT TOMLINSON, B.A., Demonstrator of Natural Philosophy, King's College, London.

THE writer has, for several months, been engaged on a set of experiments devised for the determination of the alteration of the electrical and thermal conductivity of iron and steel, with the intention of determining, in absolute measure, such alteration for a given strength of current and imparted magnetism. But as, before the complete determination of the data sufficient for the purpose, a considerable time must elapse, he would venture to offer to the Society, in a preliminary note, some results which have already been obtained by him, as regards the alteration of thermal conductivity produced by magnetism.

In these experiments, the apparatus chiefly employed to impart magnetism consisted of an electro-magnet, with soft iron cores, 1 inch in diameter, and five inches in length, surrounded by cotton-covered copper wire, $\frac{1}{20}$th of an inch in diameter, having a resistance of nearly 1 ohm, and a coil constructed as follows:—a thin tube of polished tin, 1¼ inch internal diameter and 4½ inches long, was covered with vulcanised caoutchouc to a thickness of $\frac{1}{16}$th of an inch, and on this was wound ½ lbs. of cotton-covered copper wire, $\frac{1}{20}$th of an inch diameter, followed by ½ lbs. of wire, $\frac{1}{16}$th of an inch in diameter. Inside the first tube was placed a second, 1 inch internal diameter, connected by ebonite with the first at the two ends, the second tube being concentric with the first, and of the same length, so that, between the inner tube and the outer, should be interposed a layer of air nearly $\frac{1}{16}$th of an inch in thickness. This arrangement was employed to prevent the heat from the magnetising coil reaching the bars placed inside; also, to prevent ingress or egress of heat; the bars used with the coil were covered with vulcanised caoutchouc, so that they lay with their axes coinciding with the axis of the coil.

To measure the heat conducted along the bars two sets of thermo-elements were constructed. The first was made up of two small strips of copper, ½ inch long and ¼ inch broad, of small thickness. To these was soldered about 1 foot of silk-covered german-silver wire $\frac{1}{20}$th of an inch in diameter, the copper strips being also connected with a galvanometer by copper wires, well covered with caoutchouc, one set of each being soldered to the copper strips, so that either one or both the copper strips with the soldered German-silver wires could be employed as a thermo-element. In case it was found convenient only to employ one of these, the other was kept well covered with soluloid. These elements will be called the G. S. elements. The second set consisted of two small thermo-piles, each of twelve elements, of antimony and bismuth, and were each fitted into india-rubber tubes, so that they could be inserted into small wooden boxes, containing water, so as to fit water-tight. Sometimes these, like the G. S. elements, were used separately; at others, were made to neutralise each other's effect on the galvanometer.

APRIL 1, 1876.] 9

To measure the current produced by these elements, a delicate Thomson's reflecting galvanometer, having a resistance of 2 ohms, was employed, the scale being placed 6 feet from the mirror of the needle.

To measure the strength of the magnetising current, a tangent galvanometer, of Gaugain's construction, was used. The needle was suspended by a very fine platinum wire, attached to a graduated torsion circle. The two thick copper wires which conveyed the current were each 27 centimetres in diameter and 14 inches apart. The needle was also provided with a mirror, so that small deflections could be read off as in a reflecting galvanometer.

A magnetometer was also employed to test the magnetising impulse, but, as the readings will not be given in this paper, no description of the instrument is necessary.

To heat one end of the bars two large Leslie's cubes were employed, having each two apertures projecting about 2 inches into the interior of the cubes. The apertures in one cube were 1 inch square and placed in one side of the cube, about 3 inches apart from each other, and half way up the side. In the other cube the apertures were circular, and 1 inch in diameter, and placed in the centres of opposite sides of the cube. Into these cubes bars of square and circular section were respectively inserted, and water filling the cubes was raised to 100° C.

The first experiment was made on a soft iron bar, ½ inch square, in section. The bar was inserted into the Leslie's cube with square aperture, filled with boiling water, and into the other aperture was inserted a brass bar of the same section. The length of the iron bar was about 10 inches, and of the brass one, 18 inches. One of the G. S. elements was fastened on to the iron bar, and the other to the brass, by caoutchouc bands, the elements being insulated from the bars by thin paper. The G. S. elements were made to very nearly counteract each others effect by sliding one or other of them up and down the bars until the heat conducted by the bars to the elements was in both the same as nearly as possible. Underneath the bar was placed the electro-magnet, with a piece of white cardboard lying on the upper extremities of the soft iron cores, so that the cores were about 3 millimetres from the iron bar; the bar was also prepared by a wooden support at the other end. A preliminary experiment had been made for the purpose of ascertaining whether the heat radiated from the electro-magnet would affect the thermo-elements to any appreciable extent, and this was not found to be the case.

The water in the cube was now kept boiling for about nine hours, and after that time had elapsed it was ascertained that the flow of heat from one part of the bars to another compensated the loss from radiation and the light on the scale remained stationary. (It should be observed that, as it was impossible to cause one thermo element exactly to neutralise the other, a slight use of the adjusting magnet of the galvanometer was made so being the light near the zero of the scale.) The current from a single bichromate cell was now sent through the coil of the electro-magnet. In a few moments the spot of light began to move very slowly across the scale in a direction indicating that the flow of heat through the iron bar was being checked, and in about fifteen minutes a deflection of about 25 divisions of the scale was obtained; the current of the cell was then stopped, when the light began slowly to return, and finally settled in apparently the exact position which it held before sending the current through the coil. This experiment was repeated several times on the same day, and on several other days, but always with the same result as regards direction, namely, showing a diminution of the flow of heat from longitudinal magnetisation.

As it was thought, however, that the electro-magnet might when in action perhaps produce an apparent diminution of flow of heat by slightly disturbing the bar in its position in the aperture, though every precaution had been used to prevent the chance of this, the bar in the next set of experiments was securely soldered into the cube, and again tested as before. Here, again, some five or six trials gave the same result, and seemed to show most conclusively that the thermal conductivity of soft iron is diminished by longitudinal magnetisation.

As the method of observation, however, was tedious, and would give no idea of the amount of alteration of conductivity, other expedients were now adopted.

A piece of soft iron, which we will call a c, ½ inch long, ½ inch broad, and 2 millimetres in thickness, was soldered to two pieces of brass, A B, C D of the same breadth and thickness.

A B was 2 inches long and c D, 1 inch. The piece A B was also soldered to another piece of brass a b, having a section ½ inch square, and length about twelve inches.

The whole was placed inside a wooden box, 2 feet long, 1 foot wide, and 2 feet high, lined on the outside with linfoil.

A B passed through a circular hole, 2 inches in diameter, in the middle of one end of the box, and through two corresponding circular holes in a double screen of sheet tin, and thence into one of the square apertures of one of the Leslie's cubes. The electro-magnet was placed underneath a c, and two pieces of soft iron, about 3½ inches in length, ½ inch in breadth, and about 2 millimetres in thickness, were placed on the ends of the soft iron cores, so as to be on the same level with a c, and distant from a and c about 2 millimetres, the pieces of iron being supported from the cores by a piece of white paper. In some experiments the pieces of iron first used were carefully secured to the electro-magnet by elastic straps, and, in others, by weights placed on them. A preliminary experiment, made with the strongest current that was ultimately used with the electro-magnet, showed that neither were the iron pieces on the cores appreciably shifted on magnetising the coil, nor was the heat radiated from the coil sufficient to produce any effect on one of the G. S. elements fastened by elastic bands to the back of C D. The other G. S. element was in this case buried in sawdust, with which the box was now filled, so as to cover completely the bars and electro-magnet. The sawdust also filled the space between A B and C D, and the small portion of the brass bar a b, which was between the box and the Leslie cube, was covered with caoutchouc and cotton wool.

The lid of the box was now put on, and some time

both high and low, with a view of definitely settling this point.

Some experiments were next made with the magnetizing coil described in the beginning of the paper, but the effects produced were found to be so much less for the hard steel than when the electromagnet was employed that it was found necessary to use the thermo-piles, also mentioned above, and instead of employing the compensating magnet to bring the light on to the scale to cause the two piles, as much as possible, to neutralise each other's effects. Accordingly the following arrangements were made:

Two bars of hard steel, each 3½ inches long and ½ inch in diameter, were soldered at each end to two copper rods, each about 4½ inches in length and ½ inch in diameter. One copper terminal of each rod was inserted into a Leslie's cube, filled with water kept at the boiling point by means of a burner at a distance of 2 inches, and the other terminal into a small wooden box, varnished inside with shellac, and capable of containing about 120 cubic centimetres of water. The bars were well covered with cuanstchouc; and double screens and two thermo elements were so arranged as to send their currents through the galvanometer in opposite directions, the wires connecting them with each other and the galvanometer being well covered with gutta-percha, and passing through small holes in the sides of the boxes. The two compound bars were thus made as exactly similar as possible, and also similarly placed, the only difference being that produced by the magnetizing coil, whose axis coincided with that of the steel bar placed inside it.

Both the small boxes had originally the same quantity of water placed in them, and a previous experiment had shown that so exactly similar was the heat conducted along the bars to the water in the boxes, that when some two hours or so had elapsed, the rise of temperature of the water in each box seemed as measured by an ordinary thermometer, marked off in degrees centrigide, to be exactly the same, namely, 10° C.

But as the same experiment had shown that the pile in one of the boxes was very slightly more powerful than the other, the water in the other box was diminished very carefully by means of a small siphon, formed of india-rubber tubing, of very small bore, which was kept cleared by a pin-hole cut at one end, the tube passing through holes cut in the large box, through the sawdust, and through a small hole cut in the lid of the small box, so as to dip into the water. The little siphon was always kept charged, and, by means of the pinch-cock, any desired small quantity of water could be extracted from the box.

By this means it was found easy to make one pile so neutralise the other that a very slight use (if any is necessary) of the adjusting magnet was required, even when the magnet was near its most sensitive position with respect to the galvanometer needle.

On sending a current through a coil around the steel bar, it was in a minute or so seen that the conductivity of the hard steel was diminished by the longitudinal magnetization, and the amount of diminution was roughly determined by finding the amount of water necessary to be extracted from the box to again bring the light to the same slow rate of motion (about two divisions per minute) which it had before passing the magnetising current, and comparing this with the original amount of water in the box. The decrease of flow did not amount to 1 per cent. of the whole, even with the strongest battery used (current shown by the tangent galvanometer, 25°).

This plan was found to be highly successful for determining whether there was a diminution or not, but not equally so for determining the amount of decrease, owing to the great difficulty in this method of quickly making the light move at the same rate after magnetization as before. Another method was therefore tried, which promises to give better results.

The two piles, P_1 and P_2, were joined up with the galvanometer and a shunt s, so as to obtain equilibrium, according to Poggendorff's method of comparing the electro-motive forces of batteries.

The same quantity of water was now put into each box, and the pile P_1, being slightly more powerful than P_2, the shunt s was adjusted until there was little or no motion of the light on the scale.

The magnetising current was then passed through the coil, and the shunt again adjusted, until the piles neutralised each other.

It can be shown that if r_1, r_2 be the units of heat imparted to the water in the two boxes in the same time, $\frac{r_2}{r_1} = \frac{S}{S + s}$ when the piles neutralise each other, where s is the resistance of the portion of the circuit in which P_1 is placed.

If, then, dr_2 be the diminution of flow caused by magnetisation, and ds the diminution of shunt resistance necessary to again make one pile neutralise the other,

$$\frac{r_2 - dr_2}{r_1} = \frac{S - ds}{R + S + ds}$$

$$\therefore \frac{dr_2}{r_1} = \frac{R \times ds}{(R + S - ds)}$$

and thus the per centage of diminution of flow may be determined.

A few resistance coils were very roughly constructed for use in the shunt, and an attempt made to ascertain the actual amount of diminution of conductivity of the hard steel. This, again, appeared to be comparatively small, but as the coils used were not suitable for the purpose, the result is not given. But the writer has little reason to doubt but that, with resistance coils suitable for such thermo-electric experiments, he will be able to measure, with fair accuracy, small variations of thermal conductivity in this way.

It should be added that similar experiments to these were made with soft iron bars, both with and without copper terminals, but the results of the experiments, of which altogether upwards of a hundred have now been made, show that in every case the thermal conductivity of soft iron is diminished by temporary longitudinal magnetisation, and increased by transverse magnetisation, whilst in the case of steel, of different degrees of hardness, at any rate, for the temperatures employed, magnetisation evidently produces the same kind of effect as with the soft iron. The amount of the alteration in the case of soft iron must have reached

ON THE ALTERATION OF THE THERMAL CONDUCTIVITY OF IRON AND STEEL CAUSED BY MAGNETISM.

By HERBERT TOMLINSON, B.A., Demonstrator of Natural Philosophy, King's College, London.

The writer has, for several months, been engaged on a set of experiments devised for the determination of the alteration of the electrical and thermal conductivity of iron and steel, with the intention of determining, in absolute measure, such alteration for a given strength of current and imparted magnetism. But as, before the complete determination of the data sufficient for the purpose, a considerable time must elapse, he would venture to offer to the Society, in a preliminary note, some results which have already been obtained by him, as regards the alteration of thermal conductivity produced by magnetism.

In these experiments, the apparatus chiefly employed to impart magnetism consisted of an electro-magnet, with soft iron cores, 1 inch in diameter, and five inches in length, surrounded by cotton-covered copper wire, ⅛th of an inch in diameter, having a resistance of nearly 1 ohm, and a coil constructed as follows:—A thin tube of pasteboard, 1¼ inch internal diameter and 4½ inches long, was covered with varnished caoutchouc to a thickness of ¼th of an inch, and on this was wound 3 lbs. of cotton-covered copper wire, ⅛th of an inch in diameter, followed by 3 lbs. of wire, ⅛th of an inch in diameter. Inside the first tube was placed a second, 1 inch internal diameter, connected by ebonite with the first at the two ends, the second tube being concentric with the first, and of the same length, so that, between the inner tube and the outer, should be interposed a layer of air nearly ¼th of an inch in thickness. This arrangement was employed to prevent the heat from the magnetising coil reaching the bars placed inside; also, to prevent ingress or egress of heat; the bars used with the coil were covered with vulcanised caoutchouc, so that they lay with their axes coinciding with the axis of the coil.

To measure the heat conducted along the bars two sets of thermo-elements were constructed. The first was made up of two small strips of copper, ½ inch long and ¼ inch broad, of small thickness. To these was soldered about 4 feet of silk-covered german-silver wire, ⅛th of an inch in diameter, the copper strips being also connected with caoutchouc, one end of each being soldered to the copper strips, so that either one or both the copper strips with the soldered German-silver wires could be employed as a thermo-element. In case it was found convenient only to employ one of these, the other was kept well covered with sawdust. These elements will be called the G. S. elements. The second set consisted of two small thermo-piles, each of twelve elements, of antimony and bismuth, and were each fitted into india-rubber tubes, so that they could be inserted into small wooden boxes, containing water, so as to fit water-tight. Sometimes these, like the G. S. elements, were used separately; at others, were made to neutralise each other's effect on the galvanometer.

repeated several times on the same day, and on
as regards direction, namely, showing a diminution
of the flow of heat from longitudinal magnetisation.

But it was thought, however, that the electro-
magnet might when in action perhaps produce an
appreciable diminution of flow of heat by slightly
disturbing the bar in the position in the aperture,
though every precaution had been used to prevent
the chance of this, the bar in the next set of experiments was securely soldered into the cube, and
again tested as before. Here, again, some five or
six trials gave the same result, and seemed to show
most conclusively that the thermal conductivity of
soft iron is diminished by longitudinal magnetisation.

As the method of observation, however, was
tedious, and would give no idea of the amount of
alteration of conductivity, other expedients were
now adopted.

A piece of soft iron, which we will call a C, 4 inch
long, 1 inch broad, and 2 millimetres in thickness,
was soldered to two pieces of brass, A B, C D of the
same breadth and thickness.

A B was 2 inches long and C D, 1 inch. The
piece A B was also soldered to another piece of
brass A E, having a section ½ inch square, and
length about twelve inches.

The whole was placed inside a wooden box, 2
feet long, 1 foot wide, and 2 feet high, lined on
the outside with tinfoil.

A E passed through a circular hole, 2 inches in
diameter, in the middle of one end of the box, and
through two corresponding circular holes in a
double screens of sheet tin, and thence into one of
the square apertures of one of the Leslie's cubes.
The electro-magnet was placed underneath B C, and
a piece of soft iron, about 3½ inches in length, ½
inch in breadth, and about 2 millimetres in thickness, were placed on the ends of the soft iron cores,
so as to be on the same level with B C, and
distant from it one of about 2 millimetres, the
pieces of iron being separated from the cores by a
piece of white paper. In some experiments the
pieces of iron that were used were carefully screwed to
the electro-magnet by elastic straps, and, in others,
by weights placed on them. A preliminary experiment, made with the strongest current that was
ultimately used with the electro-magnet, showed
that neither were the iron pieces on the cores
appreciably shifted on magnetising the coil, nor was
the heat radiated from the coil sufficient to produce
any effect on one of the G. S. elements fastened by
elastic bands to the back of C D. The other G. S.
element was in this case buried in sawdust, with
which the box was now filled, so as to cover
completely the bars and electro-magnet. The sawdust also filled the space between A B and C D, and
the small portion of the brass bar A E, which was
between the box and the Leslie cube, was covered
with caoutchouc and cotton wool.

The lid of the box was now put on, and some time

Tel Journ Sept 1 77

Correspondence.

To the Editor of THE TELEGRAPHIC JOURNAL.

SIR,—I trust you will allow me space in the next issue of your valuable journal to finally reply to the statements contained in M. Clamond's second letter.

The lecture to which M. Clamond refers at the beginning of his letter was probably the one I read in March, 1875, before a provincial scientific society, on thermo-electricity, in the course of which I showed and explained the pile; but as to assigning him, or claiming honour for my father, I am not aware of right of doing either the one or the other. I have just read through that portion of the paper referring to M. Clamond, and I find that not even the name of the Isle company is mentioned.

In the next paragraph of M. Clamond's letter there is not the slightest particle of truth, for the articles on and notices of our thermo-pile which you inserted in your journal were, as you are aware, not written by us; and, with the exception of one of them, we had no idea that they were going to be published.

M. Clamond says he does not beat his positives in the moulds. It is of very little consequence whether they are heated in them or placed in them just before casting, as the tin would be oxidised precisely the same, for it is impossible to put this tin plate in contact with heated iron moulds heated to dull redness without almost instantly oxidising its surface.

The next part of M. Clamond's letter I will answer fully later on, merely remarking here that although ribbed discs are mentioned in his first patent, yet they were simply for the purpose of keeping the bars from lateral movement, and were not fitted or intended to support the weight of the bars above them.

With regard to the long positives—as we have stated from the first—our object in view in using them is to gain mechanical strength, and the gain in this direction far more than compensates for the slight loss in electromotive force. In one series of experiments the long positives showed an increase of strength equal to 30 per cent.

Messrs. Clark, Ford & Co. have, in a report which will be found at the end of this letter, given some further results obtained with the composite pile of short and long positives. It will be noticed that the weight of copper deposited by the latter in the twenty-two hours' test is only 27 per cent. less than that deposited by the short.

M. Clamond, in an unguarded moment, has published a certificate from H. Rousselon, according to which, in June or July of 1875, he is said to have fitted five-clay cylinders inside his piles at M. Goupil & Co.'s works, and says the certificate: "M. Clamond's thermo-electric piles have since that time rendered constant and regular service."

The inference to be drawn from this is—firstly, that prior to the fitting of the cylinders the piles did *not* render constant and regular service," and, secondly, that M. Clamond permitted the late company to come to great trouble through the fusing of his piles, while he knew the first thing to make them "render constant and regular service" was to fit cylinders.

I know as a positive fact that M. Clamond did not tell the board of directors anything about these inside

SEPTEMBER 1, 1877.] THE THE TELEGR

have been due to a bad contact at one of the terminals, as no sensible alteration in the relative thermo-motive force of the two series occurred.

"We consider the above results, on the whole, to be very satisfactory, as proving that the thermo-pile may be left for a considerable time without any attention.

"We are, dear sirs, yours faithfully,

CLARK, FORD, & CO.

"Cecil and Leonard Wray, Esqrs."

To the Editor of THE TELEGRAPHIC JOURNAL.

SIR,—It has often come under my observation that although the mirror apparatus for cable signalling is capable of being worked with a far greater speed on long submarine cables than Sir William Thomson's Siphon Recorder, yet the latter apparatus is nearly always preferred on account of the greater facility for checking errors, &c. I think that the generality of cable clerks prefer "mirror" to "recorder" working, as it is much less tiring and so little delay is caused, I say at all.

Now, if while working a mirror, the signals could be duly recorded by means of a Siphon Recorder, would not a great advantage be gained? All the newspaper could be checked from the recorded signals, and the speed of working would be materially increased.

Could not the signalling coil which moves the siphon of the recorder be in circuit with the secondary coil of an induction-coil? the primary coil of which would be in circuit with the mirror apparatus in connection with the cable, and through which, of course, the current on charge, or at the end, may be, transmitted from the distant station, would pass.

The *primary* coil would be of low resistance, so it would not make any material difference in the total resistance of the circuit.

The *secondary* coil would be formed of a great number of turns of fine wire, and could be provided with a shunt, supposing the induced current should be too strong. Instead of employing a shunt, the primary coil could be made moveable, so that its sliding in or out of the secondary coil could produce an increase or diminution of induced current.

But there is, apparently, a very great drawback to this plan, namely, the "kick" of the siphon, produced by the secondary induced current, or, to speak, which increases the secondary coil directly the battery current ceases to flow through the primary coil. For, by Lenz's law, "An inducing current at the moment it ceases produces a direct current"; *i.e.*, a current in the opposite direction to the first induced current, but in the same direction as the inducing one. So that, according to this, supposing the letter *a*, which consists of one "dot," was signalled from the distant station, it would be recorded like the letter *a*, which consists of one "dot" and one "dash." And again, there is another disadvantage arising from the "retardation" caused by self-induction in the primary coil.

This last effect is mentioned by Mr. G. K. Winter, F.R.A.S., in his paper on the "Use of Electro-magnetic Induction in Cable Signalling," which appeared in your Journal of September 15th, 1874. In the same paper he mentions a plan of his in which an inducing coil is placed at the extremity of a cable from which the current passes through the primary coil, the secondary coil, in circuit with mirror apparatus, being traversed by the induced current.

Now is not this plan somewhat analogous to the one I have mentioned? Mr. Winter describes a method for eliminating the "magnetic retardation" in the

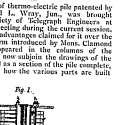
WRAY'S THERMO-ELECTRIC PILE.

THE new form of thermo-electric pile patented by Messrs. C. and L. Wray, Jun., was brought before the Society of Telegraph Engineers at their opening meeting during the current session. A *résumé* of the advantages claimed for it over the better-known form introduced by Mons. Clamond has already appeared in the columns of the JOURNAL*s*. We now subjoin the drawings of the elements as well as a section of the pile complete, fig. 1.) showing how the various parts are built

Fig 1.



together. Before, however, entering into a short description of this, it may be well to look for a moment at the construction of the bars themselves. Figures 2 and 3 will serve to show how the bars are formed, representing as they do horizontal-

Fig 2.

Fig 3.

vertical and longitudinal horizontal sections. *f f* are the negatives which are formed of an alloy consisting of two parts of antimony and one of zinc; *i i* indicate the positive metal—sheet-iron—at the heated end. *t* is the outer part at the cool end; while *p* shows the elongation or tongue which forms so distinct a feature in the casting of the bars. The effect of it is to raise very materially the breaking strain, and so get rid of the liability to fracture, to lower the internal resistance, and strange to say increase the electro-motive force.

Returning to figure 1, a vertical section is shown of a pile of 225 couples, built in three sections of 75 couples each. *a a* is the heating chamber, formed of an earthenware cylinder, against which the bars abut; this can very speedily be raised to a red heat, and so distributes the caloric uniformly, while it at the same time effectually protects the ends of the bars from fusion or oxidation. *b b* a Bunsen or other suitable burner, inside which is a cylinder of wire gauze similar to that employed in the safety-lamp. This prevents explosions when the light is applied, and at the same time by causing a more equable distribution of the gas tends to render the heating of the bars uniform—a point, it is needless to again urge here, of vital importance in any practical form of thermo-battery. It is to attain the same end that the disc *d* is placed at the lower end of the chamber. This disc screws up and down the pipe *c*, and thus regulates with much nicety the admission of air for combustion through the openings *e e*. The draught is further controlled by a perforated earthenware cover on the top of the cylinder. *f f f* represent the better-known form introduced by Mons. Clamond has already appeared in the columns of the JOURNAL*s*. We now subjoin the drawings of the elements as well as a section of the pile complete, fig. 1.) showing how the various parts are built upon the insulating annular discs, *c c c*. These discs are again supported on blocks, which thus carry the weight of the several layers of bars. Through these blocks run the binding rods *k k*, which serve to give additional stability to the entire structure.

We forbear entering into a comparison of this with the other forms of thermo-piles previously in existence, for any attempt at comparison would speedily cease to be such, and would merely resolve itself into an enumeration of the advantages which Messrs. Wray's form undoubtedly possesses over every other. We are not aware whether it has yet been brought into practical use; if not, it certainly ought to be without further delay, for, looked at theoretically, it is difficult to see what further improvements can be effected in it.

Elect Mus Augt. 76.

'Improvements in Thermo-Electric Apparatus.—Charles James Wollaston, 8, Park Place, Maryleboue, Middlesex, January 6, 1875—No. 58. This invention relates to apparatus for obtaining electricity in a convenient and economical manner from heat generated from the combustion of fuel.

Report Presented by Count du Moncel on the Thermo-Electric Battery of M. Clamond.—In this battery the thermo-electric element is of iron, and the negative element is of antimony and zinc. In M. Clamond's arrangement, as in those of Noe, the elements are connected circularly by intercalating, between a kind of crowns, insulated from each other by plates of ammonites, and having their polar extremities placed in connection with a commutator, fixed tangentially to the cylindrical surface of the apparatus, and contrived so as to cause these crowns to be grouped either for intensity or for quantity, as may be requisite. The apparatus has been employed for six months at the galvano-plastic works of M. Goupil at Auteuil. The gas consumed

2 amounts to 23 frs. per kilo. of copper deposited. This paper is accompanied with several illustrations.

New Balance of M. Mendeleef.—Requires the ac companying diagram.

ON THE NATURE OF THERMO-ELECTRICITY.

The nature of the electricity which arises when two different metals are connected in a circuit, and the places of contact of the heterogeneous metals have different temperatures, has been the subject of a good deal of speculation. In a recent number of *Poggendorff's Annalen*, M. Kohlrausch advances an hypothesis in regard to it, the salient features of which we shall here endeavour to present.

"It is usual," he observes, "to place the cause of thermo-electricity in an electro-motive force at the places of contact of the different conductors, but difficulties are met with whenever it is sought to pass to definite conceptions here. The voltaic contact forces (which in the ordinary voltaic pile are accepted as the cause of the galvanic current) have evidently helped towards this hypothesis, and the next step consisted in explaining thermo-electricity as a modification of voltaic forces through temperature. But we soon perceive that in that case the ideas hitherto held as to these forces must be given up, or if this be not done, that we must again keep separate two kinds of contact forces.

"In this state of things, the remark is perhaps not superfluous, that for a theory of thermo-electricity, we do not at all require the immediate action of contact surfaces, and that we may reach a perfect agreement with known facts, if we suppose the electro-motive force to be in the interior of the separate conductors. The places of contact have then only a secondary influence. This conception we shall here develop.

"In every thermopile, when in action, there is, with the difference of temperature, necessarily a streaming over of heat from the warmer to the colder junction; because every conductor of electricity also conducts heat. . . . Hitherto the difference of temperature of the junctions has been regarded as the cause of the electro-motive force; but with equal right we may make the attempt to accordingly suppose, that *with a heat current* of determinate amount depending on the nature of the conductor, an *electric current is connected*, provided that other electro-motive forces are first excluded."

This idea is, indeed, not entirely new. Some years ago M. L. Hermann arranged experiments that were based upon it, and were meant to confirm it, but without success. M. Kohlrausch has not taken it up, and subjected it to a purely theoretical discussion.

Starting with the supposition that when a certain quantity of heat passes through a surface element in the interior of a conductor, a certain quantity of electricity is carried away with it, from the latter being proportional to it and dependent on the nature of the substance, M. Kohlrausch develops the formula for the electro-motive force of two metals, which have different thermo-electric constants, and different falls of temperature, and this formula shows (what experiment confirms) that the electro-motive force only depends on the temperature of the junctions, and is proportional to the difference of temperature.

M. Kohlrausch demonstrates that in a homogeneous uncrystalline conductor of varying temperature, a continuous electric current cannot arise, because there is soon an accumulation of free electricity, which compensates the electro-motive force of the heat current. On the other hand, electricity has been observed in crystalline bodies, e.g., in tourmaline, during the motion of heat in their interior.

Every theory of thermo-electricity, however, must explain not only the electro-motive forces, but also the so-called Peltier phenomenon, that is, the development of heat at the soldered junction of two metals when an electric current is sent through them. The necessary supplementing of the above hypothesis forthwith, says M. Kohlrausch, "is almost offered by itself, for we have only to add the supposition that *by an electric current heat is moved*. This supposition comes to agree with the known quantitative facts regarding the Peltier heat, when the reciprocity of joint conduction of electricity and heat is extended also to the amount of this." M. Kohlrausch shows that this propagation of heat in a conductor cannot, on account of the equality of the thermoelectric constants, produce any action. At a junction, on the other hand, where these constants are different, there will be manifested, according to the direction of the current, heat production or absorption.

We may give this hypothesis a very simple expression if we take into consideration the proportionality, rendered highly probable by Wiedemann and Franz, between conducting power for heat and for electricity. That is, the heat-giving power of each electric current in any body is proportional to the electromotive force of the unit heat current in the same body.

While all the known facts of thermo-electricity are deducible from this position, there are, further, two quite unimportant consequences, which are peculiar to it, viz., first, an electric difference between two points of a body of varying temperature, and second, a difference in the heat developed by an electric current in an unequally warm conductor, according to the direction of the current.

In favour of the views here given, the following may further be marked: that the propagation of heat and electricity in a metal are nearly allied phenomena, follows from the proportional behaviour of all metallic conductors, that have been experimented with, with regard to both conductions. At least we have in heat and electricity two somewhat related things which fill the same space, and the movement of one of them has a moving influence on the other. . . . There is a moving conductor, according to the direction of the current.

Further, the remarkable fact that the most active thermo-electric bodies are very bad conductors, speaks in favour of some connexion of thermo-electricity with conduction of heat and electricity, for a mere coincidence can here have no place.

Lastly, it is to be noted that that excitation of electric properties, which is exerted by the same of pyro-electricity, appears to stand near our conception of thermo-electricity. The crystals in question are found electric only during their heating or during their cooling, that is to say, when

they are traversed by a heat current. It is possible that thermo and pyro-electricity are merely different expressions of one and the same reciprocal action between heat and electricity.

Elect News Sept 16. 75

REPORT ON CLAMOND'S THERMO-ELECTRIC BATTERIES.

By the Count TH. DU MONCEL.

The thermo-electric battery, the principle of which was discovered by Seebeck in 1821, is the most constant source of electricity possible to obtain, since the energy of its current depends solely on the differences of temperatures at which the extremities of the diverse elements composing it are maintained. The first thermo-electric batteries constructed for industrial purposes were those constructed by Nobili, and Bacquerel, with a combination of metallic alloys. To them, also, we look for the first practical realization of a battery in excellent possible size and with maximum of power. The pairing of pure elements—positive and negative metals, when they are taken as the most opposite ends of the scale of electro-motive properties, does not furnish the most energetic effects; the most convenient effects are mainly dependent on metallic alloys. Melloni first made an energetic battery whose electro-negative element was an alloy of antimony, zinc, and bismuth, while its electro-positive element of nickel, copper, and zinc. In mixing these metals proportional to their chemical equivalents, he obtained a maximum action. On the other hand, E. Becquerel, from personal researches, used antimony and cadmium for one element, and German silver for the other. From this latter combination very energetic results were obtained, and in this manner the thermo-electric batteries manufactured by Ruhmkorff were constructed. Then Pouillet, of Boston, and Clamond, have studied the question as to the best arrangement for giving highest temperatures, and for obtaining a great number of elements easily disposed for potential or for quantity as required. To Clamond must be attributed the first fixed arrangement in use. He employs as the positive battery of iron and sulphuret of lead, or galena, of little conductibility, and these he heated by a gas, coke, or petroleum stove. The results were, from the first advantageous; but shortly after it was seen rendered useless from the burning of the galena, its cracking, and the enormous increased resistance of the couples. Hence the galena was abandoned, and a zinc and antimony alloy used in preference, with iron for the other electro-positive element. Undoubtedly by taking copper, nickel, or German silver, a higher electromotive force would be obtained; but experience has shown that when copper or German silver is dissolved in the alloy for account of the positive action of the apparatus) iron is retained. The pairing between the iron and alloy was effected in this way.—The iron was doubled back, in the shape of, as it were, a hinge, and on that portion the alloy was allowed to run a plate of from 1 to 2 mm. thick. The alloy became a frame around the iron flange. The splitting of the material—which is always very weak place in parallel layers, in ordinary alloys, under the influence of alternate heat and cold—is prevented by having it used conveniently heated moulds. In these batteries the elements are arranged circularly for potential, or so as to form a crown, separated from each other by asbestos plates. Their polar ends are connected by means of a commutator, for the suppression of the electric action of the apparatus, and are so disposed as to allow of their being grouped in potential or quantity series, as required.

The thermo-electromotive force set up at the contact of a conductor with a wire carrying a current has been made the subject of a recent investigation by M. Bergman, of St. Petersburg. It is known that a change of structure takes place in a conductor by the passage of a current through it, and M. Bergman finds this change capable of producing a thermo-electric force. After reducing to zero the current in a Wheatstone bridge, formed of iron wire traversed by a powerful current, the author heated one of the arms very gently and ascertained a deflection of the [illegible] the battery changed the direction and amount of the deflection, thus proving the existence of an electromotive force in the bridge itself. *Cosmos.*

SCIENTIFIC SERIALS

Poggendorff's Annalen der Physik und Chemie, No. 6.—Paul Groth. Ueber Lichtcurven. On the reflection of light from the outside of isotropic bodies, and the change of its polarization which takes place thereby. Extract from an Inaugural Dissertation contributes a memoir On the Absorption of Electrical Currents, in which, following up the experiments of Riess, he examines Faraday's theory of electrical induction by polarization of the medium, and describes in detail the apparatus with which he has experimented, tabulates his results, and agrees with Riess's conclusion that there is no direct influx of electricity.—The next article comprises a series of communications from the Mineralogical Society of the University of Strasburg, in which Fuchs discusses the crystalline form and thermo-electric properties of sesquiliquate of potassium and chromium. Its chemical formula is very variable: $(K_2O, Na_2O, Fe_2O)\,As_2O_5$. Light thrown upon the constitution of the hexahedral forms of the species, are displayed in hexahedral tin bisulphide of the form Sulphuric acid forms pyritic and cubic-octahedral forms with parallel sides, plane, one-part of the crystal is negative towards copper, while the other half is positive.—Dr. Hunze treats of the chemical composition of leadhillite. Prof. Limpricht read years ago sketches of a mineral from Iglesias, in Sardinia, under the name of Bleilasur, and with the formula $3PbSiO_3 + 2PbCO_3 + 3H_2O + 3H_2O$. Hillside Mountain, near Leadhillsdale. The author points out that two minerals are incidental, and that the formula of leadhillite is $PbCl + 3PbO_2$. As no leadhillite has hitherto been found, $PbCl_2 + 3PbO_2$. In the next paper, by the same author, is copious and laborious researches on the constitution of silicates by means of hydrofluoric acid. The chemical compositions and crystalline forms are given of the following minerals, viz., Prehnite, diphosphitbleiweiss, diphosphitbleiweiss, dichromsaures blei, diphosphitbleiweiss, dimorphosphitbleiweiss, &c. All these bodies belong to the monoclinic system.—Dr. A. Arzruni gives a short note on Optical researches on the natural rock-salt from Stassfurt, followers by crystallographic and optical researches on compounds derived from boracic acid. Zoffner points out the connexion between the aggregation and position of the molecules in crystals, and concludes that they are cooled successively.—Dr. Hunze treats of researches on the action of hydrochloric acid on fossil remains. Papers are Dr. Andrews on ozone and Prof. Wright on the polarization of the radiant light.

3500. C. A. Faure, of Middlesex. *Improvements in the construction of thermo-electric batteries or piles, and in the application of the electric currents so derived therefrom to the production of motive power.*—Dated February 29, 1856.—The novelty of the invention consists in arranging two plates or cylinders in such a manner that there will be an opening or space between them, through which a current of air, steam, or water may pass, one of lead or "galena," one of the plates or cylinders is kept hot by artificial means, and the other cooled by the application of water. The two plates or cylinders thus form the poles of the thermo-pile, which are connected together by a suitable conductor, and which receives the electric current passing through the "galena," and transmits it to a magnet around the cores of which a number of separate insulated strands of wire are wound, each strand being separately connected with the poles of the battery or thermo-pile, thereby producing electro-magnetic power, which actuating on armature through a suitable joint or "break" and "make" contacts, a reciprocating motion to a shaft is given which may be employed for driving purposes.

publish.

On the Thermo-electrical Properties of some Minerals and their Varieties.

By A. Schrauf and E. S. Dana.

The interesting investigations of Hoor, the late eminent mineralogist of Berlin, have during the past two or three years excited considerable interest in this subject. Hoor started with the first fact announced by Hankel, that some crystals of pyrite and cobaltite are electrically positive, and others negative, and endeavored to explain the opposite character on the assumption that it was connected with and conditioned by the right and left hemihedrism, characteristic of both species. This touches an important point in physics, and if it could be sustained, Hoor's hypothesis would be very valuable. Schrauf and Dana, however, after the examination of a large number of minerals, comprising nearly all the metallic sulphides, have come to the conclusion that cause of the variation of electrical character must be sought elsewhere. They attribute it, not to an opposite molecular condition shown in hemihedral crystals, but to a change in chemical composition.

They call attention in the first place to the series published by Luboek, where for example platinum occupies a varying position according to its degree of purity. Moreover, they urge that the single case, observed by Stefan, that some specimens of granular galena are positive, while others of crystallized galena are negative is strong evidence against the influence of hemihedrism in general, as nothing of the kind can be assumed here. The force of their argument, however, lies in the fact that they have found several other well-defined cases of minerals, having varieties, and that among minerals crystallizing holohedrally. Chemical analyses were here desirable to show how far the material under investigation varied in composition. In the absence of these, the specific gravity was resorted to as an indicator of the chemical character. This afforded decisive results: the plus and minus varieties showed a decided difference in density, implying a corresponding change in composition. This was true in all cases investigated, including cobaltite and pyrite, showing where the explanation of the electrical character was to be looked for.

[1876.]—**Thermo-Electric Generator.**—This consists of a number of small bars of an alloy of bismuth and antimony and zinc in equal proportions, each bar being about one inch in length, ⅛in. in breadth, and about ⅛in. in thickness. The bars are arranged in a series with positive and negative poles so disposed of linked iron, and connected together, so that the electricity of a particular battery cannot expend a neutral element within which is placed a five-bay pipe, perforated with minute holes, through the lower part of this pipe common fighting for other ores is admitted along with a recruited portion of air. The ore is thus in fact the Bessemer furnace of the gas escaping there in the form of matte, which is afterwards roasted and smelted in the usual manner. The different kinds of lead, the different grades of silver, and the different qualities of copper, which are produced within the central furnace, are collected separately in the inner ends of the bars. The outer ends of the bars are connected with the other, and a current is thus established in the direction of the electric current. The intensity of which the pile is composed, which may consist of 100, 200, 300, 400, or any number of pairs, as may be described, the power of the pile depending on the number of elements employed. The instrument is very portable, and its become of great utility and importance, as it not only saves economical in cost than the usual methods of working. Moreover, other chemical batteries do not require to charging by replacing of [illegible] the requires to be renewed, as the use a stream of electricity as long as the [illegible] continues (the current is maintained) as long as the [illegible] remains in action, or the current. The larger piles such as for 500 or 1,500 bars, are loaded with a 500 or 1,500 cells of [illegible] series of connexion. The inventor is No. 27, Newington Causeway, and Archangle-street, London.—*The Builder*, 1876.

[1876.]—Thermo-electricity.—[illegible] do not know which form was established of facts, and how not at present the terms of pitch exchange, which would require to be healthy and strong, passed with drawings to be of *any service*.—Sigma.

The Comacho Electric Machine.

The Comacho magnetic machine, with its concentric iron tubular magnets, may be seen at 171 Queen Victoria street. There can be no doubt of the advantage of this form of magnet; but experiment on the resistance of the circuit, weight lifted, electro-motive force, and consumption of zinc, etc., would form an interesting subject. The machine, with five cells of a bichromate battery, works three or four sewing machines. Attempts to work it with the thermopile have hitherto failed. This is very likely, because the elements of the thermopile are coupled up in considerable series, so that, considering the resistance of each element, the whole resistance must be great compared with the resistance of the wire round the magnets. A thermopile should be made of low resistance by coupling a number of elements together in parallel circuit, and then taking some ten or twelve, or more, of such series coupled in succession. It is no doubt worth considerable experiment to attain a successful result from the thermopile, as in that case, by merely turning on the gas, a lathe or sewing machine be made to

The Clamond generator is a thermo-electric battery which may be very advantageously used for electrotyping, electric light, telegraphy, and various other purposes. This generator has already been described at length in our pages; Four batteries of one hundred elements each, and one of two hundred and sixty were exhibited. Besides these, in which gas is the prime agent in the production of the electric current, there was a large model of an apparatus arranged for burning coke. It consisted of two hundred elements [illegible]

On the Nature of Voltaic Electricity.

The nature of the electricity which arises when two different metals are connected in a circuit, and the places of contact of the heterogeneous metals have different temperatures, has been the subject of a good deal of speculation. In a recent number of *Poggendorff's Annalen*, M. Kohlrausch advances an hypothesis which seems to the writer a brilliant effort and likely to endure for a time at least.

"It is usual," he observes, "to explain the cause of thermo-electricity in an electro-motive force at the places of contact of the different conductors. But these forces are met with wherever it is sought to pass to definite conceptions here. The voltaic contact forces (which in the ordinary voltaic pile are accepted as the cause of the galvanic current) have evidently helped towards this hypothesis, and have at first step consisted in explaining thermo-electricity as a modification of voltaic forces through temperature. But we soon perceive that in that case the latter hitherto held as to these forces must be given up, or if this be not done, that we must again keep separate two kinds of contact forces.

"In this state of things, the remark is perhaps not superfluous, that *fact a theory* of thermo-electricity, we do not at all require the immediate action of contact surfaces, and that we may reach a perfect agreement with known facts, if we suppose the electro-motive force to be in the interior of the separate conductors. The places of contact have then only secondary influence. This conception we shall here develope.

"In every thermopile, when in action, there is, with the difference of temperature, necessarily a streaming over of heat from the warmer to the colder junction; because every conductor of electricity has a conducting heat. Hitherto the difference of temperature of the junctions has been regarded as the cause of the electro-motive force, but with equal right we may make the attempt to lay, as the cause, the other inseparable condition. We accordingly suppose, *in a with a heat current* of determinate amount depending on the nature of the conductor, *an electric current is connected*, provided that other electro-motive forces are first excluded.

"This idea is, indeed, not entirely new. Some years ago M. L. Hermann arranged experiments that were based upon it, and were meant to confirm it, but without success. M. Kohlrausch has now taken it up, and subjected it to a purely theoretical discussion.

Starting with the supposition that when a certain quantity of heat passes through a surface element in the interior of a conductor, a certain quantity of electricity is carried away with it, from the latter being proportional to it and dependent on the nature of the conductor, M. Kohlrausch develops the formula for the electro-motive force of two metals, which have different thermo-electric constants, and different falls of temperature, and this formula shows (what experiment confirms) that the electro-motive force only depends on the temperature of the junctions, and is proportional to the difference of temperature.

M. Kohlrausch demonstrates that in a homogeneous unequally crystalline conductor of varying temperature, a continuous electric current can not arise, because there is soon an accumulation of free electricity, which compensates the electro-motive force of the heat current. On the other hand, electricity has been observed to flow in the direction of a homogeneous, during the passage of heat in their interior.

Every theory of thermo-electricity, however, must explain not only the electro-motive force, but also the so-called Peltier phenomenon—that is, the development of heat at the soldered junctions of two metals when an electric current is sent through them. "The necessary supplementing of the above hypothesis for this end," says M. Kohlrausch, "is almost offered by itself, for we have only to add the supposition that by *an electric current heat is moved*. This supposition comes to agree with the known quantitative facts regarding the Peltier law, when the reciprocity of joint conduction of electricity and heat is extended also to the amount of it. M. Kohlrausch shows that this propagation of heat in a conductor can not, on account of the equality of the thermo-electric constants, produce any action. At a junction, on the other hand, where these constants are different, there will be manifested, according to the direction of the current, heat production or absorption.

We may grow this hypothesis a very simple expression if we take into consideration the proportionality, rendered highly probable by Wiedemann and Franz, between conducting power for heat and for electricity. That is, the heat-ideal to the electro-motive force of the unit heat current in the same body is proper.

While all the known facts of thermo-electricity are deducible from this position, there are, further, two quite unimportant consequences, which are capable of being—namely, first, an electric difference between two points of a body of varying by an electric current if the temperature in the heat developed according to the direction of the unequally warm conductor, second, a heat current in a homogeneous conductor, as.

In favor of the views here given, the following may further be remarked: that the propagation of heat and electricity is a most law nearly-allied phenomena, of follows from the proportional between all the metallic conductors, that have been examined with, with regard to both conductivities. At least we have in heat and electricity two somewhat related things

* In Bois-Reymond, "Berner Schriftbuch," Oct. 19, 1874, p. 228.

which fill the same space, and, however it is to be conceived, we may expect that the movement of one of them has a marking influence on the other.

Further, the remarkable fact that the most active thermo-electric bodies are very bad conductors, speaks in favor of some connection of thermo-electricity with conduction of heat and electricity, for a mere coincidence can here have no weight.

Lastly, it is to be noted that that excitation of electric properties of a kind is denoted by the name of *pyro-electricity*, appears to stand near our conception of thermo-electricity. The crystals in question are found electric only during their heating or during their cooling—that is to say, when they are traversed by a heat current. It is possible that thermo and pyro electricity are merely different expressions of one and the same reciprocal action between heat and electricity.

Self-Movement of Electricity.

The Return of Thermo-Electric Currents.

According to our contemporary, *L'Electricité*, M. Exner, of Vienna, has discovered that a bismuth antimony pair immersed in a gas incapable of acting chemically on either of these metals, yields no current when one junction is heated. Also that if two bars of copper are soldered together to form a "pair," no current is produced when either junction is heated or (as would be expected in a circuit of one metal), not even when both strips are exposed to the action of chlorine, but that if one strip only is exposed to chlorine one and then one junction be warmed, a thermo-electric current is set up. According to Exner, therefore, all so-called thermo-electric currents are due to chemical action. It would be easy for some of our ardent young physicists to put to the test this very remarkable announcement, and see whether it is Herr Exner, or all the authorities on thermo-electricity from Seebeck to Tait, on whom we are to rely for the facts.—*Nature*.

the heated gases pass upwards to the top; finding no means of escape there, they curl over, and descending outside the iron tube, i.e., between it and the elements, they finally make their exit by means of the channel already referred to. The elements are thus heated partly by radiation from the iron tube and partly by the heated gases on their way downwards to the chimney. Not only is the danger arising from the gas jets impinging on the elements thus removed, but the consumption of gas is said to be reduced by one-half. Should a bad connection occur, it is short-circuited by a piece of wire, and a defective element can readily be cut and replaced by a sound one.

A small gas regulator fits keep the pressure of gas, as far as may be, constant; is employed with each machine. The consumption of gas in small-sized elements is stated to be about one foot per hour for each volt of tension. Where gas is not available for heating purposes, coke or charcoal is found to answer very well. Paraffin oil might probably be employed with advantage, although thus far it does not seem to have been successfully used as a source of heat in the thermo-piles.

Iron screens are sometimes employed to surround the pile, their object being to cool the external surfaces of the elements by causing a current of cold air to pass over them. They likewise prevent, to some extent, the fracture of the iron which takes place if the pile cools too rapidly. The subject of screens and other mechanical appliances for cooling the external surfaces of the thermo-electric elements, such as currents of water, the use of water, evaporation of moist surfaces, &c., have thus far been imperfectly investigated, and throw open a wide field for investigation, standing the labours of M. Clamond.

The electro-motive force of a therme-electric element, such as those employed in Clamond's pile, is such that as elements may practically be regarded as equivalent to one Daniell's cell in this respect, that is, they give about one volt.

The following table, published by the Thermo-Electric Generator Company, and found by experiments conducted by the author to be very correctly tabulated, gives the electro-motive force, internal resistance, and consumption of gas for the piles usually manufactured by them:—

	Size.	Electro-motive force.	Internal resistance.	Consumption of gas per hour (cubic feet).
For tension	40 bars, 60 " 120 " 150 " 250 " 380 " 500 " 80 " 60 " 100 " 200 " 400 "	2 volts 3 " 6 " 7 " 12 " 19 " 24 " 4·5 " 3 " 5 " 10 " 20 "	170 ohms 13 " 3·6 " 3·6 " 0·63 " 0·25 " 12·25 " 1·25 " ·6 " 1·7 " 2·01 " 4·0 "	— 3 " 5 " 6 " 9 " 23 " 37 " 6 " 6 " 9 " 21 " 37 "
For quantity				

* The assistance is that of the piles in their hot state; when they are cold it rises about 25 per cent.

For tension { 340 bars / 680 " } 17 volts, 375 ohms, 175 lbs. / 34 " 12·75 " 270 "
For quantity { 190 " / 400 " } 10 " 750 " 175 " / 20 " 4·0 " 270 "

CHARCOAL PILE.

For tension { 100 bars / 190 " } 5·0 volts, 170 ohms, 33 lbs. / 9·5 " 2·8 " 50 "
For quantity { 100 " / 190 " } 5·0 " ·63 " 33 " / 9·5 " ·17 " 50 "

The following, extracted from the circular published by the company, give some of the prices which are charged:—

For the tension or small-sized bars:—

2 volts	£5	0	0	40 bars.
3 "	4	0	0	60 "
6 "	6	10	0	120 "
12 "	13	0	0	250 "
24 "	20	0	0	500 "
30 "	25	0	0	600 "

For the quantity or large-sized bars:—

2 volts	£8	0	0	60 bars.
10 "	20	0	0	200 "
20 "	32	0	0	400 "

The coke-piles are charged as follows:—

10 volts (quantity)	£6	0	0	100 bars.
20 "	12	0	0	200 "
17 " (tension)	20	0	0	340 "
34 "	40	0	0	680 "

It is found that the electro-motive force of the several layers of elements varies, owing to the fact that some are more fully exposed to the heat than others. The middle layers seem to give the best results, although when first heated the upper bars are stated to give the greater electro-motive force.

So extremely sensitive are the thermo-electric piles, that it is all but impossible to find one in such a state of equilibrium as to give no evidence of a current. If it be so, the passage of the hand into the interior of it, breathing upon it, or even the approach of the body, immediately sets up an action; and whilst they are at work, the effect of a distant fire, or the opening of a window, will produce a sensible effect upon them. When two or more piles, therefore, are employed, they should, in order to secure the best working, be kept as far apart as possible, and allowed free radiation.

Electro deposition is one of the many uses to which thermo-electric piles may be turned, and plating. As an instance of what has been done, a battery of 375 elements (whose internal resistance was 4·5 ohms, and electro-motive force 11·6 volts) deposited about 180 grains of copper per hour, but then the electro-motive force was sufficient to have created a similar deposit in several successive cells, so that no practical results as a theoretical possibility of the work to be effected by them in this respect.

The mechanical power obtained from thermo-piles by electro-magnetic engines has not yet been put to any practical use, nor can it be looked for as ever likely to be worked from an economical point of view. The electric light furnished by them is powerful and constant, but a very large number of elements has to be employed in order to secure this.

For laboratory use they are very handy, and by utilising the waste heat of kitchen fires they might doubtless be employed to considerable advantage for domestic purposes.

THERMO-ELECTRIC GENERATOR COMPANY, LIMITED.

LONDON—97, New Street, Cloth Fair, Aldersgate Street. Close to Aldersgate Railway Station.

PARIS—66, Boulevard de Courcelles.

The labours of Electricians have long been directed to the production of Cheap Electricity on a practical scale, but it has been the good fortune of M. CLAMOND, of Paris, after years of experiment and labour, to reach the long-desired success by perfecting his Thermo-Electric Pile or Battery.

The Piles or Generators are constructed of metals having great electric properties. The Electricity is given out without any intermediate agency. Fuel alone, such as Gas, Coke, Charcoal, is consumed. The economy in maintenance is very considerable in comparison with other Batteries, and the current obtained is constant and free from polarization or exhaustion.

The superiority of the Clamond Pile over other batteries for Electroplating and Electrotyping purposes has been practically demonstrated by its adoption in France in the Ministry of War, the Mint, Bank of France, School of Mines, &c., &c.; in the ateliers of Messrs. Gueret, Chevenard, and other Industrial Institutions; whilst the value and economy in Telegraphy have been placed beyond question, by the result of many months working at the Exchanges Telegraph Company's Office in Bartholomew House, where the Pile has superseded all other Batteries previously in use.

M. CLAMOND, the inventor, has received, at the annual meeting of La Société d'Encouragement pour l'Industrie Nationale, on the 29th June, 1877, its Grand Gold Medal, in recognition and appreciation of the value of his important discovery.

M. CLAMOND also received the Grand Diploma of Honour from the "Exposition Maritime et Fluviale," that year, in recognition of his invention.

The following are some of the purposes to which this system is adapted, viz.:—

TELEGRAPHY.
ELECTRO-PLATING and ELECTROTYPING.
DEPOSITION of METALS and CHEMICAL ANALYSIS.
PRODUCTION of LIGHT.
TORPEDOES and other NAVAL and MILITARY REQUIREMENTS.
The LABORATORY and LECTURE ROOM.
HOSPITAL and SURGICAL PRACTICE, and BATHS.
ELECTRIC CLOCKS and BELLS.
MINING.

By way of illustration of the capabilities of these instruments, the following may be taken as a standard of efficiency.

ELECTROTYPING, ELECTRO-PLATING, AND GILDING.

A Machine of 100 bars, with a consumption of 5 cubic feet of gas, deposits about one ounce of Silver per hour. The same apparatus, coupled for quantity, will deposit about one ounce of Copper in the same time.

400 bars, large, consuming 2 lbs. coke per hour, will deposit about four times the above quantities.

PRODUCTION OF LIGHT.

Arrangements are now in progress for producing light, suitable for Light Houses, Beacons, Theatres, &c., by large sized Batteries, which, will effect very considerable economy over all other means hitherto employed in this direction.

The Board specially draw the attention of manufacturers and others interested in the various applications of Electricity to the Thermo-Electric Piles, and invite them to inspect the Batteries, which can be seen in operation at the Company's Works, 97, New Street, Cloth Fair, Aldersgate Street (by Railway Station), on Mondays, Wednesdays, and Fridays, between the hours of 2 and 4, where prices and full particulars can be obtained, and all necessary references and testimonials supplied.

London: Printed for the Proprietor by John & Charles Adams Hill, Factory Cornwall, E.C. June 1, 1878.

SOCIETY OF TELEGRAPH ENGINEERS.

Mr. C. Y. WARNER, F.R.S., the President, in the chair. London, November.

THERMO-ELECTRIC BATTERIES.

THE adjourned discussion on Mr. Latimer Clark's paper on "Thermo-electric Batteries," was resumed by the author, who took advantage of the opportunity to explain certain improvements which had been introduced in the manufacture of those batteries, since his paper was read, by Messrs. Cecil and Leonard Wray, Jones. These improvements claimed an advantage over the form produced by M. Clamond; 1, in the castings of the bars; 2, in the method of building up the batteries so as to reduce weight and strain upon the lowest plates; 3, in the heating arrangements; 4, in the regulation of the draught; and 5, in the arrangement of the coke furnace by which the bars could be removed without the withdrawal of the entire fire.

With regard to the bars the alloy employed is the same, or nearly so, as that employed by Clamond, viz., for the negative metal, two parts of antimony to one of zinc, whilst for the positive steel bars are used. Messrs. Wray overcame, to a very great extent, the brittleness, or rather the liability to break when touched, of the alloy, by elongating the tongue of the short iron, which is then made to extend a distance of about two-thirds of the entire length of the bar. The positive metal thus extended is placed in a mould, in which the alloy is cast under pressure. The effect is to heighten the breaking strain, to increase the electro-motive force, and decidedly to lessen the resistance. Hitherto the bars which compose the battery have been built up, one row upon the other, by means of clamps, which exercised such excessive row of bars or elements increased the weight of that beneath it, and from this cause the elements of the battery became screwed. Messrs. Wray now set them in a vertical manner by giving to each row of elements an independent support. It is, however, in the heating arrangements that their improvements are most conspicuous. The power of this form of battery depends upon the subjection of the elements which constitute it, at certain points, to temperatures of as opposite a character as possible; thus one end of the bars has to be subjected to as intense a heat as they can sustain, and the other end to as intensely cold an atmosphere as can be produced. Various have been the means adopted to produce a pile which should stand this intense heat, and the action of the gases forming the products of combustion of whatever is employed to heat the pile, but hitherto they have been unsuccessful. Messrs. Wray proposes to reduce, if not entirely to obviate, this by employing an enclosure over-lapping the outer bars of the pile and the chimney heated by the flame. By regulating the flow of air and the draught they are also able to keep under control the heating and cooling process, so as to make it more gradual and uniform. On the whole the improvements suggested by Messrs. Wray are of a very practical character, and are highly spoken of.

NEW LIGHTNING PROTECTOR.

A paper was also read by Mr. Andrew Jamieson on a new form of "Lightning Protector," for submarine cables. The idea, which has been very prettily perfected, but nothing electrically new in it (vide Art. 14), nevertheless, mechanically is not improved on in the means at present adopted for the protection of cables, which usually consisted of plate protectors, vacuum tubes, and one sole platinum wire. These are usually so arranged that the atmospheric charge entering from the open line wire shall pass through the plate protector first, then the small platinum wire, and finally through the vacuum. The probability is that the intensity of the charge would be carried off at the first-named protector; but failing this, if of such power as to injure to the cable, it would so heat the fine platinum wire as to fuse it, whereby the line would become interrupted until an officer was sent to replace the melted wire, and as this is usually at the shore end of the cable, it unfortunately occupies some time to do so. Mr. Jamieson connects his open wire to a corrugated barrel within a corrugated cylinder, the corrugations intermeshing each other, and so forcing innumerable points by which the intensity of the atmospheric charge may be carried off. He then connects the barrel of what may be regarded—having reference to previous arrangements—the plate protector, to a spring which normally rests against a small pillar, and which is in connection with another spring similarly arranged. Each of these springs is withheld from touching the pillar in question by a piece of fine platinum wire attached to its end, the other end of each piece of wire being connected with the cable. The result is that supposing a charge to have passed through the barrel, it will pass into the first-named piece of platinum wire, which will fuse, and the tension of the spring having been thus removed it will fly back to its pillar of platinum wire. Thus the cable is saved from interruption and still protected, the lineman's journey to the cable but is saved, and if necessary the arrangement may be repeated *ad libitum*. The discussion was carried over for the next meeting.

At a recent session of the French Physical Society, papers of which the following are abstracts, were presented:

RESISTANCE OF THE BATTERY IN ELECTRIC BATTERY.

M. Rolland has studied by Thomson's method the resistance of the clamond thermo-electric elements. His observations are represented by a curve having for abscissæ the times, and for ordinates the resistance of the element. During the first twenty minutes the curve rises, describing several sinuosities and then becomes parallel to the axes of abscissæ. When the heating ceases the curve rises at first very rapidly and then descends oscillating. M. Rolland remarks that the method employed supposes the electro-motive force to be constant, and that consequently the curve may be the result of the variation of the resistance and of that of the electro-motive force. The progress of the temperatures similarly observed on a copper-iron pile is represented by an analogous curve.

Resistance of Thermo-Electric Battery.

M. Rolland has studied by Thomson's method the resistance of the Clamond thermo-electric elements. His observations are represented by a curb having for abscissæ the time, and for ordinates the resistance of the element. During the first twenty minutes the curve rises, describing several sinuosities and then becomes parallel to the axes of abscissæ. When the heating ceases the curve rises at first very rapidly, and then descends oscillating. M. Rolland remarks that the method employed supposes the electro-motive force to be constant, and that consequently the curve may be the result of the variation of the resistance and of that of the electro-motive force. The progress of the temperatures similarly observed on a copper-iron pile is represented by an analogous curve.

Arthon.

THERMO-ELECTRIC PROPERTIES OF LIQUIDS.—By using an improved apparatus, which he describes at a recent meeting of the Royal Society, Mr. G. Gore, F.R.S., has discovered several exceptions to the effect he formerly obtained, viz., that acid liquids are thermo-electro-positive, and alkaline ones thermo-electro-negative; and, reasoning upon the results obtained in his most recent experiments, concludes:—

SCIENTIFIC AMERICAN SUPPLEMENT, No. 120. APRIL 20, 1878

CLAMOND'S IMPROVED ELECTRIC THERMO-PILE

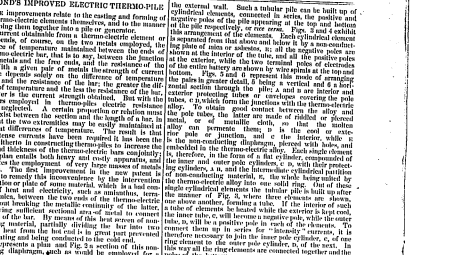
THERE improvements relate to the casting and forming of the thermo-electric elements themselves, and to the manner of grouping them together into a pile or a decimeter.

The current obtainable from a thermo-electric element or pair depends, of course, on the two metals employed, the difference of temperature maintained between the two ends of the element—between the bar, that is to say, between the junction of the metals and the free ends, and the resistance of the bar. With a given pair of metals the strength of current available depends solely on the difference of temperature kept up and the resistance of the bar; the greater the difference of temperature and the less the resistance of the bar, the greater is the quantity of electricity obtained. But with the metal bars employed in thermo-piles electric resistance may be neglected. A certain proportion or relation must always exist between the section and the length of a bar, in order that the maximum effect may be established at any very great differences of temperature. The result is that when intense heat is employed it has been found to be the most economical disadvantage, pierced with holes, and embedded in the thermo-electric alloy. Each single element is thus formed of a flat cylinder, compounded of the inner and outer portions of the two metals.

Figs. 1, 2, and 3 represent a vertical and a horizontal section through the pile; *a* and *a* are interior and exterior protecting tubes or envelopes covering the pole tubes, *c*, *c*, which form the junctions with the thermo-electric alloy. To obtain good contact between the alloy and the pole tubes, the latter are made of riddled or pierced metal—of sheet metal cloth, so that the molten alloy may permeate them; *b* is the cord or asbestos, and *d* the cement which closes the ends of the annular chamber thus formed. The poles, *e*, *f*, are then soldered to the ends of the single cylindrical elements, which are built up one upon the other, by means of clamps, which exercised such excessive row of bars or elements increased the weight of that beneath it, and from this cause the elements of the battery became screwed. Messrs. Wray now set them in a vertical manner by giving to each row of elements an independent support. It is, however, in the heating arrangements that their improvements are most conspicuous. The power of this form of battery depends upon the subjection of the elements which constitute it, at certain points, to temperatures of as opposite a character as possible; thus one end of the bars has to be subjected to as intense a heat as they can sustain, and the other end to as intensely cold an atmosphere as can be produced. Various have been the means adopted to produce a pile which should stand this intense heat, and the action of the gases forming the products of combustion of whatever is employed to heat the pile, but hitherto they have been unsuccessful. Messrs. Wray proposes to reduce, if not entirely to obviate, this by employing an enclosure over-lapping the outer bars of the pile and the chimney heated by the flame. By regulating the flow of air and the draught they are also able to keep under control the heating and cooling process, so as to make it more gradual and uniform. On the whole the improvements suggested by Messrs. Wray are of a very practical character, and are highly spoken of.

NEW LIGHTNING PROTECTOR.

A paper was also read by Mr. Andrew Jamieson on a new form of "Lightning Protector," for submarine cables. The idea, which has been very prettily perfected, but nothing electrically new in it (vide Art. 14), nevertheless, mechanically is not improved on in the means at present adopted for the protection of cables, which usually consisted of plate protectors, vacuum tubes, and one sole platinum wire. These are usually so arranged that the atmospheric charge entering from the open line wire shall pass through the plate protector first, then the small platinum wire, and finally through the vacuum. The probability is that the intensity of the charge would be carried off at the first-named protector; but failing this, if of such power as to injure to the cable, it would so heat the fine platinum wire as to fuse it, whereby the line would become interrupted until an officer was sent to replace the melted wire, and as this is usually at the shore end of the cable, it unfortunately occupies some time to do so. Mr. Jamieson connects his open wire to a corrugated barrel within a corrugated cylinder, the corrugations intermeshing each other, and so forcing innumerable points by which the intensity of the atmospheric charge may be carried off. He then connects the barrel of what may be regarded—having reference to previous arrangements—the plate protector, to a spring which normally rests against a small pillar, and which is in connection with another spring similarly arranged. Each of these springs is withheld from touching the pillar in question by a piece of fine platinum wire attached to its end, the other end of each piece of wire being connected with the cable. The result is that supposing a charge to have passed through the barrel, it will pass into the first-named piece of platinum wire, which will fuse, and the tension of the spring having been thus removed it will fly back to its pillar of platinum wire. Thus the cable is saved from interruption and still protected, the lineman's journey to the cable



CLAMOND'S IMPROVED ELECTRIC THERMO-PILE.

like partitioned metal plates, a form which permits of their sectional area being increased without increasing their length. Great differences of temperature with a very small distance between the poles, and consequently a much greater conductivity of electricity with less metal employed and less heat expended, are thus obtained. This diaphragm, or the paired plates, *d*, *d*, forms, to some degree, the function of a porous vase in a voltaic cell, while the uniting of two bipoles in contact in such a manner as to permit the passage of electricity, prevents them mixing too quickly.

Fig. 4 represents another mode of making elements suitable for the construction of small thermo-piles for domestic purposes. The frame is a section of a group of elements, *yy* being a perforated plate or flat cylinder of porcelain, Parian, earthenware, or other non-conductor of heat and electricity. *p p* are perforations into which a thermo-electric alloy, say, zinc and iron or zinc and platinum, is cast; *r r* are wires of German silver, or other thermo-electric metal, being cast into the alloy at their upper ends, the lower pole, the other end passing through a hole in the material of the diaphragm, and being bent over at *s*, where it is likewise cast into the alloy. If preferred, the wire may be coated with asbestos paper, or other insulating material, as shown at *r r*, and cast into the alloy itself. In either case the end of the wire is curved into the form of a loop, so as to afford a sufficiently extended surface to the metal to insure good contact. Fig. 5 shows how the thermo-electric junctions are formed and connected with each other in series. The perforations in the diaphragm may with advantage be formed like a double cone, as shown at *p p*, Fig. 6, so as to retain the alloy more firmly in its place. The plates, *d*, *d*, or earthenware diaphragm is laid with its face of the mould or hearth on the upper plane placed with holes, *p p*, resting in sand, and *r r* in the holes in the perforated plate, *y*. Holes are arranged opposite to *p p* to be filled at once by the fusion of the separate bars of the diaphragm, with its accompanying pile of metal alloy. In casting the diaphragm, which is composed of a circle, or more segments placed together, may form a cylindrical battery. Small piles so formed can be heated over an oil-lamp, gas flame or lamp chimney.

The thermo-electric elements from into a pile or large hollow upright tube, while the heated junctions are round the internal wall, and the cool junctions are round the external wall. Such a tubular pile can be built up of cylindrical elements, one above the other, the positive and negative poles of the pile appearing at the top and bottom of the pile respectively, or they may be built up of flat and 4 exhibit arrangement of the elements. Each cylindrical element is separated from that above and below it by a non-conducting plate of mica or asbestos, *n*; all the negative poles are shown at the interior of the tube, and all the positive poles at the exterior, while the two terminal poles of the series of the entire battery are shown by wire attached to the top and bottom. Figs. 5 and 6 represent this mode of arrangement in a somewhat larger detail. Fig. 5 is a vertical and a horizontal section through the pile; *a* and *a* are interior and exterior protecting tubes or envelopes covering the pole tubes, *c*, *c*, which form the junctions with the thermo-electric alloy. To obtain good contact between the alloy and the pole tubes, the latter are made of riddled or pierced metal—of sheet metal cloth, so that the molten alloy may permeate them; *b* is the cord or asbestos, and *d* the cement which closes the ends of the annular chamber thus formed. The poles, *e*, *f*, are then soldered to the ends of the single cylindrical elements, which are built up one upon the other, by means of clamps, which exercised such excessive row of bars or elements increased the weight of that beneath it, and from this cause the elements of the battery became screwed. Messrs. Wray now set them in a vertical manner by giving to each row of elements an independent support. It is, however, in the heating arrangements that their improvements are most conspicuous. The power of this form of battery depends upon the subjection of the elements which constitute it, at certain points, to temperatures of as opposite a character as possible; thus one end of the bars has to be subjected to as intense a heat as they can sustain, and the other end to as intensely cold an atmosphere as can be produced. Various have been the means adopted to produce a pile which should stand this intense heat, and the action of the gases forming the products of combustion of whatever is employed to heat the pile, but hitherto they have been unsuccessful. Messrs. Wray proposes to reduce, if not entirely to obviate, this by employing an enclosure over-lapping the outer bars of the pile and the chimney heated by the flame. By regulating the flow of air and the draught they are also able to keep under control the heating and cooling process, so as to make it more gradual and uniform. On the whole the improvements suggested by Messrs. Wray are of a very practical character, and are highly spoken of.

NEW LIGHTNING PROTECTOR.

A paper was also read by Mr. Andrew Jamieson on a new form of "Lightning Protector," for submarine cables. The idea, which has been very prettily perfected, but nothing electrically new in it (vide Art. 14), nevertheless, mechanically is not improved on in the means at present adopted for the protection of cables, which usually consisted of plate protectors, vacuum tubes, and one sole platinum wire. These are usually so arranged that the atmospheric charge entering from the open line wire shall pass through the plate protector first, then the small platinum wire, and finally through the vacuum. The probability is that the intensity of the charge would be carried off at the first-named protector; but failing this, if of such power as to injure to the cable, it would so heat the fine platinum wire as to fuse it, whereby the line would become interrupted until an officer was sent to replace the melted wire, and as this is usually at the shore end of the cable, it unfortunately occupies some time to do so. Mr. Jamieson connects his open wire to a corrugated barrel within a corrugated cylinder, the corrugations intermeshing each other, and so forcing innumerable points by which the intensity of the atmospheric charge may be carried off. He then connects the barrel of what may be regarded—having reference to previous arrangements—the plate protector, to a spring which normally rests against a small pillar, and which is in connection with another spring similarly arranged. Each of these springs is withheld from touching the pillar in question by a piece of fine platinum wire attached to its end, the other end of each piece of wire being connected with the cable. The result is that supposing a charge to have passed through the barrel, it will pass into the first-named piece of platinum wire, which will fuse, and the tension of the spring having been thus removed it will fly back to its pillar of platinum wire. Thus the cable is saved from interruption and still protected, the lineman's journey to the cable

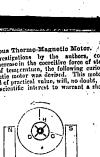
---

electric currents may be obtained from a charcoal fire, from the waste heat of a furnace, or from gas. Where gas is employed as the source of heat, the apparatus is arranged as shown in Fig. 10, which consists of a thermo-electric tube having its interior heated by a flame or brazier. The heating surface is increased by being vertical, and is protected against the immediate contact of the flame by a return flue which causes the products of combustion to re-traverse the interior before finally passing off by the chimney. The tube is surrounded on the outside by an envelope of cold water, so as to act as a refrigerator to the outer poles. Two other sources of heat are utilized by the inventor, namely, the steam boiler and then at a high temperature, and waste steam. Fig. 7 shows the arrangement of the tubular poles, *c f*, being made to harbour steam boiler tubes, as in the Field boiler. Fig. 8 shows the second plan in which the tubes receiving steam to be condensed are enveloped by the thermo-electric tubes, which are isolated from them by rings of constrictions or other material.

The manufacture of Clamond's new pile in England is in the hands of Latimer Clark, Muirhead & Co., Westminster, London.—*Telegraphic Journal.*

A Curious Thermo-Magnetic Motor.

During investigations by the authors, concerning the increase in the coercitive force of steel by changes of temperature, the following curious thermo-magnetic motor was devised. This motor, though devoid of practical value, will, no doubt, be of sufficient scientific interest to warrant a short description.



In the figure, a disc or ring of thin steel, D, is mounted on an axis, so as to be quite free to move. The edges of the wheel are placed opposite the poles H and S, of a magnet. In this position the wheel of course becomes magnetized by induction.

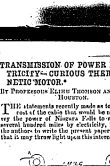
If now, any portion of the wheel, as H, be suddenly heated, the disc will move in the direction shown by the arrow. The cause of this motion is as follows:—The section, H, when heated, has its coercitive force thereby increased, and being inpowerfully sensitized by the induction of the pole S, than the portion, C, (near finitely adjacent to it) the attraction exerted by the pole, S, on the latter portion is thereby sufficient to cause a movement of the disc in the direction shown by the arrow. If the portion C be heated instead of H, a slow motion in the direction shown by the arrow will also result.

To assure success, the disc must be sufficiently thin to prevent its acquiring a uniform temperature. If the source of heat be at the same time applied at diametrically opposite portions of the disc, as at H and D, adjacent to the poles, the same effect will be produced. Since the amount of heat expended is practically the same in either case, the former is the more economical when compared with the latter. It will be readily understood that this motion is of no value as such, but may be regarded as an interesting example of the interconvertibility of force.

TRANSMISSION OF POWER BY ELECTRICITY.—CURIOUS THERMO-MAGNETIC MOTOR.*

BY PROFESSEUR ELIHU THOMSON AND EDWIN J. HOUSTON.

THE statements recently made as to the size and cost of the cables that would be needed to convey the power of Niagara Falls to a distance of several hundred miles by electricity, have induced the authors to write the present paper, in the hope that it may throw light upon this interesting subject.



As an example of some of the statements alluded to we may cite the following words. That much by a certain electrician, who asserts that the thickness of the cable required to convey the current that could be produced by the power of Niagara, would require a copper cable of 4 inches in diameter. Another writer, in the report of Lake Superior, another statement estimates the cost of the cable at about 50 dols. per lineal foot.

As a matter of fact, however, the thickness of the cable required to convey such power is of no particular moment. Indeed, it is possible, should it be desired, to employ even the total power of Niagara through a cable of *less than one inch in diameter*. The cable not exceeding one-half of an inch in thickness. This, however, is an extreme case, and the conditions of practical working would not require such ratios as to size.

The following considerations will elucidate this point:—Suppose two machines connected by a cable, one at each end, to work. One of these machines is for the purpose of driving the other, it, used as an electrical motor, is receiving power by the current transmitted to it from A by the cable C. The other terminals, 2 and 2, are either put to earth or connected by a separate conductor. Let us suppose that the electromotive force of the current at the terminals of A were, by the excitation of B, a number of volts which we will call *e*, that of A, the electromotive force of the current which flows is evidently the difference of the two. Let the resistance of A and B together be equal to unity, and that of the cable of any equal convenient between the 01 of this unit. Then the current which flows will be $C = \frac{e}{1+1} = \frac{e}{2}$. If, now, an additional machine, A', like A, and an additional motor, B', and an additional mile of cable be introduced into the above circuit, the electromotive force of the latter and the resistance will be doubled, the current strength remaining the same as C. Or $\frac{2e}{1+1+1} = \frac{2}{3}$. Here it will be seen that the introduction of the two additional machines, A' B', has permitted the length of the cable, C, to be doubled without increasing the strength of the current which flows, and yet allowing the original E. M. F. at the terminals of A, and a double tension at B. If we power or, in other words, a *double resistance* in the external circuit without *increase of current*. Moreover, one, the number of machines at A to, say, one thousand, and of those at B to A proportion, and the distance between them, or the length of the cable, one thousand, or in the case we have supposed, make it one thousand miles, the diameter remaining the same. Then, although the *same current* will flow, yet *we have a thousand times the expenditure of power at one end of the cable and a thousand-fold recovery of the other end, without increase of current.* And the same would be true for any other proportion.

Since the electromotive force is increased in proportion to the increase of power transmitted, the insulation of the cable and machines would require to be proportionately increased.

As an example it may be mentioned that a Gramme electric machine used for the purpose of A in the figure, may have a resistance of, say, 40 ohms, and produce an electromotive force of, say, 100 volts. Such a machine might require from three to five horse-power when used in connection with a similar motor, B, for recovery of the power transmitted.

If the resistance of the motor B be, say, 40 ohms, and the cable transmitting the current a distance of one mile be 1 ohm, then the current $C = \frac{100}{40+40+1} = \frac{100}{81}$. If, now, one thousand machines and one thousand motors, and a thousand miles of cable, each of the same relative resistances, be used, the current $C = \frac{1,000 \times 100}{1,000 \times 81}$, which is manifestly the same value as C. If our supposition of the power used to drive the machine be correct, then these five thousand horse-power would be expended in driving the machines, and possibly about 50 per cent. of this amount recovered. Then we have from 1,500 to 2,000 horse-power delayed a distance of 1,000 miles. What diameter of copper cable will be required for such transmission? Since this cable is supposed to have the resistance of one ohm for one mile, and since a mile of wire of one inch diameter is .0 of such line. It, however, its diameter be only 500 miles, then the resistance per mile may be double, or the section of the cable be decreased one-half, or its diameter will be less than one-fifth of an inch.

For the consumption of 1,000,000 horse-power a cable of about three inches in diameter would suffice under the same conditions. However, by proportionately increasing the number of machines, the cable could be proportionately reduced, until the theoretical minimum, which we have given in the first part of this paper, might be fulfilled. The enormous electromotive force required in the above combination would, however, necessitate such perfect insulation of the cable that the practical limits might soon be reached. The increased power required to be conveyed in any one direction would, of course, require a proportionately increased speed of the motor; it may be hardly conceivable that any one would avail advantageously use the enormous expense of speed we have referred to.

Stripped of its theoretical considerations, the important fact still remains, that with a cable of very limited size an enormous quantity of power may be transmitted to considerable distances, and converted into its equivalent of mechanical work by means of power generated by the force of steam, and therefore be regarded as practicable, always, however, remembering that a loss of about 50 per cent. will be almost unavoidable.

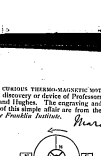
It may be mentioned that Dr. C. W. Siemens and Sir William Thomson have recently made statements that are in general accordance with the views here expressed.

THERMO-ELECTRICITY.

—We have at various times and in various places discussed the question, What part will Thermo-Electricity play in the future as regards Electric Lighting? The answer at present is not altogether satisfactory; yet we may fireplace could be so utilized as to provide at least a sufficiency of electric light for an ordinary room. As is not to this point that we desire now to call attention, but to the waste of power in using the current from one dynamo-electric machine for the coils of the electro-magnets of the other. The following quotation will be read with interest, and probably suggest all that we intend to suggest at present:—"I desire of last June, with a thermo-electric pile, consisting of thirty pairs of bismuth and antimony, 1½in. square and ¼in. thick, with the radiation of red hot iron at one extremity and ice at the other extremity, a soft iron electro-magnet, under the inductive influence of the electricity thus generated, supported ninety-eight pounds weight, the most powerful thermo-electric magnet I have heard of; but it must be observed that this is no maximum, for whoever employs a larger elementary battery will, no doubt, obtain greater effects, not only as regards inductive influence on soft iron, but all others in which the influence of temperature may be exerted. There is an ample field for investigation open for those who leave leisure on this subject. Who knows but hereafter electro-magnetism may be employed as a prime mover, and that a thermopile may be the exciting cause?" (P. Watkins in Phil. Mag., Sept., 1837.] It may be that we shall have to record a speedy answer to this question.

A CURIOUS thermo-magnetic motor, devoid, probably, of practical value, but having some scientific interest, has been devised by Prof. Houston and Thomson *Journal* of the Franklin Institute). A disk or ring of thin steel is mounted on a vertical axis so as to be quite free to move with its edges opposite the poles of a horse-shoe magnet. The wheel of course becomes magnetized by induction. On heating a section of its edges to move, The reason is, that the heated section has its coercitive force increased, and so, being less powerfully magnetized by the induction of the adjacent pole, than the part next it, the attraction exerted by the pole on this latter part is sufficient to cause motion. A constant source of heat given continuous rotation. The disk must be sufficiently thin to prevent its acquiring a uniform temperature. The best may be applied at diametrically opposite parts, with similar effect. What renders the motor of little value is the amount of heat required, being so enormous as compared with the force developed.

A CURIOUS THERMO-MAGNETIC MOTION is the joint discovery or device of Professors Thompson and Hughes. The engraving and description of this simple affair are from the *Journal of the Franklin Institute*.



During investigations by the authors, concerning the increase in the coercitive force of steel by changes of temperature, the following curious thermo-magnetic motor was devised.

In the figure, a disk or ring of thin steel D is mounted on an axis, so as to be quite free to move. The edges of the wheel are placed opposite the poles H and S of a magnet. In this position the wheel of course becomes magnetized by induction.

If now any section of the wheel, as H, be suddenly heated, the disk will move in the direction shown by the arrow. The cause of this motion is as follows: The section H has its coercitive force thereby increased, and being thus powerfully sensitized by the induction of the pole S, than the portion C (near finitely adjacent to it) the attraction exerted by the pole S on the latter portion is thereby sufficient to cause a movement of the disk in the direction shown by the arrow. If a constant source of heat be applied at H, a slow rotation in the direction shown is maintained.

To insure success, the disk must be sufficiently thin to prevent its acquiring a uniform temperature. If the source of heat be at the same time applied at diametrically opposite portions of the disk, as at H and D, adjacent to the poles, the same effect will be produced. Since the amount of heat expended in producing motion of the disk is so enormous when compared with the force developed, it will be readily understood that this motor is of no value as such, but may be regarded as an interesting example of the intercovertibility of force.

Annales der Physik und Chemie, No. 3.—In Wied. Annalen, they modify, but by Sir W. Thomson and M. Le Roux, with regard to the thermo-electric behaviour of stretched wires. Here Cohn has recorded a number of experiments which he made on an integral di-suretion. He finds that the intensity of the thermo-current between a stretched and unstretched wire of the same metal, depends (apart from all *permanent* properties), not only on the pre-ent tem-ture of the latter, but also, in very sensible degree according to the material used, on the upper and lower limits between which, since the last energies relense from tension, have been raised (the *maximum* alone, not the *time*, being here determined). In a thermo-chain of two similar wires, stretched with equal weights, but of which one (a) has last borne a greater, the other (b) a less weight, the current flows from *b* to *a*. In iron and steel the previous ten-ion even affect the direction in which the thermo-current varies with increasing or decreasing tension. Taking the direction of the current which arises with the *first* weak stretching, it is opposite for hard and soft wires, and the di-cendence above referred to is then established. Here Cohn thus formulates his general conclusion: "A stretched wire behaves, *ceteris paribus*, differently, according as it has before been stretched more weakly or more strongly, and this different continues till the next alteration of the tension."—Herr S. Weber contributes a useful notice on the electro-

LES PILES THERMO-ÉLECTRIQUES

A LUMIÈRE DE M. CLAMOND

Les piles thermo-électriques imaginées par M. Seebeck, en 1821, n'avaient été considérées pendant longtemps que comme des générateurs d'une grande constance, susceptibles d'être employés avec beaucoup d'avantage dans les expériences scientifiques, mais incapables d'être appliqués en pratique en raison de la faiblesse de courant qu'ils produisaient; l'application que fit, il y a quelques années, M. Marcus du pouvoir thermo-électrique considérable des alliages métalliques avait été faite, dès l'origine, par M. Seebeck, qui indique même l'usage d'anti-moine et de zinc comme un de ceux qui donnent couramment employés mais on n'est qu'à une époque d'emploi des piles thermo-électriques ont été appliquées, et la combinaison qui donne les meilleurs résultats est celle que M. Ed. Becquerel a indiquée et dans laquelle l'argentan est remplacé par un alliage, pour les mêmes raisons scientifiques cette combinaison donne les meilleurs résultats. Pour les mêmes raisons industrielles elle ne pourrait pas être facilement employée d'abord parce que le prix de l'appareil serait excessivement élevé, ensuite parce que la grande résistance du système ne pourrait pas être vaincue par une température aussi basse que celle à laquelle peuvent être exposées les autres alliages. De notre côté, nous avons employé le fer et le zinc avec limes de fer adoptés par M. Clamond, quoique ne donnant pas par elle-même une force électro-motrice aussi considérable, peut cependant donner meilleurs résultats par la plus grande différence des échauffements que l'on peut lui communiquer.

talliques (1) et la possibilité de les chauffer à une température élevée sans détériorer la pile, firent entrer la question des piles thermo-électriques dans une nouvelle phase, qui fut exploitée avec succès par plusieurs physiciens et en particulier par MM. Farmer, Bunsen, Ed. Becquerel, Clamond, Noé, etc. On put alors obtenir des piles dont l'intensité électrique pouvait être comparée à celle des éléments à acide, et ces piles furent même employées avec beaucoup d'avantages pour la galvanoplastie et l'électrotypie; mais, de tous les appareils de ce genre, ceux qui donnèrent les plus grands effets furent sans contredit les piles de M. Clamond.

Dès l'origine de son invention, c'est-à-dire en 1870, M. Clamond avait prévu qu'il pourrait un jour obtenir avec ce genre de pile de la lumière électrique et voici ce que j'en disais dans mon *Exposé des applications de l'électricité*, t. I, p. 426, publié en 1871 : « MM. Mure et Clamond construisent en ce moment, dans ce système, des batteries de 1500 grands éléments, qu'ils prétendent être de la force de 50 éléments Bunsen. Si, comme tout le fait espérer, la dépense se produit dans les mêmes conditions que dans le cas étudié (chauffage au coke), la dépense sera environ de 30 centimes par heure, et la pile thermo-électrique pourra ainsi devenir une source économique de lumière électrique. »

Ce résultat toutefois ne put être obtenu par suite des mauvaises conditions d'installation de la pile, et parce que la galène que M. Clamond employait alors s'altérait au feu. Néanmoins ces expériences purent le convaincre que le problème pourrait un jour résolu, et c'est en effet ce que nous voyons aujourd'hui. Toutefois, pour arriver au résultat si important que nous avons pu constater, il a fallu que M. Clamond se livrât à de nombreuses expériences et à de nombreuses recherches, et ce n'est qu'après neuf années qu'il a pu résoudre complètement le problème. Aujourd'hui une pile Clamond, disposée un peu comme un calorifère et dont les dimensions ne dépassent pas 1 mètre 50 cent. de hauteur sur 80 centimètres de côté, peut fournir quatre foyers de lumière électrique valant chacun de 15 à 20 becs de gaz en n'exigeant pour toute dépense d'action électrique qu'une combustion d'environ 9 kilogrammes et demi de coke par heure. C'est, comme on le voit, un résultat vraiment merveilleux et d'autant plus important qu'un appareil de ce genre ne nécessite pas la présence d'un mécanicien ou d'une personne compétente. L'appareil peut être placé dans une cave et disposé même de manière à pouvoir être employé comme calorifère, et toute personne est susceptible de pouvoir le faire fonctionner, puisqu'il ne s'agit, pour cela, que de le chauffer comme un calorifère ordinaire.

Mais disons sur quel principe repose cet ingénieux appareil.

Si deux métaux différents se trouvent soudés ensemble par une de leurs extrémités et qu'on chauffe cette partie soudée, le mouvement de la chaleur, se produisant d'une manière différente dans les deux métaux, détermine une force électro-motrice qui fournit un courant électrique que l'on peut recueillir aux extrémités des deux lames. Les métaux simples dont la réunion donne les effets thermo-électriques les plus marqués sont le bismuth et l'antimoine, mais, comme nous l'avons dit, les alliages et certains minerais métalliques donnent des effets beaucoup plus énergiques. Dans l'origine, la pile de M. Clamond se composait de barreaux de galène soudés à des lames de tôle; mais il dut bientôt y renoncer, et il eut recours à un alliage composé d'antimoine et de zinc, tout en conservant la lame de fer comme lame électro-positive. En disposant ces éléments en couronne, en superposant plusieurs de ces couronnes l'une au-dessus de l'autre et en projetant la flamme d'un foyer central sur les différentes soudures de ces éléments à l'intérieur des couronnes, il put obtenir, avec une pile de dimension assez petite, un courant électrique d'une valeur égale à celui de deux éléments Bunsen. Mais, dans ce système, la force électro-motrice du couple était en rapport avec la différence de température des deux extrémités de chaque barreau, et il fallait, en conséquence, que ces barreaux fussent un peu longs pour obtenir un effet énergique. D'un autre côté, il arrivait

(1) La découverte du pouvoir thermo-électrique considérable des alliages métalliques avait été faite, dès l'origine, par M. Seebeck, qui indique même l'usage d'anti-moine et de zinc comme un de ceux qui donnent couramment employés mais on n'est qu'à une époque d'emploi des piles thermo-électriques ont été appliquées, et la combinaison qui donne les meilleurs résultats est celle que M. Ed. Becquerel a indiquée et dans laquelle l'argentan est remplacé par un alliage. Pour les mêmes raisons scientifiques cette combinaison donne les meilleurs résultats. Pour les mêmes raisons industrielles elle ne pourrait pas être facilement employée d'abord parce que le prix de l'appareil serait excessivement élevé, ensuite parce que la grande résistance du système ne pourrait pas être vaincue par une température aussi basse que celle à laquelle peuvent être exposées les autres alliages. De notre côté, nous avons employé le fer et le zinc avec limes de fer adoptés par M. Clamond, quoique ne donnant pas par elle-même une force électro-motrice aussi considérable, peut cependant donner meilleurs résultats par la plus grande différence des échauffements que l'on peut lui communiquer.

souvent que l'appareil reçoivait des coups de feu et que le métal fondait autour des parties des lames de fer qui y étaient soudées; c'est ce qui fait que M. Clamond n'avait pu employer ce genre de pile pour les grands effets qu'il cherchait à réaliser. Il dut donc modifier entièrement la disposition primitive de sa pile, et, après de nombreux essais, il arriva à la disposition dont nous parlons aujourd'hui et qui est tout à fait remarquable; néanmoins les premières piles de M. Clamond sont encore employées aujourd'hui dans les ateliers de M. Goupil et autres où elles fonctionnent toujours d'une manière satisfaisante. Nous laissons maintenant la parole à M. Clamond pour décrire sa nouvelle invention et exposer les nouveaux principes sur lesquels elle est basée.

TH. DU MONCEL.

NOTE DE M. C. CLAMOND

SUR SA NOUVELLE PILE THERMO-ÉLECTRIQUE

Présentée à l'Académie des sciences

Par M. TH. DU MONCEL, en séance du 5 mai 1879

La nouvelle pile thermo-électrique que j'ai l'honneur de présenter à l'Académie réalise, dans l'ensemble et les détails de sa construction, des dispositifs très-importants qui ont complétement changé le rendement obtenu jusqu'alors de ce genre d'appareils et en font des puissants générateurs d'électricité capables de produire économiquement la lumière électrique.

Les piles thermo-électriques construites jusqu'ici étaient un assemblage de prismes ou barreaux qui, après avoir été fondus dans des moules spéciaux, étaient ensuite réunis et soudés les uns aux autres.

La chaleur était communiquée aux soudures chaudes des couples, par le contact de flammes, combiné parfois avec le rayonnement de surfaces chauffées par ces mêmes flammes. Les prismes se refroidissaient progressivement sur toute leur longueur, par le rayonnement et le contact de l'air, on obtenait la différence de température nécessaire entre les deux séries de soudures.

Les appareils ainsi compris présentent dans leur principe même des imperfections radicales au point de vue du rendement.

1° Ils entraînent la nécessité de donner aux couples une certaine longueur pour qu'ils puissent se refroidir suffisamment et maintenir la différence de température indispensable entre les deux séries de soudures. Cette longueur crée une résistance électrique considérable du couple et, partant, une faible intensité du courant produit.

2° Ils comportent une consommation inutile du calorique; car le calorique qui, par le rayonnement et le contact de l'air, s'échappe des surfaces latérales du prisme, se trouve ne pas avoir parcouru toute la longueur du barreau, et, par conséquent, ne donne pas le maximum d'utilisation dont il est susceptible au point de vue de sa transformation en électricité.

3° L'emploi des flammes ou des surfaces rayonnantes rend le chauffage des couples très-difficile à régler et n'est guère pratique qu'avec le gaz pour combustible et des appareils de petites dimensions. De plus, comme les surfaces de chauffe, représentées par les sections des couples ou des appendices polaires dont ils sont quelquefois munis, sont très-faibles, une petite proportion du calorique développé par la combustion est seulement recueillie, les produits de la combustion se dégageant à une très-haute température.

Dans le nouveau système, je me suis attaché à éviter les vices précités. A cet effet, l'appareil est composé de trois parties entièrement distinctes.

1° Le collecteur qui est un assemblage de pièces de fonte de fer légères, de formes telles qu'elles présentent une suite de carneaux dans lesquels circule l'air brûlé provenant d'un foyer quelconque. Ces pièces offrent une très-grande surface au mouvement des gaz chauds qu'elles n'abandonnent qu'à une température très-voisine de la leur; elles emmagasinent une petite proportion du calorique développé par la combustion et seulement recueillie, les produits de la combustion se dégageant à une très-haute température.

Dans le nouveau système, je me suis attaché à éviter les vices précités. A cet effet, l'appareil est composé de trois parties entièrement distinctes.

1° Le collecteur qui est un assemblage de pièces de fonte de fer légères, de formes telles qu'elles présentent une suite de carneaux dans lesquels circule l'air brûlé provenant d'un foyer quelconque. Ces pièces offrent une très-grande surface au mouvement des gaz chauds qu'elles n'abandonnent qu'à une température très-voisine de la leur; elles emmagasinent la chaleur qu'elles communiquent ensuite aux couples.

2° Le diffuseur de calorique qui forme l'extérieur de l'appareil et est constitué par des lames métalliques présentant à la circulation de l'air ambiant une surface considérable.

3° Le système thermo-électrique proprement dit qui est placé entre le collecteur et le diffuseur, de manière à ce que les séries opposées des soudures participent aux températures différentes de ces deux organes. L'écoulement de la chaleur se produit du collecteur au diffuseur en traversant les couples, parallèlement à leur longueur, sans perte appréciable de calorique par les surfaces latérales; réalisant ainsi le maximum du rendement de transformation dont les substances employées sont susceptibles.

Le système thermo-électrique est combiné de manière à rendre sa construction économique et pratique, sa manipulation facile et sûre, et sa résistance intérieure aussi faible que possible. La longueur des prismes est très-faible et n'est pas la plus grande des trois dimensions.

Les lames métalliques qui les relient présentent un dispositif particulier qui a pour effet de répartir les points de soudure ou contacts sur toute la section du barreau. Enfin, dans des moules dont l'emploi est très-simple, on coule d'un seul jet, un grand nombre de ces couples qui, par l'opération même, se trouvent réunis en séries et constituent une chaîne flexible, aussi longue que l'on veut, dont les extrémités sont les deux pôles d'une pile élémentaire thermo-électrique.

Ces chaînes, pressées entre le collecteur et le diffuseur, desquels elles sont convenablement isolées, peuvent être reliées les unes aux autres par leurs extrémités libres, ce qui permet de réaliser à volonté tous les accouplements et combinaisons que l'on se propose.

En résumé, l'appareil peut être assimilé à un calorifère chauffé par un foyer ordinaire dans lequel est brûlé un combustible quelconque et dont les parois, par suite des systèmes de construction précédemment exposés, transforment en électricité une portion du calorique qui s'écoule au travers. L'extérieur du calorifère, présentant une très-grande surface diffusante, rend ces appareils éminemment propres au chauffage et leur permet de remplir la double fonction d'éclairer et de chauffer.

Le coefficient de transformation des alliages thermo-électriques énergiques est beaucoup plus élevé qu'il n'était communément préjugé, et je me propose de faire ultérieurement à ce sujet des communications fixant quelques-unes de ces données.

Pour le moment, en prenant l'appareil au point de vue de son rendement pratique, c'est-à-dire considérant le poids de combustible brûlé sur la grille et les données numériques du courant produit, voici quelques chiffres d'après les expériences que M. G. Gabonellas a faites depuis deux mois; expériences qui concordent d'ailleurs avec les miennes.

Ces expériences ont été faites sur un appareil dont la surface de chauffage est de 20 mètres carrés, qui mesure 1 mètre de diamètre et peut faire marcher simultanément deux lampes, système Serrin, avec un pouvoir éclairant variant de 30 à 50 becs carcels pour chaque lampe, le foyer ayant été soumis à différentes conditions de tirage et de chauffage.

La résistance intérieure d'un demi générateur est :

R = 1,5 ohms.

La force électro-motrice en chauffe normale est :

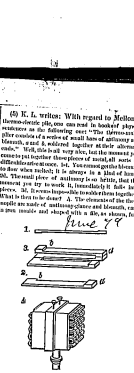
E = 109 volts.

Ce qui pour la pile entière représente une force électro-motrice de 218 volts. Cette force électro-motrice équivaut à celle de 121 couples de Bunsen fraîchement montés (1,8 volt par Bunsen). La consommation en chauffe normale est en moyenne de 9 kilogrammes de coke à l'heure.

L'équivalent du courant résultant des données précédentes, est de 1,333 unités électro-mécaniques, lesquelles représentent 136 kilogrammètres par seconde.

C. CLAMOND.

(5) R. L. writes: With regard to Mellon's thermo-electric pile, one can read in hundred of physics treatises as the following one: "The thermo-electric pile consists of a number of small bars of antimony and bismuth, 2 and 3, soldered together at their alternate ends." Well, this is all very nice, but the moment you come to put together these pieces of metal, all sorts of difficulties obtrude themselves. Yes, but you must get the bismuth to flow when melted; it is always in a kind of lump. Oh. The small piece of antimony is on bottom, but the moment you try to work it, immediately it falls into pieces. Ah, I have a capsule to enable it to run together. What is that to be done? A. The elements of the thermo-couple are made of antimony-zinc and bismuth, cast in pans ironite and shaped with a file, as shown, full



size, in Fig 4. The bars of antimony must be tinned on both heads, at 6, with very fusible solder by means of a small soldering iron. The bars of antimony and bismuth may be held together between copper screws, and the spaces between the bars filled with pieces of wood, which may be allowed to remain to impart greater solidity to the pile, but they must not extend beyond the joints. The vertical rows of the pairs each are then soldered, and these are united when all of the pairs are complete. The end pieces of each row must have an offset at right angle to the bar, as shown in Fig 2. Fig. 3 shows the combination of the end pieces of two vertical rows. When the pack of 20 or 25 pairs is completed, lay it in a wood or square case of brass, having first soldered to the middle of the first and last bars short copper wires, which pass through two loop lined holes in the case and are provided with permanent binding screws. The vacant spaces are then filled with plaster of Paris, which is allowed to expand away so as to leave the ends of the bars bare, and these are then blackened. In making this instrument a great deal of patience is required, as a breaking of a number of the bars is unavoidable.

NOË'S THERMO-ELECTRIC PILE.

By ALFRED NIAUDET.

THIS thermo-electric pile is constructed in various forms of which the figure represents the most simple and the smallest.

The elements are in plan placed horizontally and radiate like the spokes of a wheel; the heated junctions lie towards the centre, and the cold junctions towards the outside, as shown in fig. 1.

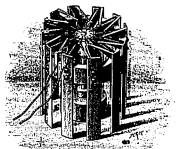


FIG. 1.

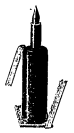

FIG. 2.

The two metals are 1st, German silver, and 2nd, an alloy of antimony, which melts at a temperature a little above the fusible point of antimony; but the exact composition of which has not been made public.

These two metals are soldered together (at least at the hot junction) without the intervention of any other metal; the wires of German silver have fixed at their extremities little capsules of brass which serve as moulds into which the other metal is cast. One of these little capsules is visible in fig 2, which represents a single element of the natural size; it remains attached to the element and forms part of the apparatus.

In the same capsule a little lug of copper penetrates, the extremity of which is equally held in the cast metal, and by means of which the heat is conducted to the hot joint.

The opposite extremities of the lugs of copper are joined and arranged in a little circle and heated by a peculiar flame from a lamp burning methylated spirit, or by a Bunsen burner.

In order to concentrate the heat of the flame the latter is covered by a circular disc of mica, which is held by the copper lugs.

Each cold junction is slightly different: here the fusible metal is soldered to a plate of copper, to which are soldered the German silver wires of the following element.

The plate of copper exposes a large surface, and has for its object the cooling of the junction by radiation in the first place, and by contact with the air in the second.

These plates of copper can be plunged into water at their upper extremities, so that the cooling of the cold junctions can be more effectually done; but practically this expedient is not always adopted.

The cooling by the influence of the air is simpler and is practically found to be sufficiently effectual.

These piles have been tested with great care by M. Waltenhofen of Prague; he has compared them with those of M. Marloye, and finds them to be very superior to them.

The results of experiments by M. Stephan, show that the thermo-electric elements of Marloye have an electro-motive force of one-eighteenth of a volt; but that this maximum corresponds to a temperature very near the fusing point of the metal of which the elements are composed.

Under similar conditions, M. Waltenhofen has found that the elements of Noë; have an electro-motive force of one-ninth to one-tenth of a volt.

Practically, these maximum values must not be expected, and when several elements are connected together, these maxima are never obtained, because all the elements do not become heated to the same degree, and about one-sixteenth of a volt for electro-motive force, and one-fortieth of a Siemens' unit (*) for resistance represents about the power of the pile.

A very useful addition to the apparatus, consists in the addition of a gas regulator for the prevention of the overheating of the pile. This is liable to happen from an increase on the pressure of the gas supply, an increase in the heat being thereby produced, which may fuse the metal of the elements and thus destroy the pile.

The regulator is particularly useful with the large piles, composed of a great number of elements, but can be dispensed with in the smaller piles of the kind illustrated.

With a small pile of 12 elements, an electric bell can be rung and similar experiments made; with 20 elements, water can be decomposed in a voltameter.

With 40 elements, a Planté secondary pile can be charged, or an induction coil worked; in fact, these answer for all the usual physical experiments made with an ordinary battery, and for small industrial operations, such as plating with gold, silver, or nickel, &c.

A great advantage of these piles consists in the fact that they attain their full power in one or two minutes, and the moment they are no longer wanted, the gas can be put out and all expense ceases.

In fine, and this point is important, *the pile does not deteriorate or change from constant use.* This is not the case with those which hitherto have been made, and which, after a time, considerably increase their resistance, so that the strength of the current they give, becomes at last so weak as to render the pile useless.

(*) Waltenhofen—Dingler's Polytechnisch. Journal, 1877. Vol. 22 ; page 169.

SUDRE'S THERMO-PILE.

ONE of the most important of the new French thermo-piles, designed for the electric lighting of large shops, offices, halls, and theatres, is that of M. Jean Marie Sudre, a detailed notice of which we are compelled, from want of space, to defer until our next. It will be remembered that Clammond's pile failed because of the heat source coming in contact with the thermo-electric joints themselves, and gradually consuming them. In Sudre's pile this danger is obviated by interposing a guard material between the heat source and the junctions. The heat source may be steam or hot liquid, heated air or gas circulating in flues past the protected hotter thermo-electric junctions. A large heating surface is offered to the circulating medium. Coke or coal is burned in the pile, which requires no skilled attendance except occasional stoking. Three electric lights, steady and brilliant, can be produced from it, and, as the waste of an intermediate dynamo-electric machine is suppressed, at a cost much less than the cost of gas. Any lamp may be used, but an improved form of Serrin is at present preferred. This thermo-pile is about to be introduced into England by Mr. Applegarth.

SUDRÉ'S THERMO-PILE.

In designing his new form of thermo-pile, M. Sudré has had several objects in view. The characteristic points in the invention are: 1st. Low internal resistance of the couples under a very small volume, and the arrangement of these couples in chains in a particular manner, so as to facilitate their grouping together, and mounting; 2nd. The arrangement of the couples between heating and cooling surfaces; 3rd. The peculiar method of conducting the heat to the one set of metallic junctions; and 4th. The peculiar method of cooling the other set of junctions.

In designing the form of the bars of which the couples are composed, two points have to be considered—1st. The resistance; and 2nd. The tendency of the bar to become equally heated from end to end. *Now*, as M. Sudré points out, the resistance of a bar varies as $\frac{\text{length}}{\text{sectional area}}$, and if this proportion be preserved constant, the resistance will remain the same; but the greater the length of the bar, the slower will the heat diffuse itself along the bar. But if the bar be made very long and correspondingly large in sectional area, great bulk will be obtained. The problem then is to determine what dimensions the bars should have to give the best effect consistent with smallness of volume. M. Sudré finds that for differences of temperature of from 12° to 120°, the bars should be 10 to 12 millimetres long, and for temperatures ranging up to 200°, from 20 to 30 millimetres long.

In short couples the method of soldering the points of union of the two diverse metals is a matter of the greatest importance. The junction should be made so that the one metal (in the form of a plate) should be in contact with the whole of the surface of the section of the bar, but at the same time should not penetrate to any depth in the latter, for the effect of its so doing would be to much diminish the electro-motive force of the couple. To obtain this double object, the extremity of the plate forming a couple is cut in the form of a comb (fig. 1), the teeth of which are twisted on themselves, as shown by fig. 2, so that whilst the surface of the twisted metal remains the same, its length becomes much reduced. The twisted cut portions form the connections on to which the bars are cast.

The plate with the twisted prolongations is best, as shown by fig. 2.

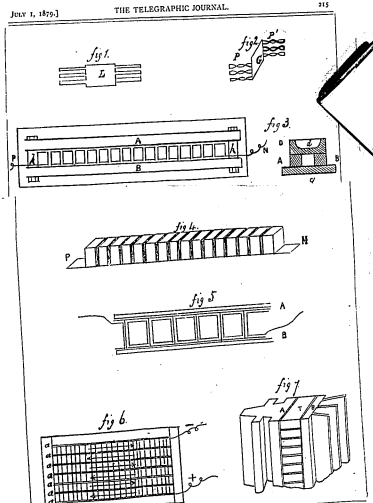
Each side of the full part a of the plate is coated with silicate of soda or other heat resisting material.

The mould in which the alloy bars are cast is shown by fig. 3. It is composed of a base c, two side pieces A B, maintained parallel by two cross pieces x and x', and of a cover D, carrying a longitudinal furrow pierced with holes, d, equal in number to the number of couples to be contained.

The plates being prepared as described, are placed in the mould between the two side pieces A B; the cover D is then placed on the top and the melted alloy run in, so that the series of plates become bedded in blocks of the alloy, as shown by fig. 4.

The chains of blocks so formed are arranged in the following manner:—

Two metallic plates, A and B, fig. 5, which are represented as pieces but which may be cylindrical or curved, are covered on one side with a thin layer of an electrically insulating substance such as enamel. Between these two isolated surfaces is placed one or more of the thermo-electric chains, in such a manner that the extremes of the couples rest upon the enamel surfaces. If several chains are arranged side by side between the two same plates, then they must be arranged so that the opposite poles of two contiguous chains are side by side;



Prof. Bunsen, by the employment of different metals from those hitherto tried, found that he could increase the strength of the current, and M. Marcus, of Vienna, using alloys instead of simple metals for the positive and negative element, reduced the cost, while increasing the power of the battery. From a thermo-electric battery constructed on his principle, and also from a modified form, devised by Wheatstone, a current sufficiently strong to produce brilliant sparks, decomposse water, &c., was obtained. This was in 1865, and but little progress has, until now, been made in this branch of science, with the exception of the improved forms of thermo-pile devised by Noë and by Messrs C. and L. Wray, although the utilisation of heat—especially solar heat—for the production of electricity has long attracted the thoughts of many experimenters.

M. Clamond has for some time been at work upon the subject, and has so far succeeded that his thermo-electric battery has been employed since 1872 in M. Goupil's factories. These batteries are formed of iron, as the electro-positive element, and an alloy of antimony and zinc for the negative; they are soldered together and arranged in a circular form, which can be built up as high as may be desired. The junctions of the metals are heated in the interior, but the electromotive force being proportional to the difference of temperature between the two extremities of each bar, it was necessary to make the bars long if a strong current was desired, and then the results were less satisfactory, owing to the increased internal resistance of the melting of the metals where they were soldered, &c.

It is these hindrances to its extended use which M. Clamond has sought to obviate in his latest form of battery, which is composed of three distinct parts. The *collector* consists of a number of pieces of cast-iron so arranged that the heated air can circulate within them; a large surface is thus exposed to the heat, which the iron collects and communicates to the couples. The *diffuser* is the outside of the apparatus, and is made of sheets of metal. The *thermo-pile proper* is placed between these two, and is so arranged that the junctions of the metals are alternately at the temperature of the collector and the diffuser. Heat passes from the collector to the diffuser along these couples, which have no great length. In some forms which are very easily worked, a number of these couples are made into a flexible chain of any desired length, the extremities forming the poles of the battery. These chains, insulated from the other parts of the apparatus, can be united to each other by their free ends, so that a variety of couplings and combinations may be made. The model now in use for lighting a workshop in Paris is about 25 metres high, and 1 metre in diameter, the exterior form being that of a polyhedron, to the sides of which the thermo-electric chains are attached; these are composed of small cubes of zinc and antimony joined together by plates of tin, to which they are soldered. Each half of the apparatus has 30 chains of 100 couples each, or 6,000 couples in all. To the outer surface of these chains are fixed the sheets of copper which form the diffuser or heat distributer.

Another model, made for the recent exhibition at the Albert Hall of the various systems of electric lighting, is square and much smaller, though of the same power.

Each half of the cylindrical battery can be made to supply a powerful electric light, while the square one can produce four lights of half the brilliancy. The electromotive force is, according to prolonged experiments, 216 volts, about equal to 120 Bunsen cells, while the resistance is 31 ohms. The large battery consumes only 9 or 10 kilogrammes of coke an hour, and the smaller one even less, about 6½ kilogrammes. Moreover, the large surrounding adopts it admirably for use in heating, as well as for lighting, and it can thus be made to serve the double purpose of giving warmth and light.

M. Sudré has also designed his thermo-pile with a view to obtaining one of small volume and having a low internal resistance; the other peculiarities of his battery consist in the manner in which one set of junctions are heated while the other set are cooled. He has also determined what is the best length for the bars forming the couples, in order that the necessary difference of temperature at the two extremities may be maintained, while yet making them as small as possible. This he finds should be from 10 to 30 millimetres, according to the difference of temperature required. His manner of soldering together the two different metals is also novel and ingenious. In order that contact may be made with the whole surface of the bar, he cuts the plate, forming one metal, into the shape of a comb, twisting the teeth of this comb together, thus retaining a large surface, which yet has only a short length. The bars are fastened on to these twisted parts and the uncut part of the plate is coated with silicate of soda. The couples are formed in a mould in which the plates are fixed, the melted alloy is then run into the mould so that a block is formed of the alloy and the plates, firmly united. These chains or blocks are then placed between two plates, coated on one side with enamel or other electrically insulating substance; several chains may thus be arranged side by side, each chain being both calorically and electrically insulated. The parts of the chain are electrically insulated by the thickness of the plates, but heat can flow across the couples. The chains are next placed between a collector and a diffuser; the collector is filled if the source of heat be gas, in order to expose a greater surface. The diffuser is also ribbed for the same reason when the heat is merely allowed to radiate into the air. The whole battery is so arranged that the collectors form the inside of a circle within which the heated air is circulated.

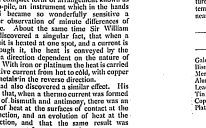
THE RISE OF THE THERMO-PILE.

It is giving a short sketch of the development of the thermo-pile, we shall first say a few words on the history of thermo-electricity in general.

As early as 1707, the thermo-electric properties of tourmaline had been pointed out by a German writer, who, under the initials of J. G. S., published a book entitled "Curious Speculations During Sleepless Nights." Indeed, in ancient days, Theophrastus had shown that tourmaline, like amber, could be electrified by friction; but he does not appear to have had the idea that the electrification might be due to the *warming* produced by friction. In 1759, Alpinus, in Germany, called attention to the same fact, and pointed out that electricity of opposite kinds was manifested at opposite ends of the crystal. In 1760 Canton observed similar phenomena with the topaz; and, towards the close of the century, other observers, notably M. Haüy, showed the thermo-electric properties of various other substances.

It remained, however, for Professor Seebeck, of Berlin, to discover, in 1821, that when the junctions of two metals forming part of a circuit was heated, an electric current flowed through the circuit; Seebeck is, therefore, justly regarded as the discoverer of thermo-electricity. The apparatus he employed to illustrate this consisted of a simple frame of antimony and bismuth, with a suspended magnetic needle placed within. The approach of the flame of a spirit lamp to either of the junctions produced a deflection in one or other direction.

Professor Jas. Cumming, of Cambridge, extended Seebeck's experiments, and, in 1823, ascertained that the unequal distribution of heat in the circuit was the cause of thermo-electricity, and he drew up a table of positive and negative thermo-electrics. He also made an important discovery in what is called the thermo-electric *inversion* of various metals at different temperatures, a fact now constantly made use of in the construction of thermo-piles. It means that a metal which is thermo-positive to another at one temperature may be negative to it at a higher or lower temperature. This may be seen from fig. 1, which was given by Sir William Thomson, in



the Bakerian lecture for 1856 (Phil. Trans.). In 1830 Dr. Botto, of Turin, made a thermo-electric battery of platinum-iron pairs; and, in 1831, Nobili devised the compact form of arrangement known as the thermo-pile, an instrument which in the hands of Melloni became so wonderfully sensitive a machine for observation of minute differences of temperature. About the same time Sir William Thomson discovered another fact, that when a metal circuit is heated at one spot, and a current is passed through it, the heat is conveyed by the current in a direction dependent on the nature of the metal. With iron or platinum the heat is carried by the positive current from hot to cold, with copper and other metals in the reverse direction.

Peltier had also discovered a similar effect. His theory was, that, when a thermo-current was formed in a circuit of bismuth and antimony, there was an absorption of heat at the surfaces of contact at the warmer junction, and an evolution of heat at the colder junction, and that the same result was obtained if a current from any exterior source were passed through such a circuit.

Sir Wm. Thomson, who thoroughly investigated the subject, pointed out that this explanation was incomplete, for, when a junction is at the neutral point, no Peltier effect can occur; the two metals being thermo-electrically identical.

The following table, prepared by Professor Tait, gives the temperatures at which certain metals are neutral to each other:—

Iron	-	-	-	+	357 °F.
Tin	-	-	-	+	45
Brass	-	-	-	+	27
Lead	-	-	-	-	—
Zinc	-	-	-	—	31
Copper	-	-	-	—	68
Cadmium	-	-	-	—	69
Aluminium	-	-	-	—	113
Silver	-	-	-	—	115
Palladium	-	-	-	—	181
German Silver	-	-	-	—	324

Professor Tait has also observed that the thermo-electric lines of the various metals, for varying temperatures, are approximately straight lines, a fact which greatly simplifies the calculation of electromotive forces for any desired combination.

In 1837 Dr. Andrews, of Belfast, found that fused salts could be employed as thermo-electric, and constructed a battery with platinum wires, dipping into fused salts.

The first patent taken out in this country for a thermo-electric battery, was that of Moses Poole, in 1843. Poole used two pairs of German silver and iron rods, cemented in plaster of Paris; the lower ends were heated in a sand-bath, while the current of cold water was kept flowing over the upper ends. This battery was used for depositing metals.

In 1852 Mr. J. Roberts and C. Watt obtained patents, the former (among other things) for using hot air to excite the battery; the latter, for a combination of antimony and bismuth pairs.

We should also mention that, in 1847, Alexander Bain had employed a thermo-pile for regulating clocks, by means of a plate or lens, driven by trainwork, and containing a slot through which the sun's rays passed at certain times of the day. In 1853 H. Kemt employed the pile for thermometric measurements.

The first application (and perhaps the only one) of the thermo-pile to telegraphic use, was made by Mr. C. F. Varley, who, in a patent obtained in 1856, described a pile to be used in conjunction with Inductum coils, for telegraphing over short lines.

In 1862 Dr. Matthiessen read a paper before the Royal Society, in which he pointed out that some substances, such as silver, copper, and bismuth, have their conductivity increased by having heated for a considerable period, while others, such as tellurium, have their conductivity diminished by like treatment. Dr. Matthiessen had previously investigated this and kindred subjects most laboriously, and had drawn up the table given below—namely, and had drawn up the table given below—namely, the first really accurate one published, most either the first really accurate one published, most either, in experimenters having observed the fact that, in measuring the electro-motive force of any pair of junctions produced by a given difference of temperature between the opposite junctions, the mean temperature of the circuit should be constant, or nearly so.

THERMO POSITIVE :—

	Silver and copper = 1.	Microvolts per degree Centigrade.
Galena	+ 21'96	+ 45'0 65
Bismuth	+ 7'32	+ 4'18
Mercury	+ 2'32	
Aluminium	+ 1'28	
Lead wire	+ 1'02	
Tin wire	+ 1'00	— 0'1
Copper	+ 1'00	— 0'1
Platinum	+ 0'72	— 0'9

THERMO NEGATIVE :—

Silver	... ...	—	370
Graphite	... ...	—	705
Zinc	... ...	—	727
Iron (piano wire)	... ...	—	5·20 — 1·73
Antimony	... ...	—	5·87 — 23 to 28
Antimony 2, Zinc 1...	...	—	2770
Tellurium	... ...	—	79·70 — 102
Selenium	... ...	—	29100 — 897

The above table is extracted from Dr. Matthiessen's paper in the Philosophical Transactions for 1858.

Referring to the left-hand column of figures, it will be seen that he takes silver as his zero metal, and, calling the effect of a silver-copper pair 1, he measures the electro-motive force of all the other couples by this standard, these above silver being considered thermo-positive metals, and those below it thermo-negative. The mean temperature was 19° to 20° C.

The right-hand column is a table calculated from this by Professor Jenkin, showing approximately the thermo-electric force of each couple in micro-volts for each degree Centigrade. Professor Jenkin, however, takes lead in his zero instead of silver. The tensions above lead are, therefore, positive, and those below are negative, and to obtain the power of any positive and negative couple we must add the two together; thus bismuth and antimony have a force of 44 + 23 as compared with that of silver and copper, or a tension of 68 microvolts for each degree Centigrade.

(To be continued.)

SUDRE'S THERMO-ELECTRIC GENERATORS.

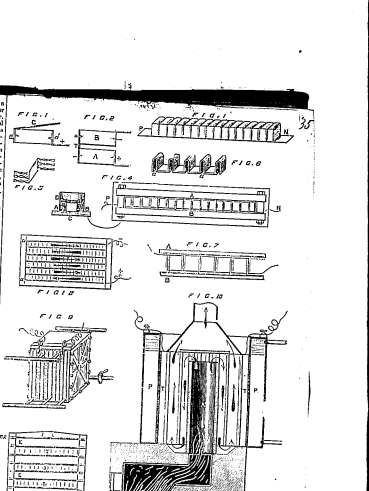
THE Abbé Moigno has described in the *Cosmos* a series of magneto and dynamo machines he has had the effect of inducing some experimentalists to devote a little attention to the possibility of devising a thermo-electric generator, which, while comparatively simple in itself, would dispense with the steam-engine or other motor that adds to the cost of the electrical power by the machines at present in use. If report can be credited, M. Sudre, of the Boulevard St. Denis, Paris, has obtained results so satisfactory with his thermo-electric pile that he has taken out patents in the chief countries. The following are the characteristic points of the invention :—1st. The construction of thermo-electric couples having a feeble internal resistance under a very small volume, and their disposition in chains for facilitating assemblage and dismounting. 2nd. The maintenance of the differences of temperature necessary between the two soldering-points of each couple by placing these couples between two surfaces with which they are electrically connected. One of the surfaces is designed to heat the warm soldering, and makes part of a metallic system called the "collector," which has the effect of collecting and storing the caloric from the source of heat, and communicating it to the couples across the isolated foil. The other surface is designed to cool the cold soldering, and makes part of a metallic system (with the employment of liquids sometimes), termed the "diffuser," which has for its object to draw and collect the caloric from the couples, and to cause it diffusing it into the air, or for transporting it to the cold, or of a medium to a point where it is desired to utilise it.

In the construction of thermo-electric couples and chains an isolated thermo-electric couple is ordinarily composed of a piece in metal or alloy, A, Fig. 1, and of a paler piste of iron, copper, German-silver, or similar metal or metallic alloy to each of its extremities. The plates do not ordinarily interfere in the production of the electric force obtained, and it is the bar A, such as that of antimony and zinc, which constitutes in a great measure to the total effect produced. When it is desired to use two metallic or similar alloys, of which the effects are combined, and which are easily fusible, such as the bismuth and antimony, the couple is formed then of two bars A and B (Fig. 2), which are joined together by a cross-bar T, which binds them and is soldered to each. The total resistance of a couple is compressed, by, of the resistance of the plate C (Fig. 1). 2nd. of the resistance of the bar A, ordinarily formed of alloys sufficiently resistant; 3rd, of a particular resistance at the points of contact or soldering, *a*, *a'*, of the pair and end of the bar. *Resistance of the Plate.*—This metallic plate should be of a metal sufficiently conductive, such as copper, iron, German-silver, or zinc, composition, and sufficiently large and thick for presenting but a feeble resistance. It should have also the least length or unfolding possible, and conditions which are realised in the following fashion. *Resistance of the Bar.*—To obtain for the bar A very feeble resistance under a small volume, M. Sudre takes as starting point the formula $R = K \frac{L}{S}$, in which R is a specific coefficient for the matter employed; L, the length of the couple; and S, its section. As the resistance depends upon the relation $\frac{L}{S}$, one should in diminishing these two dimensions into the same relation diminish the volume of the couple without increasing its resistance. The length of the couple depends equally upon the difference of temperature employed, and in the greater as these differences are greater. For the difference of temperatures from 10 to 120 degrees he gives to the couples a length of 6 to 12 millimetres, and for those of 300 degrees a length varying between 18 and 24 millimetres. *Resistance of the Soldering.*—But about couple also the formation of the products of the two points of contact or soldering is of the highest importance. The junction should be made so that the plate should be in contact with the points of the whole section of the bar, and at the same time it is necessary to give little depth in the bar, so as not to diminish too much the electromotive force of the couple; for the difference of temperature really effective is that of the temperatures of the two solderings, and this difference diminishes as we degree to the plates penetrating deeper into the bars approach one another. To obtain this the ends object the extremity of the plates is cut in the form of a cusp, the teeth of which are lodged upon themselves in such a manner as to present a bi-bevelled surface, which holds them, as it were, screwed into the metal. This cut portion is shown in the cut model at the end of the bar in such a manner that the teeth are imbedded in the metal. The ends of each plate should be cleaned at the insertions of the plate which are distributed on the whole section of the bar.

In the case where the couple is composed of two cast bars (Fig. 2) the cross-bar T will carry the couple to each extremity. Having thus explained the condition to be realised and the means of realisation in the construction of a thermo-electric couple, M. Sudre proceeds to explain of employing the bars, as in a single cast of metal or alloy, so that the bars cast simultaneously are found bound and coupled together, and forming a flexible thermo-electric chain, easy to handle, facilitating the mounting of the apparatus, and realising the minimum of resistance desired.

Fig. 3 represents the plates cut and bent twice at the time of using it for the formation of the couple. The centre C is bent, and the two bent parts are cut and twisted as described. On each side of the full part D of the plate is pasted with silicate of soda, or fixed by any other means, a slide plate of a non-conducting substance capable of resisting the contact of the cast metal, such as paper of animalins (or powder), mica, terra-cotta, or other suitable material. The mould (Fig. 4) is composed of a foot G, of two side pieces A, B, maintained parallel by two cross-pieces of a corer D carrying a longitudinal former E, grooved with holes equal in number to the number of couples contained. The plates prepared as we have described are placed in the mould between the two side pieces A, B, as is represented in Fig. 4. Then, placing the cover D on the top and running in the cast alloy, the interior of the mould is filled, and the bent extremities of the plates are bedded in the cast metal. In taking the mould in pieces, we obtain a cast bar, as represented in Fig. 5, composed of as many elementary couples, equal in length, which can be varied at pleasure, and this chain is found to be a thermo-electric chain, the extremities of which, P and N, are the poles. The paper of animalins (or selenite) may be used in various ways: in plates, folded, and bent, as Fig. 6 indicates. The prepared plates are then placed in the slits *a*, and the whole is then placed in the mould the cast of the metal will be placed in forms of a chain, analogous to that of the preceding case. In the case represented in Fig. 2 (where the thermo-electric couple has been formed of two cast bars A, B, the formation of the chain will be in an analogous manner. First of all the bars of metal the less fusible, these A for example, will be cast separately, and will carry at each extremity a cross bar T, cut into a cusp, as before directed. Then prepared, the first series of bars should be of the same form as the best in any two metals, A and B (without the paper in the mouths in lieu of the plates. The fusion of the second metal B in finding the open extremities of the cross-bars will form a thermo-electric chain composed of couples similar to those of the preceding case.

Two metallic plates A and B, Fig. 7, which are represented as plates, but which may be cylindrical or curved, are maintained at their faces by a thin layer of isolating substance of electricity. This substance should be a thin layer of enamel applied on the metal, or a layer of mica if the temperature of the plate is elevated; or it may be a varnish, a leaf of vulcanised india-rubber, or a thin gummy or oily stuff if the temperatures employed are less elevated. Between these two isolated surfaces is placed one or more thermo-electric chains in such a manner that the extremities of the couples which constitute these chains press upon the isolating surfaces. When more chains are used side by side between the two same plates they should be returned each time in such a manner that the opposite poles of two contiguous chains are found side by side; they may be easily coupled in tension. Fig. 8 shows this arrangement, and the manner in which the current flows according to the directions of the arrows. The contiguous chains should be also isolated the one from the other by an isolating band *a*, of asbestos, of vulcanised paper, mica, indiarubber, or other isolated. In the case where the surfaces A and B are curved, and where it is formed between two contiguous chains should be filled up with isolating matter, such as animalins (or selected parts, to avoid the lateral loss of caloric; all the elements of the chains are electrically isolated by the relating thickness of the plates, but they are not isolated calorically, so that if by any means the plate A (Fig. 7) is maintained at a high temperature, and that B at a lower temperature, the caloric will flow across the isolated leafs and penetrate the couples, through which it will continue its course from one soldering to the other. The difference of temperature between the two will be within very little of the temperature between the soldering of the couples. As long as A and B preserve their respective temperatures a thermo-electric current will be furnished by the battery formed by the chains, and will be collected as shown by Fig. 8. The plates A and B, Fig. 7, form part of two systems having for their object, one, the "collector," [illegible]



BRIGHT'S TYPE-PRINTING TELEGRAPH.

Kelly's Journal, 1852

THE principle upon which this apparatus, the invention of Sir C. T. Bright, is worked, is decidedly novel: it is briefly that of causing the letters to be printed by inserting different artificial resistance into the line circuit at the sending station.

Fig. 1 shows the transmitting apparatus at the sending station. It consists of a key-board, the keys of which are of ivory or wood, so as to be insulated from each other, and are marked with the letters of the alphabet. Each of the keys is fixed upon a metallic spring a, one end of which is connected to a resistance coil b. The other end of each resistance coil is connected to earth. Immediately beneath the keys, and along the entire key-board, there is a metallic bar c, c, moving on centres d, d; when at rest it is pressed by a spring against the metallic plate e, which is connected to earth. A metallic pin f, attached to the under side of the spring of each key, breaks the connection between c and e when any of the keys is depressed, and contact then being made between f and b, the resistance coil belonging to the key is placed in the circuit.

Fig. 2 shows the working parts and connections of the type-printing instrument at the receiving station; o and h are the coils of a differential relay, and the upper portion of the figure represents a

FIG. 1.

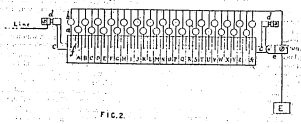


FIG. 2.

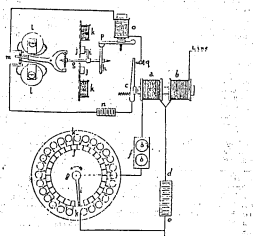

local circuit, made or broken by the armature lever c. The lower portion also shows some of the parts comprised in the upper portion, and these are indicated by the same letters. Coil b is connected to the line wire, and to the pole of a battery whose other pole e is connected to earth. Coil a is also connected at one end to d, and at the other end to the adjustable rheostat f, composed of resistance coils which can be adjusted to equal the resistance of the line circuit, and can be varied to compensate for any change in the latter. The other end of f is connected to an axle g, g, upon which is fixed the type-wheel h, and also a metallic arm i, i, which, when the axle is in motion, passes over and makes contact with a series of metallic plates k, k, k, to which are connected a series of resistance coils l, l. Two or more type-wheels may be carried by g, g, so that two or more duplicates of a message may be printed simultaneously. L, L is an electro-magnet, and m its armature; n is a local battery by which L, L is worked, and the axle g, g, rotated thereby when the local circuit is closed by the action of c. A train of wheel-work, actuated by L, L in place of n, is an electro-magnet acting on p. When the instrument is in the position shown in the figure, being inserted at the sending station is completed by the motion of i and h, and i rotate until i reaches the particular plate k, by which the resistance inserted at the line, whereupon the current being balanced, c is separated from the type-wheel axles, and against h by p.

CLAMOND'S NEW THERMO-PILE, having a heating surface of 30 square meters, keeps two Serrin lamps lit, each giving a light equal to from 30 to 50 gas-jets. The internal resistance is only 11 ohms; the electromotive force 218 volts, or the value of 121 Bunsen cells; and the consumption of coke is 2 kilogrammes per hour.

THE RISE OF THE THERMO-PILE

(Continued from page 249.)

BUNSEN, MARBACH, AND STEAN, in 1867, exhibited piles of various alloys, but the first really good thermo-pile appears to have been that which Mr. Farmer, of America, exhibited in the Exposition of 1867. Mr. Farmer employed German silver and an alloy of copper, zinc, and nickel. This pile lost power rapidly, owing to increase of internal resistance, and the bars frequently broke in cooling.

In 1866, three patents were taken out by Lieut.-Col. James Baker, for various forms and improvements of thermo-piles. Baker was the first to employ the "Stellas" form of pairs, and he arranged them round a cylindrical or polygonal stove, with protecting cylinders of thermo-constituting material. This form is the one now most commonly employed. Baker also made a pile with bars of our thermo-electric metal, connected by copper wires.

In 1868, Mr. L. Moore and M. Clamond patented a pile of iron and galena pairs; and, in 1874, M. Clamond obtained letters patent for an improved form of this pile, a detailed account of which we give.

Three patents were taken out in 1872-5, by M. Faure, but are not sufficiently practical or interesting for description. In the latter year, Mr. C. J. Wallaston patented a pile composed of strips of tinned iron and German silver, the strips being set in a perforated fire-tile, and the hot junctions either enamelled or bedded in a non-conducting composition. The heat was supplied by gas, and a governor regulator, controlled either by clockwork or by a peculiar form of galvanometer-needle was used to adjust the supply. Mr. Wallaston also proposed to employ water-cups to cool the outer junctions.

M. Clamond's battery consists of tinned sheet-iron for the positive elements, and an alloy of two parts of antimony with one of zinc for the negative. The alloy, which melts at 800° F., is cast into bars from 1 to 2½ inches in length, and from ⅛th to 1 inch in thickness. The shape and disposition of the elements are shown in fig. 2. Forty-20 of these pairs give an electro-motive force of about 1 volt, and are, therefore, nearly equal to one Daniell cell.

The heat is usually supplied by gas, as in fig. 3, or by coke, as in fig. 4; but, in a recent modification, M. Clamond employs a "collector," composed of pieces of cast-iron, among which hot air circulates; a large surface is thus exposed to heat, the iron communicating the heat to the couples.

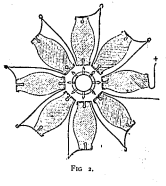

FIG. 2.

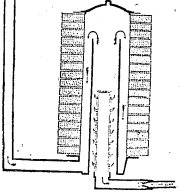

FIG. 3.

M. Clamond's latest achievement is the production of the electric light by means of his thermo-electric battery. For this purpose he has constructed a pile of 6,000 small couples, and with it he produces two powerful lights (or four lights of half the brilliancy). The E.M.F. of this battery is said to be 216 volts, and the resistance 31 ohms. Coke is used as the heat source, the consumption being 10 kilogrammes per hour. A small pile of the same number of pairs, and said to be of equal power, consumes only 6½ kilogrammes per hour.

If a thermo-pile be short-circuited, its effectiveness is reduced, the powerful current flowing through it tending to heat the cool junctions and cool the hot ones. In an elaborate and exhaustive paper upon M. Clamond's battery, read by Mr. Latimer Clark before the Society of Telegraph Engineers in 1876 (to which we are indebted for many of the above facts, as also for the illustrations), it was shown that a battery, short-circuited by a resistance equal to its own, had its E.M.F. rapidly reduced by 17 per cent. The pile may, conversely, be "polarised," by passing a powerful current through it, the effect being to heat one series of junctions and cool the alternate ones, thus leaving the pile in a condition to give out a sensible current. This follows from what has already been said respecting Sir William Thomson's and M. Peltier's investigations.

One of the chief applications of the thermo-pile is the deposition of metals. Mr. Clark states that in practice it was found that a battery of 375 pairs, having a resistance of 2·5 ohms, and a tension of 146 volts, deposited about 180 grains of copper per hour. He also points out, however, that these figures do not represent the effectiveness of the battery, as a similar deposition could have been produced in several successive cells.

In 1876 and 1877, Messrs. Crompton and L. Wray obtained patents for improvements in thermo-piles. These improvements may be summed up as follows. The bars (alloy of antimony, zinc, and iron) are cast under pressure; this increases the E.M.F. A strip of tinned iron is cast in them, extending nearly through their entire length; this adds materially to their strength, and to some extent increases the E.M.F., and decreases the resistance. The successive layers of couples are supported by a metal framework, the weight of the upper layers being thus prevented from falling upon the lower ones. An internal cylinder of earthenware is employed to keep the flame from impinging directly upon the bars, and also to cause the bars to cool more slowly, fractures being thus avoided. The supply of gas and air is regulated, and a wire-gauze chimney is used to prevent explosions.

M. Noë and M. Sudré have introduced important

modifications of the thermo-pile; but as these have been fully described in this Journal (June 15 and July 1, 1879), we need not refer to them here.

The following are some of the principal points to be observed in the construction of the thermo-electric battery:—

1. The materials should not be costly.
2. They should not be liable to fuse.
3. They should be protected from sudden heating and cooling.
4. They should not be acted upon by the products of combustion; or they should, at any rate, be protected therefrom, and from the deposition of moisture.
5. The disposition should be such as to allow a defective pair to be easily replaced.
6. The whole combination should possess strength and solidity.

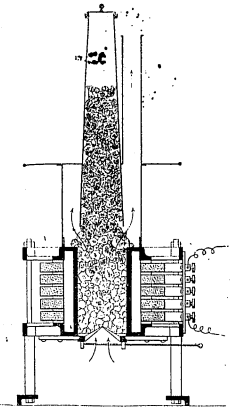

FIG. 4.

The present article is written in the hope that our countrymen will take up the subject and show that this branch of electrical science has not been abandoned to continental inventors.

Journal of the Telegraph.

A New Thermo-Electric Battery.

M. CLAMOND, a French electrician, has succeeded in devising a thermo-electric battery, producing a current sufficiently powerful to yield the electric light. A factory in Paris is now, indeed, lighted by this means. The apparatus consists of three parts: an inner one, composed of pieces of iron arranged in the form of a crown, which can be heated in the interior. This is called the collector, its purpose being to collect the heat and then communicate it to the adjacent thermo-pile proper. This consists of a flexible cloth, of any desired length, composed of cubes of antimony and zinc, soldered together by sheets of tin. In the complete apparatus there are 6,000 of these "couples," outside which are fixed the plates of copper to diffuse the heat of the collector. A large surface is thus exposed to the air, in order that as great a difference of temperature as possible may be maintained between the collector and the diffuser, for upon this difference the strength of the current chiefly depends. M. Clamond has been so successful that with one of his batteries he has been enabled to light two of Serrin's lamps, and with a smaller but equally powerful battery he can light four less brilliant lamps. This is done with the consumption of nine kilogrammes, or about twenty pounds of coke an hour for the larger, and six and one-half pounds for the smaller thermo-electric battery. The apparatus, moreover, gives warmth as well as light, since its large exterior surface causes it to radiate a considerable quantity of heat.

"The production of heat by friction may be readily exemplified by the following experiment due to Tyndall. A glass tube containing water (fig. 310), and closed by a cork, can be rotated rapidly about its axis. While thus rotating, it is pressed by two pieces of wood, covered with leather. The water is gradually warmed, and finally enters into ebullition, when the cork is driven out, followed by a jet of steam. Friction, then, may produce an intense heating of the bodies rubbed together, without any corresponding loss of heat elsewhere."

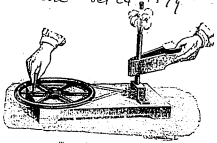

Fig. 310. Heat produced by Friction.

"The relations existing between electrical and thermal phenomena had considerable influence in leading to correct views regarding the nature of heat. An experiment devised by Foucault illustrates these relations, and at the same time furnishes a fresh example of the production of heat by the performance of mechanical work.

"The apparatus consists (fig. 312) of a copper disc which can be made to rotate with great rapidity by means of a system of toothed wheels. The motion is so free that a very slight force is sufficient to maintain it. The disc rotates between two pieces of iron, constituting the armatures of one of those temporary magnets which are obtained by the

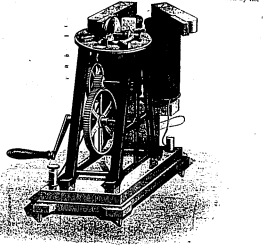

Fig. 312. Foucault's Apparatus.

passage of an electric current (called electro-magnets). If, while the disc is turning, the current is made to pass, the armatures become strongly magnetized, and a peculiar action takes place between them and the disc, consisting in the formation of induced currents in the latter, accompanied by a resistance to motion. As long as the magnetization is continued, a considerable effort is necessary to maintain the rotation of the disc; and if the rotation be continued for two or three minutes, the disc will be found to have risen some 50° or 60° C. in temperature, the heat thus acquired by the disc being the equivalent of the work done in maintaining the motion. It is to be understood that, in this experiment, the rotating disc does not touch the armatures; the resistance which it experiences is due entirely to invisible agencies."

"The most precise determination yet made of the numerical relation subsisting between heat and mechanical work was obtained by the following experiment of Joule.

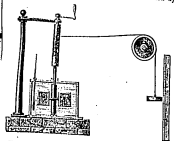

Fig. 313. Determination of the Mechanical Equivalent of Heat.

He constructed an agitator which is somewhat imperfectly represented in fig. 313, consisting of a vertical shaft carrying several sets of paddles revolving between stationary vanes, these latter serving to prevent the liquid in the vessel from being bodily whirled in the direction of rotation. The vessel was filled with water, and the agitator was made to revolve by means of a cord, wound round the upper part of the shaft, carried over a pulley, and attached to a weight, which by its descent drove the agitator, and furnished a measure of the work done. The pulley was mounted on friction-wheels, and the weight could be wound up without moving the paddles. When all corrections had been applied, it was found that the heat communicated to the water by the agitation amounted to one pound-degree Fahrenheit for every 772 foot-pounds of work spent in producing it. This result was verified by various other forms of experiment, and may be assumed to be correct within about one foot-pound."

Sur les appareils thermo-électriques de M. Clamond

Nous avons assisté, rue Saint-Ambroise, dans les ateliers de M. Denayrouse, à une expérience de lumière électrique faite avec un régulateur de M. Saisse et une pile thermo-électrique de M. Clamond.

Nous devons dire que l'effet général a été des plus satisfaisants. La régularité était très-grande et les interruptions excessivement peu fréquentes. Ses petites éclipses n'avaient pas une durée qui pût être gênante même pour les ouvriers d'art travaillant dans ce vaste atelier.

Si, au lieu de nourrir un seul bec, la pile Clamond avait pu donner de la lumière à deux ou à trois, il est incontestable que les petites irrégularités eussent été parfaitement indifférentes à l'œil.

Nous nous sommes retiré fort enchanté de l'expérience, qui se répète, paraît-il, quotidiennement et qui a duré, devant nous, un temps plus que suffisant.

M. Denayrouse nous a annoncé de plus que les chaînes thermo-électriques qui garnissent son poêle ont une durée en quelque sorte indéfinie. C'est un fait que nous n'avons pu vérifier et pour lequel nous devons nous rapporter à la bonne foi de notre informant; mais les chaînes que nous avons examinées nous paraissent en parfait état de service et n'avoir subi aucune espèce d'altération.

M. Denayrouse annonce que la quantité de lumière qu'il produit brûle neuf kilos de charbon par heure, ce qui est considérable par rapport à ce que consomme une machine dynamo. En effet, pour produire la même lumière avec des courants d'induction et un moteur fort ordinaire, on ne dépenserait point quatre kilos à l'heure. Mais il importe de faire à ce propos quelques remarques fort intéressantes.

D'après les calculs et les observations qu'il a faites, la lumière produite ne représente que 6 0/0 du chimique correspondant au charbon consumé.

Il en résulte que l'on peut concevoir facilement que la thermo-électricité n'est point arrivée à ses colonnes d'Hercule.

M. Denayrouse annonce, ce qui ne nous paraît point exagéré, qu'il est certain de produire la même effet avec six kilos de dépense horaire dans un foyer actuellement en construction.

En outre, si l'on place la pile Clamond dans un atelier où il y ait besoin de se chauffer, il est clair que les 91 0/0 qui restent de chaleur produite seront parfaitement utilisés.

La lumière produite ne coûtera dans ce cas que les 6 0/0 de 6,000 grammes, soit 360 grammes, ce qui est un prix parfaitement insignifiant.

Dans le cas où l'on ne pourra pas placer le poêle dans l'intérieur d'un atelier, on pourra monter un calorifère chauffé avec la chaleur perdue de la pile Clamond.

Nous dirons même que nous avons rencontré dans l'atelier de M. Denayrouse deux habiles chimistes belges établis à Nancy qui, ayant besoin de calorifères, ont ordonné qu'on les construisît de manière à pouvoir les revêtir avec les chaînes thermo-électriques de M. Clamond.

W. DE FONVIELLE.

Le degré de précision de nos mesures est mis en évidence par la petitesse des erreurs des quatre fractions qui forment notre quadrilatère de jonction. Ces erreurs, successivement de corrections, lorsque les lignes sont égales, ou résultats d'une, à

$$+0'',18, -0,54, +1'',8, -1'',12,$$

et ne dépassent pas, comme on le voit, les erreurs de ce genre qu'on rencontre dans les meilleures triangulations où les côtés ne dépassent pas 6 à 10 lieues.

Le problème de la position géodésique des deux extrémités est donc résolu, et le méridien de France s'étend aujourd'hui en une extension depuis les îles Shetland jusqu'en Sicile.

Commandant PERRIER,
Membre de l'Institut des Sciences.

La suite prochainement.

LES CONDITIONS CLIMATOLOGIQUES
DU DÉPARTEMENT DE LA MANCHE.

M. Henri Mangon a récemment présenté à l'Académie des sciences et à la Société d'agriculture, une très intéressante étude météorologique sur le climat d'une partie de la Normandie et sur l'influence qu'il exerce sur la maturité des récoltes.

« *Température.* Le climat maritime des côtes de la Manche, dit le savant professeur, est remarquable par sa douceur et sa régularité. La température moyenne des mois les plus froids de l'année est très supérieure à 0 degré. Habituellement, il gèle seulement un peu pendant quelques nuits de l'hiver et il n'est rare que la neige du sol ait la température soit inférieure à 0 degré. L'hiver de 1870-1871 constitue une exception des plus extraordinaires. La moyenne du mois de décembre 1870 a été de + 2°,3 au lieu de + 5°,01, et celle de janvier 1871 de + 2,15, au lieu de 5°,62. La température a descendu à — 8°,5, le 27 décembre 1870, et à — 11 degrés pendant les nuits du 2 et du 4 janvier 1871.

« La chaleur de l'été est aussi modérée sur nos côtes que le froid de l'hiver est peu intense. La température de juillet est de 17°,11. En 1876, elle a atteint le chiffre de 18°,06, et la plus haute température observée a été de 25°,4 le 25 juillet, de 28°,3 à l'ombre en 1870, époque, d'ailleurs, que des changements assez brusques entre le milieu du jour, le soir et le matin.

« Quand un sérieux de la côte, on remarque des figures très légères au branchement de la carte de bleu à brun gris. Les lignes sont bonnes et suivent tous les ans. Le raisin, au contraire, ne se sur les espaliers les mieux exposés, arrive très rarement à maturité.

« *Pluies.* Au point de vue de l'agriculture on ne peut pas caractériser un climat par la température seulement. La distribution par saison des pluies est un élément indispensable à connaître. Dans la Basse-Normandie, la hauteur moyenne annuelle de pluie est de 85^{cm},19, chiffre dépassé dans beaucoup de localités moins exposées, et qui excède de un mètre celui qui exprime la hauteur de la pluie à Paris. Le maximum de la pluie est en juin, pour le mois entier, de 8^{cm},15. Le minimum est en novembre et est égal à 6^{cm},05. En juillet et août la pluie est assez abondante et assez bien répartie pour qu'elle n'ait pas besoin d'être remplacée par l'irrigation. Le mois de septembre est le plus sec. Il est suivi de près par le mois de février. Le nombre de jours de pluie est de 150 environ. Il est plus grand en hiver qu'en été, mais la quantité absolue de pluie n'est pas très considérable dans le Bocage, les orages sont très rares et se distribuent d'une manière régulière entre les différents mois de l'année. Les averses sont donc très nombreuses et peu abondantes.

« Ces pluies fines, et en fréquentes, combinées avec une température douce et régulière, caractérisent et favorisent une région de pâturages. Si l'on ajoute à l'action sur la végétation, qui assure l'alimentation permanente à l'herbage par de l'eau fraîche, on comprendra les causes de la richesse et de l'étendue. »

Après ces documents météorologiques, l'auteur étudie l'influence du climat sur le développement et la maturité des plants de grande culture, a été conduit aux conclusions suivantes :

1° Dans un climat doux et régulier, comme celui où ont été faites ces observations, il y a presque toujours avantage à faire de bonne heure les semis d'automne.

2° On peut calculer avec une grande exactitude, un mois ou six semaines à l'avance, l'époque de la récolte d'a plantes dont on vient de parler, en faisant chaque année la somme de degrés de température observés depuis les semis, en excellant les tableaux numériques des observations moyennes de température.

—o—

CORRESPONDANCE

Monsieur le Rédacteur,

Permettez-moi, à mon tour, quelques observations au sujet de l'article de M. Jousset de Bellesme sur la manière dont certaines chrysalides de certaines espèces de papillons (Attacus, n° du 10 janvier 1880). J'ai publié en 1868 dans les Annales des Sciences naturelles (t. XXVIII, 5e série) un long mémoire sur la glande mandibulaire des insectes. Dans le chapitre consacré aux nymphes, j'ai démontré par de nombreuses expériences sur diverses espèces, entre lesquelles celle du Bombyx du mûrier, que le cocon est destiné à protéger et à diminuer l'évaporation des chrysalides, comme l'avaient admis par Réaumur et bon nombre des naturalistes, la dessiccation est retardée pour les chrysalides ainsi, et non le froid. Quand on les retire immédiatement du cocon, en exposant, au moyen d'instruments délicats, quelles ont toujours à la surface un pli rempli de température ou l'air ambiant, mais privé du cocon, leur surface s'hiver souvent un peu au-dessus de cette température, environ 1°, quelles épuisent une diminution rapide de poids.

Agréez, etc.

MAURICE GIRARD.

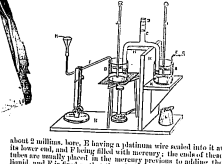
La Nature
LA PILE THERMO-ÉLECTRIQUE
DE M. CLAMOND

Si l'on mesure l'importance d'un problème au nombre des solutions proposées pour le résoudre, le premier rang appartient, sans aucun doute, à la production *économique et pratique de l'électricité*. Les méthodes connues peuvent se diviser en trois grandes classes :

THERMO-ELECTRIC BEHAVIOUR OF AQUEOUS SOLUTIONS WITH MERCURIAL ELECTRODES.

BY C. GOOD, M.A., F.R.S.*

In order to investigate this subject I devised and constructed the following apparatus:—A and B are two thin glass basins, 81 millims. internal diameter (= 5,153 sq. millims. of mercury surface), and 0·6 centims. deep; each containing a layer of mercury about 2 centims. thick, covered by a layer about 3 centims. deep of the aqueous solution to be examined. C is a thin bent glass tube, about 2 centims. diameter, filled with the liquid, and closed by means of a bung at D. E and F are stout glass tubes,



about 2 millims. bore, E having a platinum wire sealed into it at its lower end, and F being filled with mercury; the ends of these tubes are usually placed in the mercury previous to adding the liquid, and the E fixed so that the solution cannot enter it. G and H are terminal wires of platinum, touching the mercury but not the liquid. I and J are thermometers, with their bulbs immersed in the pools of mercury. Each cup is closed by a bung (not shown in the sketch) to prevent loss of liquid by evaporation, also to support the thermometer and keep the tubes steady. The whole is supported on wire gauze placed upon an iron tripod, with a Bunsen's burner beneath, and A is placed on a shelf level with it. K K K K is a wooden frame for supporting the apparatus, and L is a weight to keep it steady. This kind of apparatus was used in all the experiments, and acted very satisfactorily, I devised one of different construction for a similar purpose many years ago. (See *Phil. Mag.*, June, 1870).

The mercury employed was prepared by distilling the ordinary mercur in vacuo, and then shaking it strongly in succession with nitric acid, water, solution of cyanide of potassium, distilled water, and filtering it. Distilled water was used in making all the solutions.

In using the apparatus the mercury was first poured into the basins; the tubes E and F placed, taking particular care that the mercurial column in F made contact with the pool very completely. Two very small holes 1 millim rubber bungs were next inserted in the lower ends of the bent tube C, the tube then put in position, and filled with the liquid. The solution was now put into the basins, the long F inserted tightly, the shallow ones plattened of the exact height inserted in A and B. The contacts to the instrument, and, if necessary, a minute swing of the needle was obtained by repeated suction at proper intervals of time. It was now heated. About seven or eight minutes was usually occupied in bringing the temperature to the required number of degrees, the deflections at the various temperatures being noted. After an experiment had been made, the mercury and solution of both vessels were mixed and cooled, and the experiment filtered, before repeating it with the same liquid.

Care was taken to select solutions which had the least amount and less positive metals were, therefore, not employed. No liquid was used which precipitated any visible film or dulness upon that metal when treated with it. It was found necessary to heat each solution to about 180° F., and keep at, and then cool it previous to making experiments, otherwise the results obtained in repetition experiments were not quite uniform. In a previous research on the thermo-electric properties of liquids ("Proc. Roy. Soc." No. 188, 1878, pp. 513—520), in which platinum electrodes were employed, such previous heating was less necessary, probably because the thermo-electric currents were then stronger. After heating and cooling the liquid, it was freely shaken with the mercury, and then filtered, previous to making experiments with it. With every liquid, one or more repetition experiments were made in order to obtain uniform results and confirm their reliability; the amount of difference of deflection of the needles in such experiments did not exceed one degree. The galvanometer employed was an astatic one, having two coils, each of 50 ohms resistance, the two being connected and used as one of 100 ohms resistance.

I have ascertained by separate experiments of a different kind that mercury, when sufficiently agitated with solutions, neutral to test papers, or salts of the alkali metals, renders some of those liquids feebly alkaline; the effect, however, is so slight, requires such extensive and long-continued contact of the substances, that it appears consistent with the view that chemical action is not the cause of the currents in these thermo-electric experiments.

By arranging the results in a series with the solution at the top, in which the hot mercury was the most positive at 180° F., and that at the bottom in which it was most negative, the following order was obtained. The horizontal line separates those liquids in which the hot metal was positive from those in which it was negative.

	Amount of deflection.
1. Phosphate of ammonium	28·0+
2. Carbonate of sodium	19·0
3. Sulphide of sodium (50 grs.)	13·0
4. Sulphate of ammonium	12·75
5. Carbonate of potassium	12·5
6. Sulphate of potassium	12·0
7. Borax	10·0
8. Nitrate of potassium	10·0
9. Nitrate of strontium	10·0
10. Nitrate of sodium	8·0
11. Phosphate of sodium	8·0
12. Nitrate of barium	7·5
13. Nitrate of sodium	6·0
14. Formiate of sodium (100 grs.)	6·0
15. Ferrocyanide of potassium	5·0
16. Formic acid (30 minims)	5·0
17. Nitrate of ammonium	4·25
18. Formiate of sodium (50 grs.)	4·0
19. Selenic acid (20 minims)	3·75+
20. Formic acid (40 minims)	3·5
21. Sulphate of sodium	2·5
22. Bicarbonate of sodium (10 grs.)	2·5
23. Microcosmic salt (100 grs.)	2·0
24. Boracic acid	2·0
25. Selenic acid (10 minims)	1·5
26. Sulphuric acid (1 in 80)	1·25—
27. Ammonia alum (50 grs.)	2·0
28. Cyanide of potassium (25 grs.)	2·0
29. Hyposulphite of sodium	1·0
30. Ammonia alum (100 grs.)	1·0
31. Sulphuric acid (1 in 20)	0·75
32. Sulphuric acid (1 in 40)	0·75
33. Sulphuric acid (1 in 80)	0·0
34. Cyanide of potassium (5 grs.)	1·0
35. Cyanide of potassium (50 grs.)	4·0
36. Cyanide of potassium (100 grs.)	9·0

To ascertain whether this order agreed with that of a series arranged according to the different degrees of electropositive force of the various couples, I simultaneously employed two apparatuses similar to that already described (but with basins of 75 millims. internal diameter), changing one of them with one solution, and the other with another which was next to it in the above series, connecting them with the two wires respectively of the differential galvanometer, so that their currents circulated in opposite directions through the coil of thin insulated wire, ascertaining which gave the strongest current at 180° F. By this means the following series was obtained, in which the couple giving the strongest positive current is at the top, and that giving the most powerful negative current at the bottom of the series. The horizontal line separates those liquids in which the hot metal was positive from those in which it was negative. The relative positions of the solutions in the two series, although they agree in the main, are not identical; for instance, nitrate of potassium occupies the eighth place in the first series, and the second place in the second series; phosphate of ammonium, sulphate of ammonium, &c., are also changed in position. Such changes were probably affected by the circumstance, that whilst in the first series the electrodes were 81 millims. diameter (=5,153 sq. millims. of surface), and the current from a single apparatus circulated through a continuous double length of wire in the coil of the galvanometer, in the second series the electrodes were only 75 millims. diameter (= 4,418 sq. millims.), and

the current from a single apparatus circulated through a single half length of the coil. The temperatures at which the deflections were noted were also different in the two series. The surface of one electrode in the smaller apparatus was about $\frac{1}{7}$, and in the larger one $\frac{1}{9}$ of that of one of the platinum electrodes in the apparatus already referred to.

	Difference of amount of deflection.
1. Sulphate of ammonium	19+
2. Nitrate of potassium	19
3. Phosphate of ammonium	19
4. Sulphide of sodium (50 grs.)	19
5. Carbonate of sodium	0·75
6. Carbonate of potassium	1·0
7. Sulphate of potassium	1·5
8. Nitrate of strontium	0·25
9. Phosphate of sodium	0·25
10. Borax	0·25
11. Selenate of sodium	1·5
12. Nitrate of barium	0·25
13. Nitrate of sodium	1·0
14. Formiate of sodium (100 grs.)	1·0
15. Microcosmic salt (50 grs.)	0·75
16. Formiate of sodium (50 grs.)	0·75
17. Formic acid (30 minims)	2·0
18. Nitrate of ammonium	2·0
19. Sulphate of sodium	2·5
20. Sulphite of sodium (10 grs.)	0·25
21. Microcosmic salt (100 grs.)	0·25
22. Boracic acid	2·0
23. Ammonia alum (25 grs.)	very slight —
24. Cyanide of potassium (25 grs.)	0·75
25. Ammonia alum (100 grs.)	1·0
26. Hyposulphite of sodium	1·0
27. Cyanide of potassium (5 grs.)	3·0
28. Cyanide of potassium (50 grs.)	12·0
29. Cyanide of potassium (100 grs.)	2·25

Remarks.—Many of the remarks which I have made in a previous paper on the thermo-electric properties of liquids ("Proc. Roy. Soc." No. 188, 1878, pp. 513-518) respecting the cause of the currents, apply to the results obtained in the present research; and I consider that the causes of the currents and of their direction are similar in the two cases.

On examining the results it will be observed that the effects are not, manifestly related to the chemical nature of the solutions; thus, the liquids in which hot mercury is positive include those of acid, as well as those of alkaline reaction; and similarly with the substances in which cold mercury is positive. To what extent chemical action occurred in the experiments and operated as a cause of electric currents, would be a difficult point to examine, because the amount required to produce such feeble currents would be so extremely small; the result of a general examination of the phenomena, however, does not support the hypothesis that the currents were of chemical origin.

The evident cause of the currents was heat, and the direction of them was probably due to molecular changes in the liquid attendant upon alteration of temperature. In nearly all cases the magnitude of the current increased with the amount of difference of temperature; the apparent, but not real, exceptions were those in which the current was concentrated from or occurred.

The strength of the solution manifestly affected the quantity, and in some cases the direction of the current, as may be perceived with the solutions of potassic cyanide (Nos. 1, 2, 3, and 4), selenic acid (Nos. 5 and 6), ammonia alum (Nos. 7, 8, 9, and 10), potassic alum (Nos. 11 and 12), sulphuric acid (Nos. 15, 16, and 17), and phosphate of sodium and ammonium (Nos. 33 and 34). If the cause of the current, in the case of sulphuric acid, was chemical action, the direction of the current would probably not have been reversed by mere alteration of temperature, or by variation of strength of the mixture. If, also, the cause of the currents in general was of a chemical nature, the currents would probably have been stronger generally with the stronger solutions, and would have increased in all cases, with the strength of the solution, until the latter was much more concentrated than those which were employed.

Stirring either portion of the liquid influenced the deflection in 50 cases out of 72, increased it in 40, and decreased it in 10 of those cases. Stirring the cold portion altered the current in 21 cases out of 36, and stirring the hot portion changed it in 29 cases out of 36. Stirring the cold portion also had a greater average magnitude of effect upon the current than stirring the hot portion. Stirring a liquid of acid reaction increased the current in 13 cases out of 20, decreased or reversed it in 3 cases, and had no effect in 4 cases. Stirring an alkaline one increased the deflection in 12 cases out of 24, decreased it in 5, and had no effect in 7. The effects of stirring upon the amount of deflection were greater in alkaline liquids than in those of acid reaction.

INFLUENCE OF PREVIOUSLY HEATING THE SOLUTION.—Having observed, even with solutions formed with water which had been prehaded to expel dissolved air, that unless such liquids be heated further heated to 180° F., and cooled, after the salt, &c., had dissolved, the currents obtained in successive experiments with such a solution were not quite uniform in amount, but always decreased, I examined this circumstance.

Twenty ounces of distilled water were boiled and cooled; the salt to be employed was then dissolved completely in it, and the solution shaken with pure mercury. The mixture was then divided into two equal portions, one of those portions raised to a temperature of 180° F. in a covered glass vessel, and the evaporated water condensed and returned to the mixture, so that the solution remained unaltered in composition; the liquid was then cooled. These preheated and non-preheated portions were employed respectively to charge the two apparatuses already described. The two thermo-pairs were then simultaneously excited, their currents allowed to circulate in opposite directions through the coils of the galvanometer, and the deflection noted when the hot portions of the two liquids had simultaneously acquired a temperature of 102° F. The following is a brief statement of the results:—

Twenty ounces of distilled water and 200 grs. of crystals of sodic phosphate. The non-preheated portion of solution yielded the strongest current; deflection 1°.

Twenty ounces of water and 2 ounces of sulphuric acid. The non-preheated portion gave the strongest current; deflection 25°.

Twenty ounces of water and 200 grs. of boric nitrate. The non-preheated portion yielded the strongest current; deflection 1°.

The same mixture as the last; one portion of the solution was preheated with mercury, instead of being preheated alone. The non-preheated portion gave the strongest current; deflection 1° at 180° F.

In each of these five experiments the non-preheated portion of liquid yielded the current of greatest electromotive force. This accords with the previously stated observation that repetition experiments always yielded weaker currents.

In order to ascertain whether preheating the one portion of salt before dissolving it had the same effect upon the current as heating it after it had been dissolved, the following experiments were made:—Preboiled and cooled 20 ozs. of distilled water, and divided into two exactly equal portions. Took two portions of 50 grs. each of partly dehydrated sodic carbonate; heated one portion to 180° F. for fifteen minutes until it ceased to evolve moisture (it lost 12·4 grs.), and cooled it. Dissolved the two separate portions of salt in the separate quantities of water, and treated the solutions against each other in the two apparatuses. No difference in the direction of current occurred at any temperature up to that of 180° F.

In another experiment of this kind, 200 grs. of ammonia alum were divided and treated as above. The solution of the non-preheated salt gave the strongest current; deflection 72° at 180° F.

Remarks.—The conclusion I draw from these last two experiments and results, combined with those of the previous ones, is that preheating the salt either before or after solution usually lessens the current, both in thermo-electric experiments, and in thermo-electrogenetive liquids.

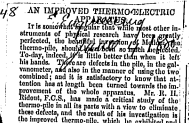
In the several classes of cases described in this paper, it is evident that the currents are not due to chemical action, but to molecular changes and alterations of molecular disturbance, and that the difference of electromotive power in different liquids is not due to differences of chemical action, but probably to differences of molecular arrangement of the solutions. Also that in the class of experiments where the liquids compared had the same chemical composition, but had been differently treated, the differences of molecular arrangement were less, and the currents obtained were consequently more feeble. A difference of strength of current caused by repetition of experiments, or by continuance of heat, also renders manifest the change of molecular arrangement; and the above method may be employed for detecting molecular differences in conducting liquids having the same chemical composition.

In the class of cases in which the differences of molecular arrangement were the least, and the currents the most feeble, the direction of the currents was the most uniform. This is in accordance with the common truth in science that the smallest phenomena are the most constant.

* Abstract of a Paper presented to the Royal Society.

AN IMPROVED THERMO-ELECTRIC APPARATUS.

It is somewhat singular that while most other instruments of physical research have been greatly perfected, the [illegible] apparatus, the thermo-pile, should [illegible] as much. To-day, indeed, it is little better than when it left his hands. There are defects in the pile, in the galvanometer, and also in the manner of using the two combined; and it is satisfactory to know that attention has at length been turned towards the improvement of the whole apparatus. Mr. H. H. Sidnell, F.C.S., has made a critical study of the thermo-pile in all its parts with a view to eliminate these defects, and the result of his investigation is the improved thermo-pile, which he exhibited and described recently to the Physical Society.



As ordinarily made the thermo-electric metal junctions of the pile are too deep. Fig. 1 represents the usual method of soldering the metals, bismuth (Bi) and antimony (Sb), to form the junction J, and the consequence is that one side of the junction is better than the other, the result being that a local current is set up which short-circuits itself through the junction. Mr. Hildust avoids this waste of energy by placing the bars in a glass tube T, and constructing the junctions as shown in Fig. 2, where the bismuth (Bi) is connected to the antimony (Sb) by a little piece of copper (Cu) soldered on. The junctions at one side in the cold, while that at the other is the hot; W W are connecting wires. Again, the ordinary bars are too long and give unnecessary resistance, the mass of matter to be heated too great, and the junctions too little or slender. In the new pile these defects are obviated by making only a single pair, and that of small length, and using

[illegible]

The faults of the galvanometer commonly employed are that the space between the needles, which is the most effective part, is not utilised by the wire; the needles are not of the best shape, and the suspension is troublesome. Mr. Hildust's remedies consist in forming the wire of a flat ribbon of copper wound on one bobbin brought close to the needles, which are flat oblong bars taken from the

[illegible]

heat; and the pile and galvanometer are connected to begin with, when in reality they should not be put in circuit with each other until the pile has been exposed for a short time to the source of heat, so as to prevent the current generated itself abstracting heat from the hotter side of the pile, and conveying it to the cooler side, thereby lessening the difference of temperature between the two junctions and lowering the efficiency of the pile.

As constructed by Mr. Browning, the well-known optician, the new instruments is very sensitive and simple. It consists of a single pair of bismuth and antimony bar $\frac{1}{2}$ in. long, and $\frac{1}{10}$ in. thick; the junction being formed by a circular wafer or fish plate of copper about $\frac{1}{32}$d in. thick, and $\frac{1}{4}$ in. diameter, firmly soldered to the ends of the bars. The external surface of the wafer is coated with bichloride of platinum overlaid with lamp-black fixed with very dilute negative varnish of photography to render it highly absorbent of heat. The pile is supported by stout copper terminals above the galvanometer on the same board, as shown in Fig. 4.

The galvanometer consists of a coil wound with 20 turns of copper ribbon insulated with a coat of shellac varnish, and a pair of astatic needles, 1 in. long, and $\frac{1}{2}$ in. wide, made as already described and supported in an aluminium cradle on a fine wire turning in an agate cup. A contact key K is placed at one side and makes the only contact required, that between the pile and coil in the middle of the apparatus.

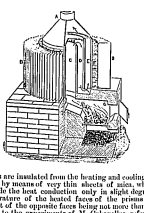
The whole is enclosed in a glass shade having an aperture B at the height of the front of the pile. A glass cone protects the front face of the latter from extraneous radiation, and a glass screen the back face. A directing magnet, N S, placed over the pile, is for adjusting the zero of the needles so as to enable the instrument to be used in any position with respect to the earth's magnetic meridian. In using the apparatus the source of heat being placed in front of the pile, the glass shade is turned round till the aperture is over against the front face of the pile, and after some 30 seconds' exposure contact is made between the pile and galvanometer by means of the key, and the deflection read off and noted.

So delicate is the apparatus that a distinct deflection was obtained from the radiation of a person standing 5 ft. distant, the temperature of the air being about 12 deg. Fahr. The fluno of a common candle affects the galvanometer when placed 3 ft. away. The pile shows that the walls of a room are at different temperatures; and in clear weather the radiation from stellar space is very evident. The new pile is moreover very convenient and portable; according to Mr. Hildust it can be got ready for use in about half a minute, while with the ordinary thermo-pile, the preparatory adjustments generally take up as much time as the experiments themselves.

THE NEW THERMO-ELECTRIC BATTERY OF M. CLAMOND.

In [illegible] to the patents of M. Snider (who is understood to be working in conjunction with M. Clamond), my [illegible] which [illegible] the [illegible] in the new form of thermo-electric battery [illegible] M. Clamond. This, as shown by our illustration, is constructed in the form of a stove, by means of which the apparatus for heating and lighting a building may be combined.

The elements of the battery (exhibited at 5) are constituted by pieces of an alloy of antimony and bismuth, connected by strips or "armatures" of cast iron; "chains" of 50 elements being produced at one casting. The iron strips connect the right-hand face of one prism with the left-hand face of the next in order, so that one set of alternate junctions becomes heated, whilst the other set becomes cooled by the "diffuser" (D). The middle portion of the strip is of about the same size as the side of the prism, and the strips are cut with three projections or teeth, which are twisted cork-screw-fashion, so as to obtain a good hold of the metal. A series of these "armatures" being arranged in a special mould, with their twisted projections bent at right angles, and the middle portions surrounded with asbestos cardboard, the alloy is run into the mould, filling the spaces between these projected middle portions, and the chain is complete. In the battery of 3,000 couples there are 60 chains of 50 couples each, and these chains may be connected either in series or in "multiple arc." The face of the prism is about 3 cm. square, and the thickness is 2 cm.



The chains are insulated from the heating and cooling surfaces (at E and B) by means of very thin sheets of mica, which, it is stated, impede the heat conduction only in slight degree. The mean temperature of the heated faces of the prisms is about 350° C.; that of the opposite faces being not more than 80°.

According to the experiments of M. Colsandlas, referred to in *La Nature*, the electromotive force of a battery of 3,000 elements, in single series, is 109 volts (equal to about 60 Bunsen cells); whilst the internal resistance is 12·5 ohms.

In regard to fuel consumption, the largest battery hitherto constructed, composed of 6,000 couples, consumed from 9 to 10 kilograms (20 to 22lb.) of coal per hour, whilst working two Serrin lamps, the light from each of which varied from 30 to 50 Carcel *bees*. If this expenditure represented the lighting power only, the apparatus would certainly be defective from an economical point of view; but in the case when the thermo-pile can be utilised also as a stove for heating purposes. Nearly the whole of the heat produced by the combustion of the fuel is, in fact, available for such purposes. The measure of practical success that many attend the persevering and praiseworthy endeavours of M. Clamond is, we think, mainly dependent upon the question of the durability of the thermo-pile, which resolves itself into that of the effect upon it of a high temperature continuously maintained, and, what is more formidable, the effect of successive heating and cooling. The combination of the most effective and unobjectionable means of heating and lighting buildings is one of the most important and beautiful problems of practical science; and we shall be glad if M. Clamond, who has done so much in this direction, should succeed in practically establishing a claim to its full solution.

* *The Electrician*, Vol. III., p. 32.

THE THERMO-ELECTRIC FORCES BETWEEN METALS AND LIQUIDS.

Contact electricity has engaged the attention of physicists of late, not only in England, but in France, Germany, and Italy, by Becquerel, Buchwalds, and Pacinotti, and some interesting experiments have been made by M. Bouty, and brought before the French Academy of Sciences.

M. Bouty's experiments consisted in measuring the electromotive force developed when two plates of the same metal were plunged in two portions of the same liquid at different temperatures. To do this he employed the usual method of null-reading method, which consisted in compensating the electromotive force to be measured by a variable difference of potential derived from a circuit of known resistance traversed by a current from a Daniell cell. The arrangement comprised, last, the liquid and plates; these tubes being connected by a long capillary siphon, and plunging one in a bath of cold water, and the other in a water bath of which the temperature could be varied at will; 20d. A Daniell cell was chosen electrometer sensitive to galvanometer, and brought back to zero in each experiment by conveniently regulating the derived electromotive force. Two sensitive thermometers give the temperature of the electrodes, and an easy calculation furnishes the value of the thermo-electromotive force in a fraction of a Daniell. The use of an electrometer avoids the passage of a current in the derived circuit, and the consequent polarisation of the plates.

In general, the two plates are not completely identical, and a slight difference of potential in one direction or the other is observed between them when the baths are at the same temperature, but when a difference of temperature establishes itself the electromotive force in series, in general, very regularly, and returns to its first value when the temperature becomes again the same in both. The most important precaution is the necessary that the liquids should be prepared with distilled water deprived of air by recent ebullition; and also to abstain from raising the t

[illegible]

temperature above 50° or 60° in measuring, in order that the mercury of the electrometer should maintain itself at a fixed level. The agitation of the liquid, while being warmed or cooled is, in fact, accompanied by the production of thermo-electric forces [illegible] sometimes very considerable electromotive forces, which are in all cases observed by M. Bouty of concentric signs to the thermo-electric forces which they partially mask.

In cases where the metal is placed in contact with a solution of a salt of the same metal, for example, copper in contact with a solution of sulphate of copper, the thermo-electric force is approximately proportional to the difference of temperature of the two plates, and does not vary sensibly with the degree of dilutation of the salt. Its mean value for 1° centigrade is 0·000088 of a Daniell cell.

The salts of copper, zinc, cadmium, protoxide of iron, suboxide of mercury, chloride of gold, and chloride of platinum give also perfectly regular results. In all cases the warm metal is externally positive. M. Bouty's observations are summed up in the following table:—

Metal.	Liquid.	EMF for 1° C. at dif- ferences of each temperature.	Mean.
Platinum.	Chloride of platinum	0·000235	0·000234
Copper	Sulphate of copper	0·000088	0·000086
	Nitrate of copper	0·000084	
	Chloride of zinc	0·000077	
Amalgam of zinc.	Sulphate of zinc	0·000081	0·000075
	Nitrate of zinc	0·000069	
	Acetate of zinc	0·000075	
	Chloride of cadmium	0·000075	
Cadmium	Sulphate of cadmium	0·000086	0·000076
	Nitrate of cadmium	0·000074	
Mercury.	Nitrate of suboxide of mercury.	0·000140	0·000140
Gold	Chloride of gold	0·000024	0·000024
Iron	Sulphate of iron (ammoniacal)	0·000251	0·000092
	Sulphate of protoxide of iron	0·000090	
	Protochloride of iron	+0·000077	
	Acetate of iron	+0·000087	
	Tartrate of protoxide of iron	−0·000127	

It may be remarked in connection with these results that zinc and amalgamated is more or less heterogeneous and gives irregular results.

ENG

It will also be observed that salts of the same oxide give very sensibly the same number, and that the numbers relative to copper and to amalgamated zinc are almost identical, hence the fact, long known, that the electromotive force of a Daniell element remains nearly constant in spite of temperature. In fact in the Daniell cell the potentials developed at the two poles act in contrary directions to modify by equal quantities the electromotive force of the element.

The regularity of the above results is not obtained when the cool metal is externally the positive pole. The metals possessing that property are often attacked by the liquid which touches them, and then, it may be said, the electromotive force is never constant; its variations range in certain cases from 1 to 100 or more of a Daniell cell to sometimes several hundredths, and measurement of it becomes uncertain. M. Bouty, nevertheless, gives the principal results of his experiments under these conditions as follows :—

Metal.	Liquid.	Mean E.M.F. for 1° C. (between 16° and 30° C.) Daniell.	Mean Daniell.
Silver	Nitrate of silver	0·000563	0·000592
	Silver bath for galvanoplasty	0·000260	
Iron	Per-chloride of iron	0·000176	0·00056
	Nitrate of iron	0·000409	
	Sulphate of per-oxide of iron	0·000410	
	Iron alum (alum de fer)	0·000134	
Nickel	Chloride of nickel	0·000208	0·00024
	Nitrate of nickel	0·000251	
	Sulphate of nickel	0·000309	

Magnesium and aluminium give values greater than the preceding, but very uncertain.

In most cases the variation of electromotive force ceased to be proportional to the temperature, the foregoing numbers being only means corresponding to differences of temperature of less than 20° C.

It may be remarked that salts of the same oxide form always sensibly the same numbers. The mean relation to the salts of the protoxide of iron is almost nothing, while for the salts of the sesquioxide it has a considerable negative value. Moreover, the electrometer betrays $\frac{1}{10}$ of sesquioxide of iron in a salt of protoxide. The sulphate of protoxide of commercial iron impurified behaves almost like a salt of peroxide.

The Thermo-Electric Power of Bismuth.

M. Exner, in a communication made by him to the Vienna Academy of Sciences, shows that the thermo-electric pile of Melloni is dependent on chemical as much as on thermic action. No current, he states, is generated if a pair of bismuth and antimony is plunged into nitrogen gas, whatever may be the temperature to which the junction is raised. The same result is obtained with many other metals. Not heat only, but chemical action must be brought into play to generate an electric current.

Electricity and Chemistry.

Herr Stroken contributes from experimental inquiry (*Wied. Ann.* No. 5), that the gases chlorine, bromine, and iodine, in regard to thermal behavior, form a group by themselves among bistomic gases. The ratio of the kinetic energy of the progressive motion of the molecules to the total energy is different for them from that for the others. In their molecules the atoms seem to have a different reciprocal action. From the behavior of bistomic gases it is inferred that neither Boltzmann nor Maxwell's supposition as to the nature of the mobility of atoms in the gaseous molecule has a general validity.

Thermo-electric Power of Iron and Platinum in Vacuo.—Professor C. A. Young, of Princetown, N.J., describes, in the November number of the *American Journal of Science*, an experiment on this question. It is stated that Exner a few months ago published a paper, asserting that the thermo-electric power of antimony and bismuth is destroyed by removing them from all contact with oxygen and immersing them in an atmosphere of pure nitrogen. From this he argues that the thermo-electric force in general is due to the contact of the gases which bathe the metals. The following experiment was tried to test the theory:—By the kindness of Mr. Edison and Mr. Upton a vacuum tube was prepared in Mr. Edison's laboratory, containing an iron wire about two inches long, firmly joined to two platinum terminals, which passed through the walls of the tube. The tube was exhausted until the spark from a two-inch induction coil would not pass $\frac{1}{4}$ of an inch in the gauge-tube, indicating a residual atmosphere of about one millionth. The wire was heated to incandescence during the exhaustion, in order to drive off any possible occluded gases. The platinum wires outside the tubes were joined to iron wires, the joinings being covered by glass tubes slipped over them, and a sensitive reflecting galvanometer was included in the circuit. By laying the tube and connected joinings in the sunshine, and alternately shading one or several of the joinings, it was found that the electromotive power of the joinings within the tube was precisely the same as that of those without, and the development of current just as rapid. There was no trace of any modification due to the exhaustion.

THERMO-ELECTRIC BATTERY.* OF M. NOE.

THIS battery is frequently used and has been experimented in Austria and Germany. It consists of different forms, of which the most useful, represented by Fig. 1, appears to us to be the best, since it requires only two Bunsen burners to set in

*Translated by the Alumnium.

action forty thermo-electric elements. There is another model, of sixty elements, with three burners, which offers the same advantages as the one represented. Each circular groove of twenty elements forms a complete circuit. We will confine the description of such a group:—The elements are arranged in a horizontal plane, radially; the heated junctions being towards the centre of the circle, and the cooled junctions at its circumference. The two metals are: 1st, German silver (called *maillechort* in France and *new Silver* in Germany), and, 2nd, an alloy of antimony and zinc which fuses at a temperature slightly higher than the melting point of antimony. These two metals are soldered to each other at the heated junction without the interposition of any other metal. The ends of the German silver wire are cast into a little capsule of brass, which forms the bottom of the mould in which the other metal is cast. This capsule is shown at *a* in Fig. 2, which represents two elements of the actual dimensions; it receives the wire of the element and forms part of the apparatus.

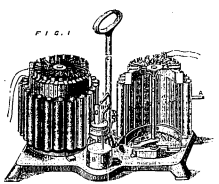


FIG. 1

Into the same capsule penetrates a small rod, *c*, of copper, the extremity of which is also enveloped by the cast metal; and by means of this rod the heat is conducted to the heated junction. The extremities of these copper rods are arranged in a circle around the axis of the battery, and between two plates of zinc, *e* and *f*, they all become heated by the same flame. In this manner the zinc plates are converted into hollow cylinders, which envelop entirely the flame of a spirit (wood-naphtha) lamp, *d*. The zinc plate has the effect of concentrating and directing the heat of the flame so to the copper rods. The object of using the copper rods at the heated junctions can be seen from the following:—The heated junctions of the elements are not sufficiently far from the flame, but only through the intermediary of the copper rod; it is therefore protected against any accident through overheating, *i.e.*, against the fusion of the alloy, which would cause the immediate breakdown of the battery. The result is the same partially, the loss of heat by radiation, when the battery rods are isolated, excepting at their extremities, within a small tube, shown at *i* in Fig. 2. The cooled junction is altogether dissimilar; the brass metal is here soldered to a plate of copper, to which is also soldered the German silver wire of the next element. This plate of copper is of large surface, forming a cylinder, and exposed to the air circulation, with the production of a cooling effect.

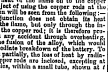

FIG. 2

These batteries have been subjected to careful experimental trial by M. Wallenhofen, of Prague; and the arrangement with the first of Noeren, and has found there to be most superior to it. It was found in the previous experiments at the Imperial Vienna, that the thermo-electric elements of Noeren may obtain an electromotive force of 1-15 volt, but this maximum is obtained only at a temperature close upon the fusing point of one of the alloys of which they are formed. Under similar conditions, M. Wallenhofen found that the Noe elements possess an electromotive force between 1-6 and 1-10 volt in practice, since they cannot be heated to the fusing point of the lead-and-zinc alloy, and when several elements are connected in series, they are never attained, because the elements are never equally heated. For ordinary experiments we may calculate upon 1-25 volt per element. The resistance of each element is 1-10 Siemens unit.

An improvement which is supplementary, but very useful in practice, consists of the addition of a regulator of the pressure of gas, by means of which the battery can be used in accidents which would cause it to be extinguished. It frequently sometimes happened that an unexpected increase in the gas pressure produced some fusion of the metal, and thus deteriorated the battery.

The safety apparatus here referred to, and which is shown in the front part of Fig. 1, consists of a glass bell-jar, open at the top, and closed by a cork. Two tubes enter this bell-jar through one cork; one, B, is a branch from the gas supply, and passes to the bottom of the vessel; the other, B, does not reach the surface of the water. Its use is to lead away any gas passing into the bell-jar, and conducting it to the small gas-jet, L, which, not constantly lighted, is only used to "test" the tubes; the tube B is closed by the water; if it should become too low the gas bubbles through the water and escapes at G, where it is inflamed. The apparatus thus constitutes a safety-valve, preventing the pressure from rising above a certain height; and can be regulated at will. The gas which escapes, when at too great pressure, cannot give rise to accidents.

With a battery of twelve elements, it is possible to work an electric bell; with twenty elements, water may be decomposed in the voltameter; with forty elements, a secondary battery can be charged, or an induction coil worked. In a word, these batteries are the best of the experimental, those for gilding, and small industrial operations, such as gilding, nickelling, &c., being carried into effect. One great advantage of this kind of thermo-electric motor is that it is set in full action in one or two minutes, and all experiments can be made in this short time. Lastly, amongst the current is no longer required, and the battery and thus is kept in order for a long period, the battery undergoing no alteration by use, as is the case of ordinary batteries have exceeded it, and which in a short time cause a considerable internal resistance, and a corresponding diminution of effect.

With these facts before us, we read without surprise the note by Professor O. Stone in our last issue, in which he says of a recently published "Record of the Progress of Astronomy during the year 1879," by Mr. Dreyer, of Dublin, one-third of the memoir is devoted to the result of astronomical work done in the United States.

An article on this subject would be incomplete without a reference to the very perfect work of Messrs. Alvan Clark & Son, of Cambridge, Mass., who appear to have distanced both the English and the Continental opticians in the excellence of their objectives, and who have secured to the United States the honor of supplying the objective for the great equitorial about to be manufactured for the Russian Government, to be used in the Pulkowa Observatory by the distinguished astronomer, Otto Von Streuve. We also notice that of the forty observatories recognized by the Smithsonian Institute, seventeen have telescopes made by this firm. In regard to the work now in progress at the Messrs. Clark's establishment, it may be stated without exaggeration that the world awaits with eager expectancy the result of their labors.

We record with pleasure the very perfect harmony with which American astronomers co-operate and work, which has doubtless been a leading point in gaining the successes that have been attained. This is in strong contrast with the constant bickering among members of the Royal Astronomical Society and many English astronomers, some of whom have not thought it humiliating to charge the Astronomer Royal with ignorance, and a stubborn adhesion to error, and to allege that members of the council of the Royal Astronomical Society suppress the papers of their fellow members from personal and unworthy motives.

Of American astronomers, it might seem invidious to make a personal reference to particular men, but the names of Newcomb, Hall, Eastman, Holden, Stone, Burnham, Draper, Swift and Rutherford are familiar in all civilized countries, and respected wherever the science of astronomy is appreciated.

M. Mascart has been making some observations at the College of France, on atmospheric electricity, with a Thomson quadrant electrometer, the deflections of the needle being transmitted to a pencil. The two pairs of quadrants are kept at equal potentials of contrary sign by two poles of a battery which communicate with the ground: the needle is connected with a vessel letting flow a continuous stream of water into the outer air. Generally the potential of the air, always positive, is found much higher, and more uniform by night than by day. From 9 P. M. to 3 A. M., it varies little, falls at daybreak, reaches a minimum about 3 P. M., and rises rapidly to a maximum about 9 P. M. It is commonly thought that there are two maxima, viz. morning and evening, and two minima, one in the daytime, the other at night. M. Mascart believes that insufficient has been too much neglected.

A NEW ELECTRIC PILE DEVISED BY M. REYNIER.

Translated for "SCIENCE."

M. Emile Reynier, the electrician, and inventor of an electric lamp, which we have more than once had occasion to present to our readers, and which its author has never ceased to improve and perfect, with the view of making its use more satisfactory, more convenient, and more economical, has now arranged a pile, which is at the same time powerful and economical. This apparatus is composed of a glass vessel in the form of an oblong square, in which is immersed a sheet of copper bent upon itself, as shown in Fig. 1. Upon the bottom of this copper hook rests a cup of parchment, into which the zinc plate is placed, as shown in Fig. 2.

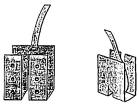

FIG. 1. FIG. 2.

FIG. 1.—THE COPPER PLATE OF THE PILE OF REYNIER.
FIG. 2.—THE ZINC PLATE OF THE PILE OF REYNIER.

This vessel or porous diaphragm has this peculiarity, that it is made up of a conical sheet of parchment, and that corresponding with the rectangular or octagonal form, just as may be chosen, it is folded upon itself (Figs. 3 and 4) as indicated by the tracings of the diagrams (Figs. 5 and 6). The strongly marked lines in the figures represent the folds of the angles, the figures indicating the faces, whilst the lighter lines represent the intermediate folds which insure the stability of the system.

FIG. 3. FIG. 4.

FIG. 3.—DEVELOPMENT DIAGRAM OF THE HEXAGONAL POROUS.
FIG. 4.—DEVELOPMENT DIAGRAM OF THE RECTANGULAR POROUS.

When the different parts are thus mounted, forming the group known as an element (Fig. 7), a solution of caustic soda is turned into the porous cup containing the zinc; into the outer vessel, a concentrated solution of the sulphate of copper. The two electrodes, zinc and copper, being placed in relation by the conductors, a constant chemical decomposition begins. This pile, which M. Reynier qualifies as

USE OF SMITHSON'S PILE FOR THE DETECTION OF MERCURY IN MINERAL WATERS. *By J. Lefort* (*Compt. Rendus*, 30, 141–142).—Orfila objected to the voltaic couple of tin and gold, devised by Dr. Smithson, for the detection of small quantities of mercury, alleging that when it was allowed to remain for some time in the suspected solution, traces of tin were dissolved, which, redepositing upon the gold plate, caused the latter to become whitened even in absence of mercury. The author shows that this deposition of the tin is liable to take place, but that no real error can result, since the metal not being volatile cannot be sublimed. There is, therefore, no sublimate to be submitted to the vapour of iodine, whereby an essential part of the operation in conducted by Smithson is omitted. Such, however, is not the case with arsenical solution; the arsenic deposits upon the gold with great readiness, and the coated foil when heated in a closed tube yields a sublimate, which, although not exactly resembling the mercurial sublimate, becomes red from formation of arsenic iodide when acted on by iodine vapour. The colour of the arsenic iodide under these conditions is very similar to that of mercuric iodide, and it becomes necessary to use the microscope in order to distinguish them. The water from the Rocher spring at St. Nectaire (Puy-de-Dôme) was examined by this process some time ago, and was stated to contain mercury. This statement is now contradicted, it being shown to contain arsenic and not mercury. In a similar manner the presence of arsenic has been detected in the mineral water of Bourbonne; and doubtless this element might be shown to be present in many other waters if they were carefully examined by this process, or by some other method of equal delicacy.

Philosophical Journal Vol 1st 1878

PROFESSOR C. A. YOUNG, of Princeton, N. J.—On the thermo-electric electro-motive power of Pd. and Pt. in vacuo.—Elsner, a few months ago, published a paper stating that the thermo-electric power of antimony and bismuth is destroyed by removing them from all contact with oxygen, and inserting them in an atmosphere of pure nitrogen. From this he argues that the source of power in general is due to the contact thermo-electric force which bathe the metals. The following of the gases which bathe the metals. The following experiments were tried to test the theory. By the kindness of Mr. Edison and Mr. Upton a vacuum tube was procured in Mr. Edison's laboratory, containing an iron wire about 2 inches long, firmly joined to two platinum terminals which passed through the walls of the tube; the tube was exhausted until a 2-inch induction coil would not pass 1 of an inch in the gauge-tube, indicating a residual atmosphere of about one-millionth. The wire was heated to incandescence during the exhaustion, in order to drive off any possible occluded gases. The platinum wires outside the tube were joined to iron wires, the joinings being covered by glass tubes slipped over them, and a sensitive reflecting galvanometer was included in the circuit. By laying the tube and connected joinings in the sunshine, and alternately shading one or several of the joinings, it was found that the electro-motive power of the joinings within the tube was precisely the same as that of those without, and the development of current just as rapid. There was no trace of any modification due to the exhaustion.—*Silliman's Journal*, p. 47.

We referred in the Philosophical Notes of the issue of November 11 to a paper read before the American Association at Boston by Prof. Young, which contained certain phenomena in thermo-electricity which were alleged to have been observed by Herr Exner. We have since received from Mr. T. Bloom of Belfast a letter in which, on behalf of Prof. Franz Exner of Vienna, he expressly disavows any such discoveries as those which Prof. Young has set himself to refute. We readily accord to our courteous correspondent the opportunity for this disavowal, since any reflections cast even inadvertently upon the accuracy of Prof. Exner's work might unfairly prejudice readers against the general reliability of the researches which he has published in another department of science, and which our readers are aware are just now exciting considerable attention.

ON THE THERMO-ELECTRIC ELECTRO-MOTIVE POWER OF FE. AND PT. IN VACUO.—Professor C. A. YOUNG of Princetown, in a paper on this subject, at the American Association for the Advancement of Science, said that Elsner, a few months ago, published a paper, asserting that the thermo-electric power of antimony and bismuth is destroyed by removing them from all contact with oxygen, and inserting them in an atmosphere of pure nitrogen. From this he argues that the source of power in general is due to the contact thermo-electric force which bathe the metals. The following of the gases which bathe the metals. The following experiments were tried to test the theory. By the kindness of Mr. Edison and Mr. Upton a vacuum tube was procured in Mr. Edison's laboratory, containing an iron wire about 2 inches long, firmly joined to two platinum terminals which passed through the walls of the tube; the tube was exhausted until a 2-inch induction coil would not pass 1 of an inch in the gauge-tube, indicating a residual atmosphere of about one-millionth. The wire was heated to incandescence during the exhaustion, in order to drive off any possible occluded gases. The platinum wires outside the tube were joined to iron wires, the joinings being covered by glass tubes slipped over them, and a sensitive reflecting galvanometer was included in the circuit. By laying the tube and connected joinings in the sunshine, and alternately shading one or several of the joinings, it was found that the electro-motive power of the joinings within the tube was precisely the same as that of those without, and the development of current just as rapid. There was no trace of any modification due to the exhaustion.

THERMO-ELECTRICITY.

Several months ago Herr Exner read a paper before the Academy of Science, Vienna, tending to prove that the current generated at a thermo-electric junction is due to the chemical action between the gas in which the junction is immersed and the metals. This was a most important conclusion, and converse to existing opinions; so that it was expedient to put it to the test. This has been done by Professor C. A. Young, of Princeton, New Jersey, who employed experiments on the thermo-electric properties of a platinum and iron pair *in vacuo*, at the laboratory of Mr. Edison, Menlo Park. The pair was enclosed in a glass bulb exhausted to one-millionth of an atmosphere, and its ends were connected to a galvanometer. On piercing the bulb in the sunlight, and alternately shutting the external and internal junctions an electromotive force equal in each case was generated, a result antagonistic to the conclusion of Herr Exner. Herr Exner has also recently promulgated his opinion that the electromotive force generally supposed to be due to the mere contact of two dissimilar metals is really due to chemical action between the metals and the air or other gas surrounding them. He adduces many experiments of his own in support of this view; but at the Physical Society, on November 13, Professors Perry and Ayrton pointed out that his experimental results were at variance with the results of several independent experimenters, such as Kuyhenek, Hankner, and others, which agree among themselves.

ON A THERMO-MAGNETIC THERMOSCOPE.

BY SIR WILLIAM THOMSON.

This thermoscope is founded on the change produced in the magnetic moment of a steel magnet by change of temperature. Several different forms suggest themselves. The one which seems best adapted to give good results is to be made as follows:

1. Prepare an approximately astatic system of two thin hardened steel wires, *r* & *r*′ & each one centimetre long, one of them, *r* &, hung by a single silk fibre, the other hung bifilarly from it by fibres about twelve centimetres long, so attached that the distance between the two on a horizontal plane should be inclined at an angle of about .01 of a radian (or .57) to one another.

2. Hang a very small light mirror, bifilarly from the lower of the two wires, *r*′.

3. Magnetize the two wires to very exactly equal magnetic moments in the contrary directions. This is easily done by a few experiments tried to make them rest as nearly as possible perpendicular to the magnetic meridian.

4. Take two pieces of equal and similar straight steel wire, soft hardened, each one centimetres long, and about .04 centimetres diameter. Magnetize them equally and similarly, and mount them on a suitable frame to fulfil conditions

5 and 6. Call them R R and R′ R′. R and R′ denoting the ends containing true north polarity (ordinarily marked B), and R R′ true south (ordinarily marked N or S). The small letters, *r*, *b*, *r*′, *b*′, more on the same plan the polarities of *r* & and *r*′ &′.

7. The magnets R R, R′ R′, are to be relatively fixed in line on their frame with similar poles next one another, at a distance of about two centimetres asunder, as thus, R R′ R′, with R B′ = two centimetres.

8. This frame is to be mounted on a geometrical slide upon the case, within which the astatic pair, *r* &, *r*′ &′, is hung in such a manner that the line of R B, B R bisects *r* &, approximately at right angles, and that R B B R may be moved by a micrometer screw through about a millimetre on each side of its central position, the line of motion being the line of R B, B′ R′, and the " central position " being that in which B and B′ are equi-distant from the centre of *r* &.

9. By aid of the micrometer screw bring the luminous image to its middle position on the scale.

10. Cause R B, B′ R′ to have different temperatures. The luminous image is seen to move in such a direction as is due to *r* approaching the cooler, and receding from the warmer of the two deflectors B R, B′ R′.—*Proceedings Royal Society, Edinburgh.*

Correspondence.

THE THERMO-ELECTROPHORE.

To the Editor of THE TELEGRAPHIC JOURNAL.

STRATHLEVEN.

SIR,—On the 19th of March last I made a communication to the French Academy of Sciences on the result of experiments I had made as to the transformation of plastic electricity. (Comptes-Rendus de l'Academie des Sciences, 19th April, 1880). Full details of these results were lately given in *Nature*, the *Engineering*, *Hardware* and *Industries* Journals.

I have received since that date from various places a number of letters addressed to my thermo-electrophore of the same nature as my thermoscope.

I have the honour therefore to briefly latent the following in your next issue:—

The thermo-electrophore, in contact with the thermoscope. This apparatus is based upon a new principle discovered by me. Nine causes of the formation of atmospheric electricity the origin of the electricity in the thunder cloud and in others is explained upon this principle. But, what is most important, I have established a definite basis of this principle on which a thermo-electrophore is transformed immediately into a source of electricity and with very little loss of energy. The formation of electricity in my thermo-electrophore takes place at the time of the passing of the vapour of certain liquids to the solid state, at the moment when the solidified movement of the vapour becomes transformed accordingly to my researches, sufficiently completely into electro-molecular movement, or current.

By means of certain arrangements I am even confident of utilizing the heat of the air.

If I am able to render my apparatus practicable, applying to my calculations, it will be possible to obtain electricity (steam engines and Gramme machines utilizing only a tenth part of the heat obtained from the coal consumed) to the extent of two-thirds of the heat expended.

I believe even that by combining the thermo-electrophore with the Gramme machine (which arrangement call the dynamophore) it will be possible to obtain a motor relatively very light (approximately four times lighter and cost) consuming a proportionately less amount of coal in comparison with the steam engine of equal power.

Accept, Sir, the assurances, &c.,

GREGOIRE BABITSCHEFF.

Vitebsk, *Dec.*, 1880.

EDISON'S LATEST IDEA.

The Direct Conversion of Heat into Electricity and Power.

FROM THE NEW YORK BUREAU OF THE PRESS.

NEW YORK, Aug. 16.

Among the most interesting of the eighty-five papers read before the American Association for the Advancement of Science to-day was one by Thomas A. Edison read by Professor George F. Barker upon the conversion of heat into power directly by means of magnetism and by the same principle the conversion of heat into electricity. Of the discovery Mr. Edison says:

"When whenever a magnetic field varies in intensity within a vicinity of a conductor current is set up in it, or vice versa whenever a conductor is moved in a magnetic field a current is set up in it. If the conductor is moved in a magnetic circle and varying the magnetizability of that core by varying the temperature, it would be possible to generate a current. This idea constituted the essential feature of the new generator, which therefore depends upon varying the magnetizability of the core.

"The principle was first applied to the construction of a simple form of magnetic engine, a model of which was exhibited to-day. The armature of the experimental engine, having the form of a small fan, is made of thin iron plates bent in the form of a ring and capable of rotation about an axis perpendicular to the plane of the magnet. By suitable gearing the armature is caused to rotate about 1,500 times a minute. A coil of wire is wound around this bundle of rings and through the entire length of the armature. When this screw is so adjusted that the coils are symmetrically disposed with reference to the poles of the magnet, there is no current, since the two coils are thereby portions of the same circuit. But when the armature is moved by the screw, so that the coils are moved nearer to the poles, there will be formed about the coils a magnetic field, since the coils are thereby brought into the region of greatest magnetic intensity. The construction of a machine of sufficient size to demonstrate the feasibility of producing electricity or power on a large scale by this principle has not been completed. The new machine will be run by a 50-horse-power engine, the equivalent of the device already exercised produced readily about a common centre. The amount of power developed by the engine is estimated, but it is stated that the pressure of combustion are 1,000 pounds to the square inch. The amount of electrical energy developed by the machine depends upon the number of turns of wire, upon the coils, the temperature range, and, in fact, upon the rate of temperature variation. Further, the rate of temperature variation depends upon the rapidity with which heat can be put into the coils, the temperature range, and the specific heats of the materials employed. Mr. Edison thinks that his device will be found to be more economical than the steam engine and dynamo. It is based on the fact that the magnetism of some of the metals, as iron, cobalt and nickel, is greatly affected by heat, and the other well-known fact that whenever a magnetic field varies in strength in the vicinity of a conductor, a current of electricity is generated in that conductor. Putting the two things together, Edison says it occurred to him that by placing an iron core in a coil of wire and varying the strength of the magnetism of that core by varying the temperature, a current would be generated. We believe some arrangement for producing electricity directly from heat is among the probabilities of the future. Many of the best inventors of the age are giving their attention to electrical matters and it is one of the most promising fields for research and investment. Where three years ago thousands were invested in this line, to-day there are millions, and still the stream continues to pour in. What the end will be there is no safety in prophesying, save that it will not be disaster.

N.Y. Tribune, Aug. 16, 1887.

Adventurer, Canton, N.Y. Aug. 25, 1887.

"I DON'T KNOW,"

was Thomas A. Edison's response to the inquiry, what is electricity? Whether he knows or not, the great inventor toys with the mysterious force with more success than all other men on this terrific ball. Inventions are numerous, and he continues his investigations as zealously as ever. The Menlo Park wizard's latest production is the pyromagnetic governor, a device by which he can turn the heat of a domestic furnace into light and get power out of heat. When electricity is fully understood the world will be supplied with many conveniences and comforts that are not even now dreamed of.

Guardian, Saltcoats, N.B. Aug 17, 1887.

"Edison's latest idea" is the direct conversion of heat into electricity and power. This was the title of a paper read by Professor George F. Barker before the American Association for the Advancement of Science to-day. The paper was read before the Academy of Sciences in this city, and by the courtesy of the president of the association, Professor Barker, I was enabled to obtain a copy of the paper in advance of its delivery. The paper, which is of considerable length, is devoted to a description of the experiments which Mr. Edison has been making for the purpose of ascertaining the practicability of the idea, and the paper, like every original production of Mr. Edison, is replete with interesting matter. The principle involved in the new invention is that of magnetism. Mr. Edison says: "Whenever a magnetic field varies in intensity within the vicinity of a conductor current is set up in it, or vice versa whenever a conductor is moved in a magnetic circle and varying the magnetizability of that core by varying the temperature, it would be possible to generate a current. This idea constituted the essential feature of the new generator, which therefore depends upon varying the magnetizability of the core." The principle was first applied to the construction of a simple form of magnetic engine, a model of which was exhibited to-day. The armature of the experimental engine, having the form of a small fan, is made of thin iron plates bent in the form of a ring and capable of rotation about an axis perpendicular to the plane of the magnet. By suitable gearing the armature is caused to rotate about 1,500 times a minute. A coil of wire is wound around this bundle of rings and through the entire length of the armature. When this screw is so adjusted that the coils are symmetrically disposed with reference to the poles of the magnet, there is no current, since the two coils are thereby portions of the same circuit. But when the armature is moved by the screw, so that the coils are moved nearer to the poles, there will be formed about the coils a magnetic field, since the coils are thereby brought into the region of greatest magnetic intensity. The construction of a machine of sufficient size to demonstrate the feasibility of producing electricity or power on a large scale by this principle has not been completed. The new machine will be run by a 50-horse-power engine, the equivalent of the device already exercised produced readily about a common centre. The amount of power developed by the engine is estimated, but it is stated that the pressure of combustion are 1,000 pounds to the square inch. The amount of electrical energy developed by the machine depends upon the number of turns of wire, upon the coils, the temperature range, and, in fact, upon the rate of temperature variation. Further, the rate of temperature variation depends upon the rapidity with which heat can be put into the coils, the temperature range, and the specific heats of the materials employed. Mr. Edison thinks that his device will be found to be more economical than the steam engine and dynamo. It is based on the fact that the magnetism of some of the metals, as iron, cobalt and nickel, is greatly affected by heat, and the other well-known fact that whenever a magnetic field varies in strength in the vicinity of a conductor, a current of electricity is generated in that conductor. Putting the two things together, Edison says it occurred to him that by placing an iron core in a coil of wire and varying the strength of the magnetism of that core by varying the temperature, a current would be generated. We believe some arrangement for producing electricity directly from heat is among the probabilities of the future. Many of the best inventors of the age are giving their attention to electrical matters and it is one of the most promising fields for research and investment. Where three years ago thousands were invested in this line, to-day there are millions, and still the stream continues to pour in. What the end will be there is no safety in prophesying, save that it will not be disaster.

N.Y. Tribune, Aug. 16, 1887.

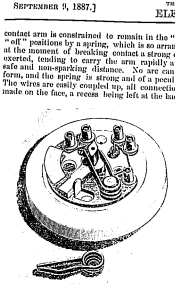
Gazette, Courier, Greenfield, Mass. Aug. 22, 1887.

At one of the sessions of the meeting of the American Association for the Advancement of Science, which has been held the past week, Thomas A. Edison read a paper upon electricity, in which he gave an account of an apparatus he is developing for obtaining electric light and power directly from coal without the intervention of the steam engine and dynamo. It is based on the fact that the magnetism of some of the metals, as iron, cobalt and nickel, is greatly affected by heat, and the other well-known fact that whenever a magnetic field varies in strength in the vicinity of a conductor, a current of electricity is generated in that conductor. Putting the two things together, Edison says it occurred to him that by placing an iron core in a coil of wire and varying the strength of the magnetism of that core by varying the temperature, a current would be generated. We believe some arrangement for producing electricity directly from heat is among the probabilities of the future. Many of the best inventors of the age are giving their attention to electrical matters and it is one of the most promising fields for research and investment. Where three years ago thousands were invested in this line, to-day there are millions, and still the stream continues to pour in. What the end will be there is no safety in prophesying, save that it will not be disaster.

N.Y. Tribune, Aug. 16, 1887.

More than one subject of general interest was taken up yesterday by the American Association for the Advancement of Science, but the topic that will attract the greatest attention was the forenoon's work, but a good second to this was furnished in the two papers of Mr. Edison. Everything said about the Niagara Canal to the four contributions on that subject was highly favorable. Engineer Peary's paper, giving the result of Engineer Menocal's observations and estimates, is easily the most important of the four. The cost of the canal is set down as about $64,000,000; six years will be required to locate and construct it, and when finished a steamship can pass from end to end in thirty hours. These are estimates only; and estimates must always be taken with allowance. One of Mr. Edison's papers was on the pyromagnetic dynamo, a machine for producing electricity directly from coal, on which the famous inventor is still at work; the other treated of a "bridge or balance for measuring magnetic conductivity." This sounds rather technical, but is perhaps eminently practical.

contact arm is constrained to remain in the "on" and "off" positions by a spring, which is so arranged that at the moment of breaking contact a strong couple is exerted, tending to carry the arm rapidly away to a safe and non-sparking distance. No arc can possibly form, and the spring is strong and of a peculiar form. The wires are easily coupled up, all connections being made on the face, a recess being left at the back of the



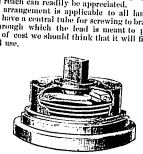
switch for leading in the wires. Provision is made in every switch for a safety fuse which can be easily replaced. The use of steel for the spring of these switches would in certain cases be found to be objectionable, especially in ship work, and we would suggest the substitution of German silver, which has been found in practice to be far preferable.

A NOVELTY IN SWITCHES.

THE want has long been felt of a handy switch to form part of, or to be easily attached to the lamp holder, both for hanging lamps and for use with brackets, in order to save the expense of running leads down to wall

switches. The Walsall Company has brought before boxes. The contact is made by a spring which is forced our notice a switch well calculated to serve those pur- by the finger between the edges of two brass tubes and when fairly engaged is held in position by the notch: it is readily released by the finger pressing the other end of the spindle carrying the spring, while a spiral spring gives a rapid "fly off." The brass tubes are connected to one lead and the lamp respectively. As attached to a suspended holder it is at once seen that it requires only one hand to put the light on and off, and the advantages of this for lamps hanging only just within reach can readily be appreciated.

The arrangement is applicable to all lamp holders which have a central tube for screwing to brackets, &c., and through which the lead is meant to pass. As a saving of cost we should think that it will find a large general use.



A neat little switch with double spring contacts is also before us, the chief merits of which are its simplicity and neatness, while ensuring as good a contact as can be desired.

ON THE PYROMAGNETIC DYNAMO, A MACHINE FOR PRODUCING ELECTRICITY DIRECTLY FROM FUEL.*

By THOMAS A. EDISON.

THE production of electricity directly from coal is a problem which has occupied the closest attention of the ablest inventors for many years. Could the enormous energy latent in coal be made to appear as electric energy by means of a simple transforming apparatus it would be inconceivable its result with reasonable economy, but it will be conceded, probably, that the mechanical methods of the entire world would be revolutionised thereby, and that another of those grand steps of progress would be taken, of which the nineteenth century so justly boasts.

The simple production of a potential difference by means of heat is as old as Seebeck and Melloni. The science of thermo-electricity thus originated has been developed by Becquerel, by Peltier, by Thomson and by Tait, and the thermo-batteries of Clamond and of Noe have found many important practical uses. The results already attained in these generators have stimulated research marvellously, and many investigators have believed that in this direction lay the philosopher's stone. Our fellow-member, Moses G. Farmer, worked long and assiduously in this field, producing, it is believed, the most satisfactory results, as regards economy, which have ever been obtained. His never succeeded in converting 1 *per cent.* of the energy of the coal into electric energy. Quite recently Lord Rayleigh has discussed with his well-known ability the law of efficiency of the thermo-battery from the standpoint of the second law of thermo-dynamics. And he concludes that for a copper-iron couple, working between the extreme limits of temperature possible for these metals, a conversion of not more than one three-hundredth part of the coal energy can be hoped for. While, therefore, as a heat engine the thermo-cell appears to follow precisely the law of Carnot, and hence may have a theoretical maximum efficiency equal to that of the reversible engine of this

EDISON'S LATEST IDEA.

The Direct Conversion of Heat Into Electricity and Power.

FROM THE NEW YORK BUREAU OF THE PRESS.

NEW YORK, Aug. 15.

Among the most interesting of the eighty-four papers read before the American Association for the Advancement of Science to-day was one by Thomas A. Edison read by Professor George F. Barker upon the conversion of heat into electricity directly by means of magnetism, and by the same principle the conversion of heat into electricity. Of the former Mr. Edison says:

"Since whenever a magnetic field varies in strength a current of electricity of a certain direction is induced in a coil of wire surrounding such field.

Mr. Edison thinks that his device for the direct conversion of heat into electricity by means of the heat from an ordinary furnace is the result of a series of experiments in that direction. He calls the machine the pyromagnetic generator.

Gazette, Cornwall, Greenfield, Mass. Aug. 22, 1887.

At one of the sessions of the meeting of the American Association for the Advancement of Science, which has just closed, the last week, Thomas A. Edison read a paper upon electricity, in which he gave some account of an apparatus he is developing for obtaining electric light and power directly from coal without the intervention of the steam engine and dynamo. It is based on the fact that the magnetism of some of the metals, as iron, cobalt and nickel, is greatly affected by heat, and the other well-known fact that whenever a magnetic field varies in strength in the vicinity of a conductor, a current of electricity is generated in that conductor. Putting the two things together, Edison says it occurred to him that by placing an iron core in a coil of wire and varying the strength of the magnetism of that core by varying its temperature, a current would be generated. We believe some arrangement for producing electricity directly from heat is among the probabilities of the future. Many of the best inventors of the age are giving their attention to electrical matters and it is one of the most promising fields for research and investment. Where three years ago thousands were invested in this line, to-day there are millions, and still the cream continues to pour in. What the end will be there is no safety in prophesying, save that it will not be disaster.

N.Y. Times, Aug. 16, 1887.

More than one subject of general interest was taken up yesterday by the American Association for the Advancement of Science, but the topic that will attract the greatest attention was the Nicaragua Canal, but a good second to this was furnished in the two papers of Mr. Edison. Everything said about the Nicaragua Canal in the four contributions on that subject was highly favorable. Engineer Peary's paper, giving the result of Engineer Menocal's observations and estimates, is easily the most important of the lot. The cost of the canal is set down as about $94,000,000; six years will be required to locate and construct it, and when finished a steamship can pass from end to end in thirty hours. These are estimates only, and estimates must always be taken with allowances. One of Mr. Edison's papers was on the pyromagnetic dynamo, a machine for producing electricity directly from fuel, on which the famous inventor is still at work; the other treated of a "bridge or balance for measuring magnetic conductivity." This sounds rather technical, but is perhaps eminently practical.

Aventure, Canton, N.Y. Aug. 25, 1887.

"I don't know," was Thomas A. Edison's response to the inquiry, what is electricity? Whether he knows or not, the great inventor toys with the mysterious force with more success than any other man on this electric ball. His secrets are numerous, and he continues his investigations as zealously as ever. The Menlo Park wizard's latest production is the pyromagnetic generator, a device by which he can turn the heat of a domestic furnace into lights and get power out of heat. When electricity is fully understood the world will be supplied with many conveniences and comforts that are not even now dreamed of.

Guardian, Pittsburgh, Pa. Aug. 17, 1887.

From a paper read by Thomas A. Edison before the American Association for the Advancement of Science it appears that he has made considerable progress in the subversion of heat into power directly by means of magnetism, and upon the same principle, the conversion of heat into electricity. He is constructing a machine of three horse-power, in which the output of electrical energy will be greater, he thinks, than in any device now known and the cost of operation less. If the consummate process of generating electricity by means of a steam engine is ever superseded by a more economical method a sensational revolution will be the consequence.

eminent philosopher, yet in practice its efficiency falls very far below this theoretical maximum.

It therefore follows that if the result hoped for is to be attained at all it must obviously be looked for in some other direction than in that of the thermo-coil. In considering the matter, another line of investigation suggested itself to me, the results of which I have the honour now to submit to my fellow members of the physical section. It has long been known that the magnetism of the magnetic metals, and especially of iron, cobalt and nickel, is markedly affected by heat. According to Becquerel, nickel loses its power of being magnetised at 400°, iron at a cherry-red heat and cobalt at a white heat. Since, whenever, a magnetic field varies in strength in the vicinity of a conductor a current is generated in that conductor, it occurred to me that by placing an iron core in a magnetic circuit, and by varying the magnetisability of that core by varying its temperature, it would be possible to generate a current in a coil of wire surrounding this core. This idea constitutes the essential feature of the new generator, which, therefore, I have called a pyromagnetic generator of electricity.

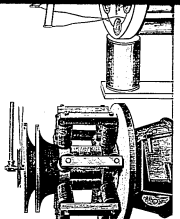
The principle of utilising the variation of magnetisability by heat as the basis of electric machines, though clearly applicable to generators, was first applied to the construction of a simple form of heat engine which I have called a pyromagnetic motor. A description of this motor will help us to understand the generator subsequently constructed.

Suppose a permanent magnet having a bundle of small tubes made of thin iron placed between its poles and capable of rotation about an axis perpendicular to the plane of the magnet after the fashion of an armature. Suppose further, that by suitable means, such as a blast or a draught, air can be made to pass through these tubes so as to raise them to redness. Suppose that by a flat screen symmetrically placed across the face of this bundle of tubes, and covering one-half of them, access of the heated air to the tubes beneath it is prevented. Then it follows that if this screen be so adjusted that its ends are equidistant from the two legs of the magnet, the bundle of tubes will not rotate about the axis, since the cooler and magnetic portions of the tube-bundle (*i.e.*, those beneath the screen) will be equidistant from the poles and will be equally attracted on the two sides. But if the screen be turned nearer one of the poles and the other nearer the other, then rotation of the bundle will ensue, since the portion under the screen, which is cooler, and therefore more magnetisable, is continually more strongly attracted than the other and heated portion. This device note, therefore, as pyromagnetic motor, the heat now passing through the tubes in such a way as to produce a disymmetry in the lines of force in the iron field, the rotation being due to the effort to make these symmetrical. The guard plate in this case has an action analogous to that of the commutator in an ordinary armature. The first experimental motor constructed on this principle was heated by means of two small Bunsen burners, arranged with an air blast, and it developed about 100 foot-pounds per minute. A second and larger motor is now about finished, which will weigh nearly 1,500 pounds, and is expected to develop about 3 horse-power. In both these machines electromagnets are used in place of permanent magnets, the current to energise them being derived from an external source. In the latter machine the air for the combustion is first forced through the tubes to aid in cooling them, and then goes in to the furnace at a high temperature.

The earliest experiments in the direction of the pyromagnetic production of electricity were made with a very simple apparatus, consisting of a charged electro-magnet, having a tube of thin iron passing through its cores near their outer ends, a coil of wire being wound around this tube, and including an ordinary sounder deliberately adjusted in its circuit. The tube beneath the coil was covered with asbestos paper. After heating the tube to redness by a gas blast directed into it at one end, a jet of cold air was suddenly substituted for the flame, the sounder at once closed, showing that the change in the magnetisability of the iron had varied the distribution of the lines of force within the coil, and thus had produced a current of electricity in this closed circuit.

The construction of a machine of sufficient size to demonstrate the feasibility of producing continuous currents on the large scale in this way was at once begun and has only just been completed. The new machine consists of eight distinct elements, each the equivalent of the device already mentioned, consisting of the two legs of an electro-magnet somewhat far apart (12 inches actually), having at one end the ordinary yoke, and at the other a roll of corrugated sheet iron ·005 inch thick called an interstitial armature: this armature having a coil of wire wound upon it and separated from direct contact by means of asbestos paper. The eight elements are arranged radially about a common centre, and are equidistant, the eight interstitial armatures passing in fact through the iron discs, which constitute the common pole piece of all the electro-magnets. The coils wound upon the interstitial armatures are connected directly in series, the whole forming a closed circuit. Through the centre of these discs a hollow vertical shaft passes, carrying at its lower end a semi-circular plate of fire clay called a guard plate, which, when the shaft is turned, revolves close to the lower ends of the sheet iron armatures and screens off half of them from the access of heat from below. The shaft carries a cylinder of insulating material having metallic contact pieces let into it on opposite sides, the line joining them being parallel to the straight edge, of the guard plate. Upon this cylinder eight springs press, each of these springs being connected to the wire of the closed circuit above-mentioned midway between the coils. The length of the metallic segment is so proportioned that the following spring touches it just as the preceding one leaves it. The springs themselves are so adjusted that each of them comes into contact with its metallic segment just as the preceding coil of the pair to which it is connected is uncovered by the rotation of the guard plate. Upon the same shaft, and above the cylinder just mentioned, a pair of metallic rings are placed, insulated from the shaft, to each of which one of the metallic segments is connected. Brushes pressing upon these rings take off the current produced by the generator.

The entire machine now described is placed upon the top of any suitable furnace, fed by a blast, so that the products of combustion are forced up through those interstitial armatures which are not covered by the guard plate, and raise them to a high temperature. The field magnets, when charged, magnetise of course only those interstitial armatures which are cold, *i.e.*, those beneath the guard plate. On rotating this plate, the interstitial armatures are successively uncovered on the one side and covered on the other; so that continually during the motion four of the eight armatures are losing heat and the other four are gaining heat. But those which are losing heat are gaining magnetism, and *vice versâ*. Hence, while currents are generated in all the armature coils, since in all the magnetism is varying, the current in the coils beneath the guard plate will be in one direction, while that in the coil exposed to the fire will be in the other. Moreover, whenever a armature passes out from under the guard plate, its condition at once changes: from losing heat and gaining magnetism it begins to gain heat and lose magnetism. Hence, at this instant, the current in its coil is reversed, and, consequently, the line connecting this coil with the one opposite to it constitutes the neutral line, or line of commutation, precisely as in the ordinary dynamo. Indeed, the action of the interstitial armature coils of the pyromagnetic dynamo resemble strongly that of the ordinary armature coils of the Gramme ring, not only in the manner of connecting them together, but also in their functions, the change of direction in the current as the magnetism of the field changes sign in the latter case, corresponding closely to the change of current in the former case, due to the direction of the temperature change. But



It will be observed that while in the Gramme ring the loops between the armature coils are connected to commutator bars, in the pyromagnetic dynamo the armature coils are connected to an equal number of brushes (in

It will be observed that while in the Gramme ring the loops between the armature coils are connected to commutator segments equal in number to that of the coils, upon which commutator two brushes press, in the pyromagnetic dynamo the loops between the armature coils are connected to an equal number of brushes (in this case eight), while the commutator segments are only two in number; so that the functions of the commutator and the brushes in this generator are in a certain sense reversed as compared with the ordinary dynamo.

The potential difference developed by this dynamo will obviously depend (1) upon the number of turns of wire on the armature coils; (2) upon the temperature difference in working; (3) upon the rate of temperature variation, and (4) upon the proximity of the maximum point of effect. No advantage will be gained, of course, by raising the temperature of the interstitial armatures above the point at which its magnetisability is practically zero; nor will it be advantageous on the other hand to cool it below the point where its magnetism is practically a maximum. The points of temperature, therefore, between which for any given magnetic metal it is most desirable to work, can be easily

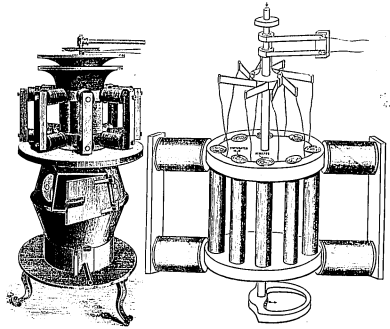


Fig. 1. (Reproduced from the "Electrical World.") Fig. 2.

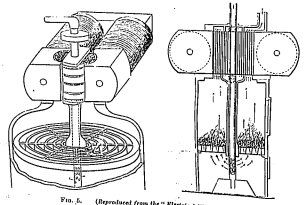

Fig. 5. (Reproduced from the "Electrical World.") Fig. 6.

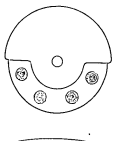
determined by an inspection of the curve showing the relations between heat and magnetism for this particular metal. Thus the points of temperature at which the magnetisability is practically zero, as above stated, are a white heat for cobalt, a bright red for iron and 400° for nickel. On the other hand, while at ordinary temperatures iron has a maximum intensity of magnetisation represented by 1,390, its intensity at 220° is 1,360; and hence no commercial advantage is gained by cooling the iron below this temperature. Nickel, however, whose maximum intensity of magnetisation at ordinary temperature is 800, has an intensity of only 330 at 220°. Hence, while this metal requires a lower maximum temperature it also requires a lower minimum one; but it may be worked with much less heat. The rate of the temperature variation is determined by the rapidity with which the guard plate revolves. And this in its turn is dependent upon the rapidity with which the interstitial armature can be cooled and heated. That it may take up and lose heat readily the sheet-iron of which it is made is very thin (only 005 inch thick, even when its durability is increased by enamelling or nickelling); it is corrugated and rolled up so as to expose a large surface (about 60 square feet for the eight armatures), and hot and cold air are alternately forced through the armature. Experiments

FIG. 3.



(Reproduced from the "Electrical World.")

FIG. 4.

already made show that the guard plate can probably be made to revolve 120 times a minute. Since the potential difference is proportional to the number of lines of force cut per second, it is evident that by doubling the speed of rotation, twice as many lines of force would flow across the generating coils per second and the output of energy would be quadrupled. Exactly what thickness of metal is the most suitable for the purpose, what the relative volume occupied by metal and by air space in the interstitial armature should be, what is the best diameter for this armature, or even the best metal, what the best limits of temperature and what the best speed of rotation to produce the maximum potential difference—all these are questions which must be decided by experiments made upon the generator itself.

The results thus far obtained lead to the conclusion that the economy of production of electric energy from fuel by the pyromagnetic dynamo will be at least equal to and probably greater than that of any of the methods in present use. But the actual output of the dynamo will be less than that of an ordinary dynamo of the same weight. To furnish 30 sixteen-candle lights in a dwelling-house would probably require a pyromagnetic generator weighing two or three tons. Since, however, the new dynamo will not interfere with using the excess of energy of the coal for warming the house itself, and since there is no attendance required to keep it running, there would seem to be already a large field of usefulness for it. Moreover, by using the regenerative principle in connection with it, great improvement may be made in its capacity, and its practical utility may very probably equal the interesting scientific principles which it embodies.

[We reproduce on preceding pages the drawings exhibited at the meeting in explanation of the paper. Fig. 1 represents the pyromagnetic generator in perspective. Fig. 2 shows diagrammatically the manner in which the coils are connected with the commutator at the top and the manner in which they are built up. The cores of thin corrugated iron are held at the top and bottom by iron plates, which are magnetised by the surrounding electro-magnets. The corrugated cores, which allow the passage of the heated gases through them, are covered with asbestos and then wrapped with wire, the ends being joined in series, as shown, and the joints connected to the brushes instead of to the commutator. The air blast passes through the shaft from above and passes out from the apertures in the revolving plate of fire-clay below the tubes. Fig. 3 shows this plate, looking from below, from which it will be seen that four tubes are cooling, being screened from the heat, and also by means of the cold air blast, and four are being heated by the passage of the heated gases. Fig. 4 shows the plate resting upon the top of the stove. The pyromagnetic motor is shown in diagrammatic perspective in fig. 5 and in section in fig. 6. The armature, it will be seen, is built of small iron tubes, part of which placed obliquely to the lines joining the poles, are continually cooled and attracted by the poles, while the remainder are demagnetised by the heat.]

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

(From the Special Correspondent of the "Electrical Review.")

THE fifty-seventh annual meeting of what was once called "the Peripatetic Parliament of Science," in other words, the British Association for the Advancement of Science, has now come to an end. It has been a noteworthy meeting in many respects. From the purely scientific side it has been an eminent success, for although nothing startlingly new has been communicated, there have been recorded decided and important advances in more than one branch of scientific knowledge. To the physicist and the chemist, perhaps, the most important of all the papers were those put before Sections A and B, sitting jointly under the presidency of Sir William Thomson, on Saturday. These dealt with that interesting but hitherto rather vaguely known subject, electrolysis. Prof. Oliver Lodge has laboured strenuously to make this field a more open and better cultivated one, and he has gathered under his standard a number of truly scientific workers whose eminence indicate the importance to be attached to the new researches of which they were on Saturday the communicators and exponents.

A second reason for marking the Manchester meeting of 1887 as one a little out of the ordinary run was the presence of a large number—closely approaching one hundred—of foreign scientists, whose fame had preceded them. Profs. Wiedemann, Quincke and Weber from Germany, and Prof. Lippmann of Paris, each had something to communicate on physical questions, and all the English members were enthusiastic in the reception which they accorded their visitors. No less cordial was the greeting which was extended to the American men of science, of whom Prof. H. A. Rowland and Prof. C. A. Young took the most prominent part in the transactions of Section A.

What was not quite so satisfactory as the nature of the subjects discussed and the great gathering of re-

ADVANCEMENT OF SCIENCE.

Production of Electricity from Fuel.

Papers by Thomas A. Edison—Other Matters Before the American Association To-day.

The Council of the American Association for the Advancement of Science met at the rooms this morning. The reports of the various committees were read, and after transacting routine business the committees adjourned. The sections met as usual at ten o'clock in their rooms, and the attendance was very large. The number of scientists registered this morning was 650, and there were a great many ladies among them.

At a session of the Biological Club in the room of Section F., the Rev. Thomas Morong advocated the establishment of a national botanical exchange for domestic and foreign plants. Dr. Vasey of Washington, J. Scroop Watson of Cambridge, Dr. R. L. Britton of Columbia College, Rev. Thomas Morong of Ashland, Mass., and Prof. Byron D. Halsted of the Agricultural Colleges, Ames, Ia., were appointed a committee with power and instructions to solicit, if possible, the Department of Agriculture in a scheme for the establishment of a botanical exchange, and to ask the Smithsonian Institution for distributing facilities. They will report through the botanical journals.

In section B, Physics, Prof. George F. Barker read two papers by Thomas A. Edison—on the Tycomagnetic Dynamo; a machine for Producing Electricity Directly from Fuel, and on a Magnetic Ratchet or Motion for Converting Magnetic Conductivity. The following is what was practically said by Mr. Edison on the new dynamo:

The production of electricity directly from coal has a portion which has been supplied for almost sixteen of the ablest inventors for many years. Could the enormous energy latent in coal be made to appear as electric energy by means of a simple transforming apparatus which accomplishes its result with reasonable economy, it will be conceded probably that the mechanical method of the entire world would be revolutionized thereby, and that another of those grand steps of progress would be taken of which the nineteenth century has been so full.

The simple production of a potential difference, by means of the contact of dissimilar substances, is the science of thermo-electricity thus established, has been developed by Seebeck, Peltier, Becquerel, Thomson, and by Tait, and the Siemens batteries of Clamond and Mile have found a commercial application.

The science of thermo-electricity thus established, way as to produce a dissymmetry in the lines of and the other and heated portion. The electric arc, therefore, on a pyro-magnetic motor, Association for the Advancement of Science in New York yesterday, was read by Thomas A. Edison, read by Professor George F. Barker, the eighty-one years trial before the Academy of Sciences at Philadelphia, and by the latter before the Division of Heat into Electricity of the American Association.

"Since whatever a magnetic field varies in strength in the vicinity of a conductor a current is generated in that conductor, it occurred to me that if a conductor, such as a coil of wire, were made and varying the magnetism by a heated core by varying its temperature, it would be possible to generate a current in a coil of wire surrounding the core."

Mr. Edison thinks that his device can furnish light for a whole house by means of the heat from a single burner, and he will soon test his experiments in that direction. He calls the machine the pyromagnetic generator.

ELECTRICITY FROM COAL.

A Whisper of a Discovery Which Thomas A. Edison Is Said to Be Developing.

Scientific Men Discussing the Possibility of Generating Electricity Directly from Coal.

Edison's Pyromagnetic Dynamo.

The best generation of electricity from coal is subject is at least of exceeding interest. If electricity can be generated in available strength by other means than by friction produced by the dynamo machine we are on the brink of wonderful changes in our methods of manufactured and in comfortable made for general comfort. Mr. Edison believes that he has discovered a means whereby heat acting upon an iron core covered by coiled wire and in magnetic circuit will produce electricity. If this can be done ingenuity ought not to be at fault to find a means of making the surplus heat from furnaces and fires in manufactories or dwellings available for producing sufficient electrical strength to light our houses.

Everybody knows that under the usual circumstances of combustions large amount of heat is carried off by the draught in the chimney which is necessary to make the fire burn. The extra heat is absolutely wasted and there has been no method of preventing it. If Edison's plan of placing his apparatus in a chimney will generate enough electricity to illuminate our houses by incandescence or are lights a great advance will be made toward the comfort of the people and the household economy. It is not necessary to confine the thought to the one subject of lighting. The electricity produced from waste heat can be used for other purposes than illumination. It can be applied to the working of machinery and then be easily managed by low motive power, and might prove in the household the one great boon which would make the sewing machine a perpetual pleasure.

THE WIZARD'S POWER.

Edison's New Invention Described Before the Scientists.

His Latest Apparatus First Made Public Through The Journal, and How It Is Made.

In Section B of the meeting of the American Society for the Advancement of Science yesterday was read the paper on his new pyromagnetic dynamo invented by Thomas A. Edison.

The great point in this invention is that it is destined to revolutionize the present power and light manufacturing methods of the world, was announced exclusively by THE MORNING JOURNAL yesterday, and the first descriptive article of the machine shows that it is even more wonderful than THE JOURNAL'S first article stated it to be.

Mr. Edison had tried to have a pyromagnetic dynamo made in time to exhibit to the scientific scientists, but he found it impossible to do so. His description of the machine and its theory, however, was very complete. The paper was read for Mr. Edison, who was not present, by Professor George F. Barker.

The new invention of electricity directly from the combustion of coal, the paper says, is confessedly into electricity, and the mechanical energy of the latter is utilized from 75 per cent of the fuel-energy of fuel. The simple production of potential difference by means of the contact of dissimilar substances, the science of thermo-electricity thus established, has been developed by Seebeck, Peltier, Becquerel, Thomson, and by Tait, and the Siemens batteries of Clamond and Mile have found a commercial application.

The science of thermo-electricity thus established, has been developed by Seebeck, Peltier, Becquerel, Thomson, and by Tait, and the Siemens batteries of Clamond and Mile have found a commercial application.

The electrical energy latent in coal be made to appear as electric energy by means of a simple transforming apparatus which accomplishes its result with reasonable economy, it will be conceded probably that the mechanical method of the entire world would be revolutionized thereby, and that another of those grand steps of progress would be taken of which the nineteenth century has been so full.

The simple production of a potential difference, by means of the contact of dissimilar substances, is the science of thermo-electricity thus established, has been developed by Seebeck, Peltier, Becquerel, Thomson, and by Tait, and the Siemens batteries of Clamond and Mile have found a commercial application.

The electrical energy already of thermo-electricity attacked in these generators have stimulated research unremittingly, and many investigators who believed that in this direction lay the philosopher's stone. Our friend, Moses G. Farmer, worked long and assiduously in this field, producing, it is believed, the most satisfactory results hitherto recorded, and his name will be remembered. He never succeeded in converting in piece of permanent magnets, the current is one per cent. of the energy of the coal into electric energy.

While recently Lord Rayleigh has discovered with his well-known ability the law of efficiency of the thermo-electric battery from the standpoint of the record, investigations, and he spectroles that for a specified couple, working between the extreme limits of temperature possible for those twilight's conventions can never rise more than one-fourth per cent of the coal energy can be tapped for. As a last engine, therefore, the thermo-electric seem to follow precisely the law of Carnot, and a large coals in this way was at once begun.

The machine is placed, upon the top of any suitable furnace, fed by a blast, so that the products of combustion are forced up through the tubes which are not covered by the guard plate, and raise them to a high temperature.

The potential difference developed by this dynamo will obviously depend, it upon the number of turns of wire upon the armature coils; (2) upon the temperature difference at working; (3) upon the rate of temperature variation; (4) upon the proximity of the maximum point of effect. Experiments have shown that the guard plate can possibly be made to receive 170 times a minute. Since the potential difference is proportional to the number of lines of force cut per second, it is evident that by doubling the speed or rotation, twice as many lines of force would thus across the generating coils per second and the output of energy would be quadrupled. Exactly what thickness of metal would be most suitable for the purpose what the relative volumes occupied by metal and by air spaces in the interstitial armature alcohol; what is the best diameter for this armature, or even the best speed; what the best limits of temperature, and what the best speed of rotation to produce the maximum potential difference—all these are questions which must be decided by experiments more upon the generator itself.

The results thus far obtained lead to the conclusion that the economy of production of electric energy from fuel by the pyromagnetic dynamo will be at least equal to and probably greater than that of any of the methods in present use. But the actual output of the dynamo will be less than that of the dynamos of the same weight. To furnish thirty sixteen-candle lights will require a pyromagnetic dynamo weighing a pyromagnetic generator weighing about one ton. It will however be possible to run this machine for with setting the screws of energy of its coal for warming the house itself, and since there is no attendance required to keep it running there would seem to be already a large field of application for it. Moreover, by varying the expenses, principle in connection with it, great improvements may be made in its capacity, and in practical utility may very probably equal the latest existing scientific principles which it embodies.

HOBSON'S LATEST IDEA.

The Direct Conversion of Heat Into Electricity and Power.

Among the most interesting of the eighty-one papers read before the Associate Association for the Advancement of Science in New York yesterday, was one by Thomas A. Edison, read by Professor George F. Barker, before the Division of Heat into Electricity of the American Association.

"Since whatever a magnetic field varies in strength in the vicinity of a conductor a current is generated in that conductor, it occurred to me that if a conductor, such as a coil of wire were made and varying the magnetism by a heated core by varying its temperature, it would be possible to generate a current in a coil of wire surrounding the core."

Mr. Edison thinks that his device can furnish light for a whole house by means of the heat from a single burner, and he will soon test his experiments in that direction. He calls the machine the pyromagnetic generator.

EDISON'S LATEST DEVICE.

PYROMAGNETIC GENERATOR.

HE TELLS THE SCIENTISTS ABOUT HIS TYCOMAGNETIC DYNAMO.

The Wizard's Method for Turning the Heat of a Domestic Furnace into Electric Energies and Lighting Houses by It.

Among the most interesting of the eighty-one papers read before the Associate Association for the Advancement of Science in New York yesterday, was one by Thomas A. Edison, read by Professor George F. Barker, before the Division of Heat into Electricity of the American Association.

"Since whatever a magnetic field varies in strength in the vicinity of a conductor a current is generated in that conductor, it occurred to me that if a conductor, such as a coil of wire were made and varying the magnetism by a heated core by varying its temperature, it would be possible to generate a current in a coil of wire surrounding the core.

Acting upon this idea, Mr. Edison placed a metal electro-magnets in a circle, all their poles in contact with one iron disk, and their magnetic poles in contact with another. Passing through the disks and isolated from them is a metal rod, around which is coiled a insulated iron core and opposite to the electro-magnetic poles permeability of the electro-magnets. The rod is connected at one end with the armature of the electro-magnets, and at the other with a ratchet wheel. A pawl is pivoted to a fixed support and rests upon the ratchet. Then the metal is magnetized, and the armature is drawn to the electro-magnets, and held, before but, when non-magnetic, is withdrawn by a spring. The rod is then heated, and the magnetic conductivity was generated in the coils of wire surrounding the rod.

The apparatus for producing currents was so modified as to furnish electric lights for a whole house by means of the heat from an ordinary furnace, and he will, perhaps be enabled to test his experiments in that direction very soon.

The proposed pyromagnetic motor is thus described by Mr. Edison: "Let us suppose a ring of iron wire wound in the form of a permanent coil. The wheel is made of tubes of thin iron or steel, and the ends of the tubes are connected with a hub, which conveys the heat or air at the center of the wheel. The

EDISON'S PYROMAGNETIC DYNAMO.

Professor Thomas A. Edison would not seem to be resting on his paper on his new invention, the pyromagnetic dynamo, but is continuing experiments with it, as appears by another paper presented to the Franklin Institute by Professor Thomas P. Barker. This paper is entitled "Experiments with Edison's Pyromagnetic Dynamo," and merely all the necessary conditions of the experiments were on hand at Menlo. Mr. Edison's paper began by stating that he had found that the magnetic qualities of iron, in the field of the pyromagnetic generator of electricity, is not confined to nickel, as believed.

It is well known that the thermo-cell appears to fail. Are heat rays, or vibrations, necessary to the flow of the current? Is the current produced by heat, or by the heat-rays? Efficiency rises the reversible action of this cell. Is the cell reversible? Is it a true cell? Is it a true thermo-cell? Is it a true thermo-cell? Is it a true thermo-

Journal, Lowell, Mass. Dec. 23, 1887.

EDISON'S NEW IDEA.

"Tone" Edison's chief d'œuvre is to be a contrivance to extract electricity from coal without the interposition of fire, water and steam to make the wheels go round for the purpose of converting the latent forces of carbon into lighting. He expects to succeed and when he does, his great life work will have been set to filling chimes.

At present only 9 per cent of the electric force known to be concealed in coal, is saved by the time it has passed through the various subterranean mazes, ending in current through a cable. If Mr. Edison saves the other 91 per cent and reduces twenty times the cost of running lights and machinery by electricity, he will have all the water hands left on Pactolus at his command. However, we suppose the agriculture will make us pay such a tremendous royalty on his machines for the first, fifteen years after their construction, that we shall have to wait half a generation before the public begins to realize on the salvage of force.

It is a pity that our system rules the government out from securing for the people at large the benefit of the great inventions and discoveries. If it were so arranged that when a citizen had perfected an invention, the government could step in and put it on record a price as it would sell for and then the market, and make it free to all, the inventor and the public would not have to share the benefit with corporations so as to enable outsiders who have done nothing to pile up millions out of the brains of the Edisons, the Fultons and the Morses.

The French government is wiser. It is not afraid of employing science. It has at its command the services of experts in all scientific departments, who are competent to put a valuation on any invention or discovery that will be of great public utility, and upon the judgment of those scientific commissions the government buys the patent, having reserved for itself the first right of purchase, and this policy has not only prevented advantage to the nation. The government of the United States pays appliances to her as to any other customer, and war rats eat of the pontiis.

In this country the government habitually trusts all the work of her inventors and scientists as a friend until, some private capitalist with more sense steps in and pilfers the spoil.

Just exhibit how much 'this' nation would have saved if twenty years ago the government had been as smart as the Western Union Telegraph company, and had employed Mr. Edison to work for it on the same or similar terms under which the great corporation contracted for his services. But the government never had in its employ any man of great genius, except as a soldier or a sailor. Why does it waste its opportunities?

News, Newark, N. J. Sept. 28, 1887.

EDISON HARD AT WORK

PLANS OF THE GREAT INVENTOR

How He Employs His Time—Waiting for Machinery Started in England to Perfect His Tyrannosaurus Motor—His New Laboratory.

A few weeks ago, in a paper read before the annual meeting of the American Association for the Advancement of Science in New York, Thomas A. Edison showed that it was possible to produce electricity directly from heat, without the aid of steam or machinery. Public interest was excited by the announcement, but the matter sank under which electricity interest was in great part forgotten, and here was a fire which demonstrated that some day the electric light and power, with all their accessories, might be as cheap as gas. In conformity with his usual custom of not talking about his inventions until he could go no further with his theory more until he had finished certain pieces of machinery. Thus, pieces could only be obtained in England, and nothing remained but to stalk the lions and await their arrival. This was done, and since then the machinery has been practically at a standstill.

Mr. Edison informed a NEWS reporter when asked what progress he had made with his new discovery that there was nothing to say except that he was waiting for machinery which was ordered and has been delayed, but which he would again take it up. Mr. Edison calls his new machine a "tyrannosaurus motor." His paper gave a technical description of it and its method of working. Instead of coal consists of placing an iron core in a magnetic field and then heating it. The expansion caused by the heating is to be transformed into motion. This motion will, however, be very small, and will require an ordinary dynamo of the same weight. He calculated that to furnish thirty-two candle power in a house would require a tyrannosaurus motor weighing between 200 and 300 pounds. Should the arrangement of the motor was that it could be placed on top of a furnace and be run by the release of the energy of the coal from warming the house itself, and would require no attendance beyond stoking the furnace. Mr. Edison's workings upon the invention.

Mr. Edison has a new laboratory established in his magnificent residence in Lakeside Park and is delighted with Orange as a home. In spite of his success in life and his accumulation of the New York banker than he. Every working day he is down at his office in New York by 9 o'clock, has a drive to the Orange depot, the Delaware, Lacka-wanna and Western Railroad, from whence he takes a train for Hoboken, where his laboratory now is. There he works generally until 6 or 7 o'clock at night. Mrs. Edison usually has an early dinner with the carriage and drives to the depot to meet him. The weather is clear, and the ride after the day in the laboratory labor is very pleasant. Mr. Edison's building on Valley road, at the corner of Main street, and upon a quarter of an hour inspecting its progress. Mr. Edison does not like to talk about his inventions until they are very near completion. He declares that he can think better when all is quiet, and is at night.

THE NEW LABORATORY.

The laboratory that Mr. Edison is building consists of one large building and four smaller ones, all of brick. The large one is well up. It has dimensions of 250 feet. The other buildings are 100 feet square and 50 feet high. The new laboratory is to be on the north side of the large one. All the buildings will be well provided with Valley road. They are each fitted out, and will cost

Courier, Gloucester, Mass. Dec. 24, 1887.

EDISON'S NEW IDEA.

Thomas A. Edison has a new idea. He has had it for some time, but has kept it to himself. He has now given it to the world. It is the production of electricity from coal by the direct application of steam power. Instead of the present method of first converting the steam into mechanical motion and then converting the mechanical motion into electricity, Mr. Edison proposes to apply the steam directly to the coal, and thus produce the electricity. He has already made a machine which will do this, but it is not yet complete. He has not yet applied for a patent, and will not do so until he has perfected his machine. He has, however, given the idea to the world, and it is probable that others will work out the problem before Mr. Edison has completed his machine. The idea is a very simple one, and the principle involved is not new. It is the application of the principle to the production of electricity that is new. Mr. Edison has not given the details of his machine, but he has explained the principle upon which it will work. The principle is that of the expansion of iron when heated. Mr. Edison has a piece of iron which he has magnetized. He has placed this piece of iron between the poles of a magnet. When the iron is heated it expands, and in expanding it moves between the poles of the magnet. This movement of the iron between the poles of the magnet produces electricity. The iron will expand and contract as long as it is heated and cooled, and as long as it does so it will produce electricity. The principle is a very simple one, and it is surprising that it has not been applied before. Mr. Edison has applied it to the production of electricity, and has made a machine which will do the work. It is probable that other inventors will work out the problem before Mr. Edison has completed his machine. The idea

gines to the world. A number of others agree with Mr. " Ilion that the field of invention most likely to afford great results is electricity. General Greely thinks that the next great invention is to be the storage, without appreciable loss, of electricity produced by natural forces, such as waterfalls, tides, etc., but he regards a motor-cycle as the economic invention most needed. Professor William Ripley of Colby University thinks the invention most needed is a means of generating electricity which shall be easily regulated and cheap enough to allow it to be used as a source of motion, light and heat, available for general supply and easily distributed to residences; farms and for manufacturing purposes. Milton Chase, a Haverhill inventor, says that the world not only wants, but must have, a cheaper motor than the steam engine—one that will work with economy of the consumption of the last of the principles he looks to electricity for this means. And Dr. Ernest C. Dana of Portland wants an electrical miracle destroyer to prevent epidemics.

But do we look to electricity for future wonders simply because our latest and most startling inventions have been in that field? The telegraph, after all, was not an accumulation on the steam engine; and perhaps the next great revolutionizing invention will be in some entirely unexpected field, and outside of electricity. Mr. Edward Atkinson thinks that the great invention" need to come, and the one most needed, is the conversion of the nitrogen of the atmosphere into food for plants without the detour by animal methods. This would certainly be a revolutionary, for it would make men independent of the soil, which has yet been limited in its way of invention. Mr. Atkinson thinks. Professor C. G. Hinchliffe of Sweden thinks also with the imagination to run his mind, is the one missing needful. "The earth will never be completely under control," he says, "until we can navigate the air with swiftness and safety. The air is the universal highway. The road is always open; it costs nothing to keep it in repair; it goes over all savage man's deep. Mountains and rivers and seas will be no barriers to the device that will overcome the initial difficulty—that of flying at all. Think of the wants [illegible] class of inventors who are simply looking for something to invent may well apply themselves to it. Mr. Stanley also wants a means of separating aluminum from clay—and Mr. Robinson of Rose-dale College joins him in this—and a means of utilizing and bringing to New England the vast quantities of sunshine now generated every day in the Desert of Sahara. This sunshine, after a means of capturing a great mass of natural energy wasted every day suggests to us the question, Why do not some of these inventors, in their specialties, aspire toward a means of utilizing the surplus energy of the ocean tides? Every day in the year the ocean are engaged in titanic, mountain labors, twice in every twenty-four hours the seas bend themselves to a lift that would turn all the wheels that there are in the world, and all that the utmost industry could set up in the future; and all this power is of course to no purpose whatsoever. It is like Atlas straining his muscles forever to hold up nothing at all.

There are some other answers to the Lewiston paper's question that people in general will no doubt regard as whimsical. Rev. Henry Blanchard, D. D., of Portland, avows himself a student of, though not yet a convert to, Henry George's doctrines, and thinks that, if George and Stuart Mill are right, the "single tax on land" is the thing that the world needs and calls for. Wiggin, the weather prophet, has a very startling idea. The world needs, in his view, a means of producing fine constantly only those atmospheric elements necessary for the nourishing of the system, "when of course the digestive organs below the true stomach will gradually be absorbed and disappear. When man's viscera disappears, the mental energy will be reserved for thought and the prime source of disease will disappear." This is in echoes which will recommend itself highly to dyspeptic and listless persons. The eliminating of the liver, for instance, from the human system has long been regarded by a considerable section of the human race as a consummation devoutly to be wished. But Mr. Wiggins's proposed means of elimination is likely to be very slow. The race might have developed into quite human form of life before the bowels had been rendered rudimentary. But for all that, the notion is not absolutely unscientific. George Francis Train's scheme seems the last with a rubicelle ad absurdum. He wants "the electric fluid—that is, the soul," kept in storage in the human body; "its generation and use of man is an electric conservative. The human system is a vast storage battery. It gets its force to keep from escaping man would live forever." But after all, good philosopher of Madison square, are you sure that that would be a thing to be desired?

ELECTRICITY FROM COAL.

Thomas A. Edison Tells What His Youthful Inventions Will Bring.

AKRON, Dec. 24.—[Special.]—Thomas A. Edison, the electrician, is spending the holidays with his father-in-law, Lewis Miller, in this city. In an interview to-day he said he was now at work on an invention that would produce electricity direct from coal discharging entirely with the use of batteries, etc., now required. Besides, he said, it would do away with the entire heat-ing of coal before it could be converted into electricity as is done by the present system of burning. "It will be [illegible] of Mr. Edison.

Journal, Indianapolis, Ind
Dec. 25, 1888.

Mr. Edison is said to be experimenting on a process of producing electricity direct from coal without the intervention of boilers or steam engines as an intermediary. Such a thing seems at first blush impossible, but with modern science, and especially with Edison, there seems to be no such word as impossible. The evolution of electricity from coal by means of combustion and steam involves a great loss in the transformation of power and consequent waste of energy. It is could be extracted directly from the coal it would add incalculably to its efficiency, force and practical value. Only experts can say whether such a thing is possible, but the fact that Edison is experimenting in that direction shows he thinks it is, and there is no telling what he will do.

EDISON'S INVENTIONS.

He Can Now Produce Electricity Direct From Coals.

Akron (O.), December 27.—Thomas A. Edison spent Christmas with his father-in-law, Lewis Miller, of this city. In an interview he said he was now working on an invention whereby electricity would be produced direct from coal, dispensing entirely with the boiler and engine, etc., now required. Besides, he said it would use the entire heat units of the coal, instead of only about 5 per cent, as is done by the present system of burning.

Press, Troy, N. Y.
Dec. 25, 1888.

Edison is trying to devise a means to produce electricity direct from coal without the intermediate process of steam production. There is more waste of coal than of any other necessary material. Only a small percentage of it, less than it produces is useful. An invention that would make all the heat available would be as great a boon to mankind as any that the human brain has made.

EDISON'S NEW IDEAS

HE BELIEVES ELECTRICITY IS THE COMING POWER.

We Must First Discover How to Produce Electricity from Coal Without Wasting Its Energy in Heat—Look at Edison's Laboratory—He Has Little Faith in Aerial Navigation.

If you meet Edison this morning he has just discovered something, and if you meet him to-morrow he has added a new find in the realm of scientific invention. It is hard to keep up with him. Probably no investigator in the field of science has ever been surrounded by such perfect conditions for prosecuting his researches. This has not always been so, of course, for Thomas Edison has discovered, among other things, the way of making money.

His laboratory is about a mile from the station at Orange, on the Delaware, Lackawanna and Western Railroad. His charming home is set far removed in the beautiful rolling foothills of Llewelyn Park. Within the inclosure where his working plant is situated stands a large three-story brick building. This is the laboratory, a perfect bastion of energetic experimenting. To the north of the building are three smaller ones, all about the same size.

AN UNPLEASANT ATMOSPHERE WHERE RUBBER GLOVES ARE NECESSARY.

One of these is for ore milling, for Edison contends that the best ore for fertilizers comes from the baser metals. The building next to this is the machine shop for assembling, where the heavier stuff is kept.

Next to this is the galvanometer room, or building, for measuring experiments with electricity. Edison's office is in the main building, and connects with the electrical establishment, and the machines rest on masonry piers that run from the bottom into the ground. The bolts and every metallic part of the instrument is of brass to avoid deflection at the needle.

Within one enters the laboratory he is confronted by a placard which informs the intruding visitor that Mr. Edison is so occupied with his work that he cannot be seen. Below are greetings to callers, and the like, unpleasantly. Happily, an acquaintance so near the door of the sanctum himself, the placard of its business-like inhospitalities. He was engaged at his usual occupation, that of experimenting with electricity, and hugged close to the corner of an office desk.

This time of writing admitted of a cursory glance at the building. There is a fine library room, with numerous shelves, and a large table covered with books and papers. There is a stenographer in attendance, and a clerk. Then there is a science room, and the large annex brilliantly lit by electric lights. There are hundreds of these being constantly tested in the building, and there is a constantly increasing number of new ones being experimented on. He has 107 men in constant employment in this place at Orange. Mr. Edison is conducting experiments

EDISON'S NEW IDEA.

What Edison is Hacking His Brains Over.

Edison's friends, Akron, O., where the wizard and Edison is spending the holidays at his father-in-law's, says, that he is working on an invention whereby electricity may be produced direct from coal, without at the same time wasting power in converting water into steam to boilers, and that into power, and that the great electrician believes that he may be able to use almost all the heat units of the coal instead of from 5 to 10 per cent, as at present. This is something which Edison has been working at for two years. With hints from this scientists whom he has consulted he has made practical headway in the solution of the great problem. From the conclusion I may in which he now assists he has apparently made some progress since he last spoke for publication on the subject, and has hopes that he may reach the heart and core of the mystery. If he succeeds he will be the greatest benefactor the human race has known since the mystical days when Prometheus stole the fire from heaven and gave it to man. All the cunning and valuable inventions with which his name has been associated, the quadruplex, the phonograph, and the incandescent light—will shrink into insignificance and will be regarded as the mere idle thoughts of a leisure moment. If he is able to discover how electric energy the most that lies in the carbon and hydrogen of coal he will have given to man the greatest gift that man can use of Nature, unless it be the secret of the winds and rains. He will have multiplied by ten the present capacity for work of every ton of coal in the world, and will thereby have decuded our mechanical powers. He will have revolutionized the world of machinery. What the Cuvies began to do in the primitive water wheel of the Egyptians of the days of Pharaoh that will Edison's device so to the newest steam engine. Steam engines and gas engines will all go to the junk shops, and new plants—when one cannot yet tell—will be taken their place. Should Edison make such a discovery, all we ask of him is that he will be moderate, and that he will not charge so high a royalty as to heap up for himself a fortune of more than a thousand million dollars during the life of his patent. It will be in his power to control the accumulated wealth of all the Rothschilds and Vanderbilts, and as concentrate on himself—the hatred and scorn that would be now lavished on Gould. Investors look out no patent on six discovery and draw up his papers in unending fans, but to suggest the gods and bad to suffer for it. It is necessary that the public may be put on to imitate him to the point of angering Zeus.

Budget, Boston, Mass.
Dec. 25, 1888.

Thomas A. Edison says he is now experimenting on an invention whereby electricity would be produced direct from coal, dispensing with boilers, engines, dynamos, etc. He thinks, he said, this would use nearly the entire heat of coal, instead of only about five per cent., as done by the present system of burning.

72

be "about sixty different though some of them entirely outside the field of electricity, though, think they can very well so-exist in the one of course, to where are closely in this inventor-man. ment. As soon as I find that something I am at work trouble, where so much is still unknown. wantingness does not lead to practical results, Am engine of forty horse power runs all the long I do not consider it as an idea machinery of shops, though there is a genuine scientific man would do nothing. I do not care larger motive power seeking."

On the third floor there is at the western extremity a good sized lecture room, where lectures on interesting points in physics and chemistry are delivered by the professors of the workpeople. Experiments are performed here before all, although he has the valuable gift of explaining his inventions in non-scientific parlance which they involve, with much clear-ness and precision. He is a man who has clear thought as well as subtlety, can grasp the idea at once.

In this room is a grand piano, one made for Josef Hofmann, and sent to Mr. Edison for his opinion. Some young phenomenon has completed his vocal education on the new talking phonograph. Dozens filled wax cylinders were before long stored on the floor. Verse-rafters are the favourite records of some pleasure-seeni, and when one is fitted on the rear cylinder of the phonograph and the glass-tipped speaking tube adjusted to the ear, as in the pictures, the sufferer hears the sound of a still harsh, clearly disarticulating the different instruments, or some vocal solo with piano accompaniment; or one conventional remarks, or an address by the inventor. The best records of the kind made in Europe was played into the ear, with every intonation, emphasis, or lassitude recorded or not. It is a wonderfully accurate talking instrument. It is an inexpressive machine. Mr. Edison's own voice is the best record of all. Its nerves regulate everything that has to be done.

The rolling of the adjoining room was blasted with electric lights, which studded its entire floor with a galaxy of little stars.

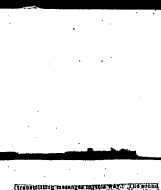
"The quarter of an hour's grace in the twenties, or more than up after a walk through the laboratory, and, after getting on the library on the ground floor, Mr. Tate, the genial business manager of the establishment, went out to see Mr. Edison.

In a moment he came in, with a cigar box under his arm, dressed in a black suit and a flannel shirt with a carelessly knotted tie. After the manner of a man who in the building would never dress, he looked as he was one of the humblest employees. He was delighted to get his best look at me as the first re-mark about at him. In the ordinary tone of conversation for the full, the inventor of the telephone, Edison, the inventor of the phonograph, is deaf. He has a round face, brown hair, good-natured, ordinary air, and fond of an easy posture when he is sitting talking, with

DRIVING EDISON'S 1,000 VOLTS

"What is your best trick in the field of science, Mr. Edison?" was the first question.

"I am not a scientific man," was the rather unexpected response. "I am an inventor. There is a difference between them. Although it may prove heresy to say so, I don't believe in pure science myself with the theory. I do believe in practical. An inventor is essentially practical. I've been at work all night, and all day, and



Thomas A. Edison.

that you rarely find the two together." I do not trouble myself about the theories. I have got the facts and through experiment I discover the principles. I am a practical man. I am always experimenting to see what I can get out of things. I don't care a rap about the theory. I'm only after the dollars."

"What was it you did first?" was the question put to the inventor who was responsible for the duplication of the cylinders for the phonograph.

"How there can be success so easily as one, and absolutely so easy as the opposite, after so many years from now if the principles are known, I cannot understand. It is as absurd, as if I really can bear it as well as you could by suggesting the epidiascope as an instrument."

"Years ago, some talk of light about the air ship as a vehicle of transportation."

"Yes, I have given a little thought to it, but not to be regarded as at all practicable for any more ordinary. Do you think this is a practical thing?"

"Make the gas, or any lighter than the air. It will always be at the mercy of the wind. None of the science of the matter is understood, and the practice of it seem feasible, or give promise of success. I have given some thought to the subject, and have experimented more or less with it. But my conclusion is that, unless some apparatus could be invented by which the balloon could be kept steering, the whole cannot be subjected to practical which will counteract the influence of the currents."

"What about electricity in connection with balloons? Can it be used in any way?"

"Nothing practical. If one can make a balloon dirigible without electricity can be questioned. But without the energy being present in heat, and the means of doing this cannot be accomplished at a reasonable expenditure, then the application of electric power as a motive power is impossible. Some other motive power will be found, probably, before many years, but it has not been discovered yet. Electricity as a motive power is a gem of the first rank, but when the means of relaying or producing electricity are considered, the cost is prohibitive. Unless this enormous waste of energy is brought down about, 330 tons of coal will do the work of 1,000 horse when it is burned and steam employed as the motive power. But this can't be done with the present means of producing electricity. The great loss of energy is in the combustion. What is accomplished this result under laboratory conditions, but these will not go to make the process available from a commercial point of view.

"Still there is nearly an immense field for advancement in electricity as a motive power. Nothing has been done in the way of storing it. The term of years required in the past has been about vanished. There is only one force, and that is energy. It comes in many forms, as the molecular movement or a mass movement, and it is the province of science to deal with the problems of the universe. Hence you see now that, if the latent force in coal can be relied on as electricity without waste as soon as it is got, it would be combustion, it will take the great place in the world. It is a question of time and conditions. It is not a matter of science as to-day, this are about on a par with buying to-get a horse and carriage for a million dollars. I was, on the 5th of February, 1851, and sold for hundreds of dollars to William Jones, of Newark, N.J., and he has it with a cosy smile. It is full of a day banner with a gold fringe and other useless frequently, no matter what may be the theme.

"Do you suppose the interstate nature of electricity will ever be discovered?" was asked him in reply.

"Yes. I think it can and will be some day. There are thousands working at these things, and from all the different men that is collected on the subject of electricity somebody will find out the secret. It will be a matter of accident or of the greatest of intellect, etc. Indeed, they are not invented—they discovered, the telephone is still not invent it. He was making experiments on telegraphy by sound, and happened upon what is the transmission of the sound waves.

"What do you think of the Keely motor?"

"I don't think much of it. The biggest work it has done so far has been to enable Keely to wear diamond studs and drive good horses. Then that invent a thing or discover a thing which will do what he says it will do, and which don't pay any facts in it, and doubt if anything ever comes of it."

"Has anything been done in this line of telegraphing from a moving train?"

"Yes. The system is perfect now. The Lehigh Valley road has twenty trains equipped for transmitting messages by means of the induction system. The idea is to have a wire along the track and through it operate it. The current is induced into the moving train. A diagram of the system has been given out by the company. I do not know whether the wires are on or off the ground, or whether they are in a pipe conduit."

Speaking of the Gilmore, which that Keely system wears on his coat, the Lehigh Valley road has its name and not the name of the inventor, Edison, with a grin. "That wear rubber gloves, and somebody told me that he saw the lineman put them on to climb the pole. I don't believe it, look."

We had one dog that received a current of electricity every morning and the old fellow survived it. We concluded to let him live after that, and he is alive to-day. He is still with me, ever after his shock. We call him Edison, because he played with the thunder-bolts."

"What else have you been doing of late?" in-quired the interviewer of Mr. Edison, as he rose to go.

"Too many things to tell you. I've been experimenting a good deal with microbes, trying to understand the beast and see how they work. I've been trying to get them in line, and see what they can be made to do. I've got a microbe in order if probably at the bottom of that, and if we could know how to catch them and take their tongs out they would be less harmful. One pencil have to harness an ox, or my colleague has been waiting half an hour, and it is time for me to be off. Good-by. I am dressed if I do not get home till as late."

So, with a cheery good night, the great inventor got into his team and drove off through the wet, leaving the impression that here was an instance of where the scientific theory is practical.

Argus, Portland, Me.
Oct. 9 1888

According to Thomas A. Edison, the next great economic invention will be the production of electricity direct from coal. That there is more or less electricity in every substance has been long claimed by scientific men.

Argus, Albany, N.Y.
Dec. 25, 1888.

Edison is reaching his brains to perfect a invention whereby electricity may be produced direct from coal, without all the intermediate processes of converting water into steam and that into power. What he is about is why does he not work to get the electric fluid direct from the sun, instead of using the power it has stored up through all the countless ages in the black diamonds? One should be an easy for him as the other.

Electricity From Coal.

A dispatch from Akron, O., where the wizard Edison is spending the holidays at his father-in-law's, says that he is working on an invention whereby electricity may be produced direct from coal, without all the intermediate processes of converting water into steam in boilers and that into power, and that the great electrician believes that he may be able to see about all the heat units of the coal instead of from 5 to 10 per cent, as at present. This is something which Edison has been working at for ten years, according to the Chicago *Tribune*. With hints from the scientists whom he has consulted he has made gradual headway in the solution of the great problem. From the confident way in which he now speaks he has apparently made some progress since he last spoke for publication on the subject, and has hopes that he may reach the heart and core of the mystery. If he succeeds he will be the greatest benefactor the human race has known since the mythical days when Prometheus stole the fire from heaven and gave it to man. All the cunning and valuable inventions with which his name has been associated — the quadruplex, the phonograph, and the incandescent light — will shrink into insignificance and will be regarded as the mere idle thoughts of a leisure moment. If he is able to convert into electric energy the power that lies in the carbon and hydrogen of coal he will have given to man the greatest gift that man can ask of nature, unless it be the control of the winds and rains. He will have multiplied by ten the present capacity for work of every ton of coal in the world, and will thereby have decupled our mechanical powers. He will have revolutionized the world of machinery. What the Corliss engine is to the primitive water wheel of the Egyptian of the days of Pharaoh that will Edison's device be to the present steam engine. Steam engines and gas engines will all go to the junk shops, and new plants — what we cannot yet tell—will take their place. Should Edison make such a discovery, all we ask of him is that he will be moderate, and that he will not charge so high a royalty as to heap up for himself a fortune of more than a thousand million dollars during the life of the patent. It will be in his power to outvie the accumulated wealth of all the Rothschilds and Vanderbilts, and to concentrate on himself the hatred and abuse that are now lavished on Gould. Promotheus took out no patent on his discovery and took his pay in unendurance. Edison, we fear, would be more modern, and he angered the gods and had to suffer for for it. It is possible that Edison may prefer not to imitate him to the point of angering Damos.

A TALK WITH EDISON.

APPLYING FORCE FROM COAL DIRECT THE NEXT DISCOVERY.

WHAT IS BEING DONE WITH THE PHONOGRAPH—SOME ELECTRIC LIGHT EXPERIMENTS IN AKRON.

From Monday's Daily Beacon.

Thomas A. Edison and Mrs. Edison, and their children, Miss Marion Thomas, William and Madeline, arrived in the city on the 12:17 Npsom train this afternoon, and will spend Christmas and the balance of the week at Oak Place, the home of Mrs. Edison's parents, Mr. and Mrs. Lewis Miller. Mr. Edison had scarcely finished his dinner when he donned hat and overcoat and set out in company with Mr. Lewis Miller to visit the station of the Akron Electric Light Co. Mr. Edison recently sent one of his dynamos to Akron and it was put up at the Standing-Ely Co.'s station, for supplying electricity for 40 incandescent lamps. After seeing that the machine worked perfectly, Messrs. Edison and Miller went across to the power house on the Akron Street Railway Co. Here they were joined by Mr. Gaud, of New York City, one of Mr. Edison's assistants, who has been in Akron experimenting at the Falls Rubber Shops on apparatus for furnishing interchangeably a current for arc and incandescent lights. The results so far attained have been quite satisfactory.

On his return to Oak Place Mr. Edison received a Beacon reporter in the living room on the third floor, where a mammoth Christmas tree has been equipped with 40 incandescent lamps which burst into a blaze on the turning of a switch. In answer to the first question about the phonograph, which is, of course, the absorbing topic in connection with the great electrician's name just now, he said:

"We employ now about 350 men and boys at our phonograph factory in Orange, N. J., and expect to increase the number to 500. I have issued an order that will require 85 machines a day for six months."

"What class of people do you assist?"

"Oh, it will be used chiefly in offices for correspondence. And then actors and singers use it."

"In what way is it useful to a prima donna, for example?"

"Well, there's one thing about that that I don't exactly understand, but it seems that singers can't judge with the ear of the imperfect tones made in their own voices. You know when you hear your singers in your ears and talk, your voice sounds very strange. There are sounds of all the tissue and bone and muscle of the head. An imperfect tooth for instance would make a defect in the vibrations. Now into phonograph you can record every voice but your own, and in the reproduction of your own tones there is something that takes out these peculiarities and imperfections of the vibrating substances of the body."

"What recent experiments have you made with the instrument?"

"I am constantly in receipt of phonograms from England. . . . got one the other day that reproduced the 4,000 voices of the Haydn and Handel Society of London. The Gaiety Theatre Co. from London is over here, you know. Some time ago one of the young ladies came over to Orange and sang into the phonograph. The phonogram was sent back to London and at the Gaiety Theatre there they reproduced the voice of one of their own singers. Sir William Thomson sent me a phonogram the other day, in which he says that the phonograph is a perfect elucidation of the mathematical conception of sound."

To the question, what the next great achievement in the line of electrical discovery would be, Mr. Edison said:

"The next thing will be some simple contrivance by which we can turn coal into electricity direct, without the intervention of boilers and engines and dynamos. We now utilize as power only 4 or 5 per cent. of the force in coal. That is, we put one horse power out of five buckets full of coal. We might as well put five or six horse power out of one bucket full. A good many men are working upon this. I have been at it for some time. It's going to be done. All that expensive machinery for getting work out of coal will be done away with."

Democrat, Watertown, Dak.
July 1, 1889

Mr. Edison says: "Undoubtedly the next great discovery will be some method of getting electricity from coal direct without the intervention of boilers to make steam, steam driven engines to run dynamos, which in their turn, with the intervention of magnetism, do work, whether in operating motors or in making light."

Record, St. Cloud, Fla.
July 2, 1889

"The great developments in electricity will result, I am firmly convinced," said Mr. Edison to an interviewer in Paris, "in discovering a more economical method of producing it. At present we only get from coal consumed about four or five per cent. of its latent electricity. The rest is wasted in heating water, expanding steam, pushing pistons, turning wheels, and finally moving a dynamo machine to operate. A process will ultimately be found for extracting ninety or ninety-five per cent. of the electricity directly from the coal. Then steam engines will be abolished, and that day is not very far off now. Already we can get electricity directly from coal to the amount of ninety per cent., but only for experimental purposes. When I was on shipboard coming over I used to sit on deck for hours and watch the waves. It made me positively savage to think of all that power going to waste. But we'll claim it up one of these days along with Niagara Falls and the wind. That will be the electric millennium."

ELECTRICITY AS FUEL.

Charles H. Carpenter's Invention for Utilizing Electric Heat.

Charles E. Carpenter, the young man who has obtained considerable notoriety lately for his unsafe fire electrical research, and his dog killing apparatus, has just completed an invention which bids fair to make for him both fame and fortune among the profession of electrical engineers. There is no application of electricity in which students of that science have not been very successful, and this is the production of heat. The difficulty does not lie in the simple production of heat, but in its concentration as one piece, so that electricity can be used as economically as common fuel. The problem with all electrical engineers, who have turned their studies in this direction, was to discover some means of heat insulation, and in this Mr. Carpenter has succeeded. He considers this is the last link in the problem to a practical way, and his opinion is said to allow been thoroughly indorsed by some very able electrical engineers of this city and Chicago, who have been shown his plans.

This secret will not be disclosed until after the patents are issued, which will be applied for in a few days. The principle of the invention is such that a person could sit with a griddle in his lap and fry cakes without feeling the heat. The heat is confined to a smooth steel surface in the middle of the griddle, and on either side and the bottom the range of insulation is perfect. The heat is applied in the same manner as it is applied to the smooth surface of a laundry roller, instead of steam, which is frequently used at present. It will also be applied under coffee urns and other utensils in the kitchen, and in the same manner as in the griddle. It will be as easy to arrange that the greatest economy in the use of the electricity is obtained as that it will cost no more than gas or other cooking fuels. A switchboard is furnished, by which the current can be turned on and off at will, and the convenience of the invention.

F. W. Stevens and John W. Estey are interested with Mr. Carpenter in securing the patents, and Mr. Stevens will apply to-day for letters patent. Two years with a capital of from $50,000 to $100,000 is asked for in the various circuits. Mr. Carpenter, the inventor, has been in the city several years, and during that time has conducted an eight cent at Taylor's restaurant. All of the time he could spare from his special business he was pursuing his studies in electricity, and the result of his application and experiments is the invention acquired by yesterday alone, inasmuch as he locked the means to complete his course at Cornell University, where he began his studies. His invention will help to prove of great practical value, and he believes it will revolutionize the whole system of using the materials necessary to produce the required degrees of heat in that which is used in an ordinary kitchen household range. A. Taylor has made a contract with the inventor to introduce it in his establishment, and is having a range put in to be operated by it manufactured after Mr. Carpenter's plans for use in his restaurant, where the first practical operation will be seen within a few weeks.

THE NEXT DISCOVERY.

Being asked what he thought would be the next field in which electrical invention would employ itself, Mr. Edison said: "Undoubtedly the next great discovery will be some method of getting electricity from coal direct without the intervention of boilers to make steam, steam-driven engines to run dynamos, which in their turn, with the intervention of magnetism, do work, whether in operating motors in making light. Such a combination would mean one bucket of coal furnishing one horse-power for ten hours a day. That is, we get five or six per cent. of the force of coal for one horse-power, whereas we ought to get five or six horse power out of one bucket. That is, we get five or six per cent. of the force of coal direct, whereas by obtaining electricity direct we should get nearly five per cent. This economy of coal is the great desideratum. I am not working in the direction of this discovery, although it would be a good thing in itself. The thing a good many men are working on—and I have been doing a good deal at it—is to get a simple and inexpensive apparatus for applying the force that is in coal to the production of heat. I think that would revolutionize the world of machines, for it would do away largely with boilers and engines. So, it is nothing like what Keely is after, because he is trying to get something out of nothing. The thing I speak of is bound to be done."

Journal, Susquehanna Bridge, N. Y.
January 12, 1889.

THOMAS A. EDISON says he is now experimenting on an inventing whereby electricity would be produced direct from coal, dispensing with boiler, engines, dynamos, etc. This he says would use nearly the entire heat of coal instead of only about five per cent. as done by the present system of burning.

Herald, Hornick, N. Y.
January 19, 1889.

Hurry It Up.

Thomas A. Edison is develing nearly all his time to experimenting with a contrivance that will produce electricity direct from coal, thus dispensing with all the costly machinery now required, besides utilizing nearly the full strength of the mineral, instead of about five per cent., as is the case at present. "It will be done," says Edison.

Times, Mohawkville, Ohio
January 1, 1889.

THOMAS A. EDISON, the great electrician, passed the holidays with his father-in-law, Lewis Miller, of Akron, O. In an interview with a reporter he said he was now working on an invention whereby electricity would be produced direct from coal, dispensing entirely with the boilers, engines, dynamos, etc., now required. Besides, he said, he would use nearly the entire heat units of the coal instead of only about five per cent., as is done by the present system of burning.

The Omaha Bee

Editor is Making the Drama.

Chicago Tribune: A dispatch from Akron, O., where the wizard Edison is spending the holidays at his father-in-law's, says that he is working on an invention whereby electricity may be produced direct from coal, without all intermediate processes of converting water into steam to drive and that into power, and that the great electrician believes that he may be able to use about all the heat units of the coal instead of from 6 to 10 per cent, as at present. This is something which Edison has been working at for ten years. With hints from the scientists whom he has consulted he has made gradual headway in the solution of the great problem. From the confident way in which he now speaks, he has apparently made some progress since he last spoke for publication on the subject, and has hopes that he may quench the heart and core of the mystery. If he succeeds he will be the greatest benefactor the human race has ever known since the mythical days when Prometheus stole the fire from heaven and gave it to man. All the cunning and valuable inventions with which his name has been associated—the quadruplex, the phonograph, and the incandescent light—will shrink into insignificance and will be regarded in the more idle thoughts of a leisure moment. If he is able to convert into electric energy the power that lies in the carbon in a lump of coal he will have given to the greatest gift that man can ask, and will have placed the control of the winds and waves in the hands multiplied by ten thousand. The work of every ton of coal in the world and will thereby have to decuplied our mechanical powers. He will have revolutionized the world of machinery. What the Curtis engine is to the primitive water wheel of the Egyptian of the days of Pharaoh that will Edison's device be to the present steam engine. Steam engines and gas engines will all go to the junk shops, and new plants—what we cannot yet tell—will take their place. Should Edison make such a discovery, all we ask of him is that he will be moderate, and that he will not charge so high a royalty as to lump up for himself a fortune of more than a thousand million dollars during the life of the patent. It will be in his power to outrival the accumulated wealth of all the Rothschilds and Vanderbilts, and he can retire on himself the hatred and odium that are now lavished on Jay Gould. Prometheus took out no patent on his discovery and drew his pay in unending fame, but the angered Olympian lord had to suffer for it. It is possible that Edison may prefer not to imitate him to the point of angering Domos.

ELECTRICAL SCIENCE.

Electricity directly from Heat.

ATTEMPTS to generate electric currents, by utilizing the fact that magnetic metals lose their magnetic properties when sufficiently heated, have been made for some years. It is only recently, however, that such experiments have been made on a practical scale, and with any promise of ultimate success. When we consider that in the most economical source of electricity, the dynamo-electric machine, we transform the energy of our fuel to the energy of steam under pressure, then through the steam-engine to mechanical work, and finally by the dynamo to the energy of electrical currents, losing energy in each transformation, our ultimate return being perhaps ten per cent of the energy expended; when we add to this the complication and expense of a steam-plant, — it would seem that, even if our means of direct conversion is not so economical as the dynamo, yet if it have any reasonable efficiency, and is simple of construction, it would supplant the older method.

In August of 1887 Mr. Edison read before the American Association for the Advancement of Science a paper on pyromagnetic generators. Briefly the principle on which his machine was built is this. If a piece of iron wrapped with wire be put between the poles of a magnet, a number of lines of force will pass through it, and therefore through the coils of the wire, depending directly on the strength of the magnet and on the magnetic permeability of the iron. Now, it is well known that the permeability of iron becomes very nearly zero when it is raised to a bright red heat: so, if we heat the iron, the lines of force through it will decrease, and this decrease will cause an electro-motive force in the coil of wire. When the iron cools, there will be an increase of lines of force, causing an electro-motive force in the opposite direction. Mr. Edison's machine, built on this principle, consists of eight horseshoe magnets arranged in a circle, the poles facing inward; and between the poles of each is a roll of this laminated iron covered with asbestos and wrapped with wire: we will call these the armatures. This is placed over a furnace, and beneath it revolves a half-circle of fire-clay, which shields half of the armatures from the heat. If this shield be turned continuously, half of the armatures are being heated while the other half are being cooled; and the electro-motive forces in the two halves, which would be in opposite directions, are added by a commutating arrangement on the shaft of the shield. A blast of cold air assists the cooling of the armatures.

In his paper, Mr. Edison gave no data as to the performance of the machine, except the statement that a generator to feed thirty incandescent lamps would weigh two or three tons.

Nothing has been heard lately of this generator: it will naturally take time to perfect it and make it practical.

Within the last month, however, attention has been called to a machine using the same general principle as that of Mr. Edison, but differing greatly in detail, — an invention of M. Menges of the Hague.

One form consists of a Gramme ring within which is a stationary electro-magnet. The two are horizontal, and are separated by a considerable air space: this space is filled by a zigzag ribbon of iron extending around the inner circumference of the ring, with which it revolves. Now, if this ribbon of iron be cold, most of the lines of force will pass through it from one pole to the other of the magnet: few will go through the armature. If, however, the ribbon be heated at points at right angles to the poles, the magnetic resistance will be increased, and most of the lines of force will pass through the armature: there will be no motion, since every thing is perfectly symmetrical. If, now, the heat be applied to the ends of the same diameter at points forty-five degrees from the pole, the symmetry disappears, and there will be a rotation. Now, the Gramme ring rotating in a field of force will generate currents as in an ordinary dynamo-electric machine. In reality, then, we have a motor-dynamo arrangement, the former transforming the energy of heat into motion, the latter transforming the energy of motion into electrical energy.

Both the 'pyromagnetic generators' of Mr. Edison and M. Menges are an advance on previous machines of this type. It is difficult to see, however, how, in their present form, either can produce any very considerable quantity of electrical energy, with any reasonable size of apparatus. The publication of reliable figures on the performance of these machines would be of great interest.

AN IMPROVED DOUBLE CURRENT KEY.

By P. TRIMMER, *of the Firvian Gulf Telegraph.*

FIG. 1 gives an elevation, and fig. 2 a plan of the connections of this key.

FIG. 1.

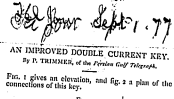

FIG. 2.

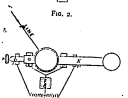


In Fig. 1, K is an ordinary Morse key. L is a brass beam, the two halves of which are insulated from each other at A. The beam works on an axis (shown by the dotted lines) beneath K, from which it is insulated, and plays between the back and front stops *b b'* and *f f'*; it is maintained in whatever position it may be last thrown by the action of K, by the rollers *r* and *r'*. These two rollers work on springs which are so adjusted that when the beam L *b* is in the position of rest, as shown in Fig. 1, *r* tends to press it downwards, and *r'* upwards. This order of things is reversed when K is depressed, as *r'* then presses L downwards and *r* presses it upwards. *s* and *s'* are two weak spiral springs by means of which the negative and positive poles of two batteries are maintained in connection with the back and front halves of L respectively. They exercise no influence over the movements of L.

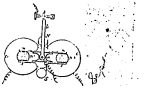
The back and front stops *b* and *f* are permanently in connection, and are to earth through the adjustable resistance marked "Shunt."

The action of the key K is as follows:—Fig. 1 shows the key at rest. The switch (not shown in the diagram) being turned to "send," the negative current passes on to the beam L at A, and at the stop *b* it divides between the shunt and line; if now K be depressed, L does not follow its movements immediately, being held in position by the spring *s*, but finally it is struck against by *f'*, at which moment the full positive current passes to line, and then L being pressed down until the stop *f* is reached, the shunt comes into play carrying off a portion of the current. The negative half of L has at the same time been raised from contact with the back stop *b*, and now occupies the same position with respect to *b* and *b'* as the positive half had previously occupied with regard to *f* and *f'*—viz., touching neither. If now K is allowed to fall back similar movements takes place first, the full negative current is sent to line at the moment L is struck, which continues until the position of rest is regained, and then the reduced current flows. This arrangement has been worked satisfactorily through 700 miles of cable from Kurrachee to Jask, but from the incomplete nature of the apparatus no reliable comparisons as regards speed with the ordinary "permanent" current keys have been obtained.

Tel Journ Oct 1. 77

THEILER'S PATENT RELAY.

THE peculiarity of this Relay consists in the novel construction of its magnetic armature and its combination with an electro-magnet, whereby the power is thoroughly utilised.



The figure gives in plan an outline-drawing of the relay. It consists of an ordinary electro-magnet *c c*, of which *p*, p_1, are the poles. Two light tongues or bars *a a*, and *z z*, of soft iron are mounted on a pivotted axis at *d*, their flat sides facing each other, and kept a certain distance apart by a short piece of brass, shown in the figure by the dark shading. The armature in fact somewhat resembles a double toning fork.

This armature is magnetised by a horseshoe permanent steel magnet, whose poles *x* and *x* are shown in the figure. These poles are in close proximity to the portions of the tongues *a a*, and *z z*, which, at the middle of their length, are made to project.

The magnet poles impart similar polarity to the ends of the tongues, to which they are respectively in close proximity to; consequently, when the electro-magnet becomes magnetised by a current, the whole armature tends to turn on the axis at *d*.

Fixed to the armature is a brass tongue *f*, which is furnished at its extremity with the usual platinum contact point playing between an insulated and a contact screw.

This Relay is found to give very good results, especially for fast speed working.

3950. "Receiving instruments and relays."—W. H. PAGET HIGGS. Dated August 19, 1872. 6d. This designs to utilise the loosening of friction by the reversing relays. One method consists in providing a continuously revolving disc of paper, or other suitable absorbent substance, moistened with water or a saline solution. On the moistened disc is placed a metal disc which is kept from revolving by a tension or friction force. The two discs are connected in circuit with the line. When the current passes, the usual friction between them is reduced, and the metallic disc consequently turns in a direction opposite to the rotation of the paper disc. An arm or tongue attached to the metallic disc is thus moved to and fro in obedience to the signal currents, and makes or breaks contact, or produces visible signals.

3130. "Receiving instruments of electric telegraphs."—J. and A. STEARNS. Dated August 17, 1872. 6d. This consists of a recorder, in which a rectangular coil of wire is made to rock to and fro between the poles of a magnet when the signal currents from the line are made to traverse it. The coil is suspended by two spiral springs coiled in opposite directions, and rigidly attached at their inner ends to the top and bottom of the coil, the whole being sustained by a single fibre at the top. A style dipping in ink, is used as the marker. The ink is stimulated to flow by the discharges from a Ruhmkorff coil.

MILITARY TELEGRAPHY.

SYSTEM OF M. TROUVÉ.

THE system of military telegraphy, invented by M. Trouvé, deserves to attract attention for two reasons; in the first place it furnishes an apparatus complete and sufficient in itself, and all that is required in the majority of cases; and, on the other hand, it has already been adopted by more than one European army, that is to say, it is not a new thing recommended only by the inventor, but a contrivance which has, up to the present, been appreciated by competent judges. The apparatus consists of a two-wire cable for connecting the two stations, a battery and a speaking instrument. Fig. 1 represents the line and the two stations, or, to speak in less technical language, the two correspondents. The officer to the right has selected his point of observation. He carries on his belt a battery, which you see at his side, and a telegraph instrument which he can put in his pocket, or hang on his epaulet between the intervals of corresponding.

The soldier who is at some distance to the left, carries on his back a bracket, similar to those used by the commissionaires in Paris; on this bracket, on the upper part, there is a large bobbin, on which is wound the cable, and on the lower part, the battery; and in addition to this he has a telegraph instrument, which is at the moment under consideration, suspended high up on the left side of the bracket.

In proportion as the soldier advances the cable unwinds itself and falls on the ground, the bobbin turning on its axis; the time for corresponding

FIG. 1.—MODE OF LAYING DOWN THE MILITARY TELEGRAPH OF M. TROUVÉ.

any hindrance to the communication. We should here remark that owing to the small electric resistance of the line, a slight leakage would be but of slight importance. The two conductors are joined to the battery of the stationary officer before the separation of the two telegraphists; the special terminals are lettered, so as to give rise to no mistake. Before starting they test their apparatus, by sending a short sentence in each direction.

After having again taken his position, the moveable telegraphist advises his correspondent by sending the word of command, and the exchange of messages can commence. The soldier carrying the bobbin seeks out paths inaccessible by carriages; if he has a certain route to traverse he would give preference to a locality where the trees would allow him to carry the wire sufficiently high to allow carriages and cannons to pass beneath it, for it will be understood that if the wire was laid the little telegraph by his hand begins to work communications. maintained without nor is it necessary ncealed; there is a ible, so that after se will be obliged to equally well at a for example, as the through the entire ground or on the

ulated conductors, gutta-percha, and der a covering of ption it can be laid , and can even be e a brook without

along the road it would run the risk of being crushed and cut by wheels passing over it. Practically, for this and analogous reasons, it is necessary to furnish the telegraphist with an assistant, for lifting the cable on the branches of trees and for various other emergencies. Further, when it is time to cease the communication, the telegraphist receives the order to return to the starting point, and there again a companion is necessary to wind up the cable on the bobbin, by means of a handle which is attached to the end of the axis to the right of the bobbin (fig. 2); he turns this and winds up the wire while the carrier walks slowly to facilitate the operation.

We have here shown two telegraphists, one stationary, the other moveable, separated by a maximum distance of a thousand metres. But the second may be accompanied by a third carrier, with a bobbin, &c., exactly the same; and when one of

continued to make room for carrying out the manufacture of his patent india-rubber, over which his arrangement with Messrs. R. S. Newall & Co., which, unfortunately, was cancelled by litigation between the parties. A few years later a partnership was entered into with Mr. (now Sir George) Elliott, and it was said that this arrangement on the part of Sir George Elliott was to induce the Gutta-Percha Company to combine with the firm of Glass and Elliott to form the present Telegraph Construction and Maintenance Company.

This was followed by a second arbitration, so that the first seven years of Mr. Hooper's patent flew past without the slightest pecuniary benefit. It is perhaps within the mark if we say that at least £25,000 was spent during these seven years to free his patent rights, and to allow of the working of his patents.

Not only did Mr. Hooper rely on his own individual resources for perfecting his patents and becoming a trial of the merits of his core, but he succeeded in removing a very strong feeling of opposition which at one time seemed too influential to admit of being overcome by a private individual. In the year 1864 several lengths of india-rubber insulated wires by different manufacturers were sent to India to test their durability and suitability for that climate. The only one which remained good was that made by Mr. Hooper. This led to the receiving several orders from the Indian Government, and established the reputation of his manufactures. We believe that about 15,000 miles of cable have been made with this core, the last of which, made and laid for the Cuba Submarine Telegraph Company in 1873, is a practical proof of its merits. Without exception it is, when well made, electrically, the most perfect cable in existence.

In the year 1870 Mr. Hooper's business as a contractor had increased so extensively that he formed a limited liability company, which was known as Hooper's Telegraph Works, Limited.

Little is known of what led to the collapse of this company, but at the time negotiations had been going on for making and laying a cable to the Cape, which, line" Hooper's Company had the contract, &c., from the Government. We have heard that the manufacture of an Atlantic cable for the French company was also being negotiated for.

Mr. Hooper was a liberal supporter of science, and we have been informed that no invention relating to submarine telegraphy which was submitted to him was dismissed without the most attentive study.

One very important matter which Mr. Hooper had worked upon was the protection of iron &c., used in the covering of cables. In his earlier patents he proposed covering of vulcanised rubber for this purpose. Attention is being again directed to the matter from the fact that two Atlantic cables are now defunct from the corrosion of the iron wires not allowing their being fished up.

It is a general opinion that Mr. Hooper largely profited by his company; this we believe is an error. If we consider that Mr. Hooper, in the first place, held over one-fourth of the total shares of the company, and that the latter was indebted to him for nearly £150,000. We can easily conceive that he would have been a great deal better off without the questionable extension of business

which it is considered necessary on the conversion of a flourishing undertaking into a limited liability concern. Few mortalities perhaps worked harder for an object whose fruit after disappointing results have followed. But not often that it is our pleasure to therefore have regretted to allow the moment to pass without adding our tribute of respect to the memory of the late William Hooper.

We fully believe that one very important benefit to submarine telegraphy, arose from his labours and those of other india-rubber manufacturers threatening the monopoly of gutta-percha as an insulator, which led to great improvements in gutta-percha cables.

VANDER PLOEG'S TYPE PRINTING TELEGRAPH APPARATUS.

THERE have perhaps been invented more varieties of type printing than of any other kind of telegraph instruments. Many of these differ from one another in but very unimportant details, and it is not often that any very distinct points of novelty are introduced. Mr. Ploeg's apparatus, however, decidedly possesses features which, as far as we know, are not found in any existing forms of printing instruments, and therefore it well deserves being brought to notice.

The apparatus consists essentially of a transmitter, a "speaker" and "reinforcer," and a receiving and printing apparatus.

The transmitter, fig. 1, is constructed with a handle 1, which in several revolutions imparts by means of a pinion 2, and wheels 3, 4, one revolution to an axis on which the needle 10 is fixed.

The handle has four optional points of rest, 6, 7, 8, 9, placed in horizontal and vertical lines, and in turning it forwards or backwards the needle 10 is turned in the same direction; the points 6, 7, 8, 9, correspond to the spaces on the dial around which the needle 10 turns.

The axis of the needle is attached and gives motion to a wheel 11, which makes or interrupts the contact in the line circuit at the points 12 and 13, and it carries by friction a bar 14, which is pushed against a stop 15 when the axis is turned from right to left, and which is pushed against a stop 16 when the axis is turned in the reverse direction. Whilst moving between 15 and 16, the bar causes an oscillation of a reverser or commutator 17, the two arms 18, 19, of which, separated from each other, sometimes put the point 20 in contact with 21, and 22 with 23, and sometimes 20 with 23, and 21 with 22. Thus the current of the battery, which enters the apparatus at 20, issues thence it by the points of contact 17, 23, and leaves it at 21 to pass along the line and return by the earth at 23, will be reversed according to the direction in which the handle 1 is turned; it will be positive in the line on turning the handle from right to left, and negative on turning it from left to right, or *vice versâ*, but always inversed in a contrary direction.

To clear the line at the point of departure of a possible overcharge of current, there is a small spring 24 which brings the line into contact with the earth between the reversals of the current.

The Latest Improvements in the Hughes Apparatus, and a New Method of Translation with the Apparatus. By M. pp Hepner-Altenecg.

Hitherto special accessories have had to be furnished to Hughes' apparatus, meant for automatic re-transmission from one line to another. There would be no use, but even inconvenience, in placing the apparatus then furnished at stations which do no translation. Hence the employment of two systems of apparatus, the one for translation, requiring operators specially initiated, and the other simple apparatus only used at extreme stations. The method here described reduces the disadvantages of this, with the aid of two improvements in the Hughes' apparatus. One devised by Hughes himself, consists in transferring the working and insulated contacts of the turning chariot to a lever fixed to the stand of the apparatus, and which reproduces the up and down movements of the chariot. This is a simpler arrangement, and gives more certain contacts. The other improvement is the purely mechanical engearing of the printer axis in the transmitting apparatus, excluding all electro-magnetic action of the sending current.

The Telegraphic. Vol. ix. No. 96.

On the Resistance of Relays.—By C. H. Haskins.—I have explained (see *Telegraphic Journal*, p. 209) the law governing the resistances of relays upon a given line. Granting the law I stated, how can this exact proportion be maintained, especially on millened lines, where new offices are frequently being opened? As it is impracticable to keep an exact balance of resistance between the relays on a line and the line wire, we must adopt some practical compromises. Have three or four standards of resistance, and apply any given circuit with the relays whose resistances approaches most closely that shown by the application of the law. For instance, you may have five standards for relays :—70 —100—150—250—400, and, suppose line is very long, with only five or three offices upon it, some one of these relays will carry near the desired resistance. And another fact should be remembered—that a relay with a light armature and short lever will work freely with less current than one with a heavy armature and lever; because, when the armature is held by the spring or rest, the power required to overcome its inertia and set in the relay " is in direct proportion to the weight to be moved. Therefore, a light armature and lever will close freely with a comparatively feeble current.

A New and Improved Switch Board.—The general features of the switch are so familiar that only a brief description will be necessary, in order to point out the improvements which have been adopted to simplify the operation of changing the loops from one main line to another. Some of the studs are split longitudinally, which is the case of the ordinary pattern. These split studs are split to their parts insulated with hard rubber. The right-hand side is connected with the left-hand side of the next succeeding stud, and also through to those used for connecting the instrument to the line. By inserting the plug on the plate, and inserting right and left of the stud, the circuit through the relay on a sterling-point, passes through the vertical stop out around the loop back to the stud, splitting the stud on the further side, then by a permanent connection on the back of the board to the second loop, through which it can be made to pass by a similar manipulation of the studs to either of the lines corresponding to the board. On the right-hand side a number of studs are placed, and are so arranged that by use of a plug the loop section of the board may be used for such line or lines desired. The advantages claimed for this switch are as follows :—The loops being arranged in the above manner, the operators will more readily notice their position, and can, with greater facility, connect such as are wanted than by the plans heretofore in use. The loop studs being directly in line with each other, the placing of a branch office in connection with the lines can be effected more speedily, and without so much examination of the board, as when they are placed in any other position. This switch was designed by Mr. James B. Yoakly, agent of the Gold and Stock Telegraph Co., 7 Baltimore office.

Telegraphic Litigation.

The Western Union Telegraph Co. vs. the St. Joseph and Denver City Railroad, American Union Telegraph Co., and others.

In the United States Circuit Court, at Topeka, Kansas, July 31st, Judge McCrary rendered his opinion in this case, which effects the telegraph line on that road from St. Joseph, Mo., to Hastings, Neb., which was one of the Western Union telegraph lines forcibly seized by the railroad during the night of February 26th, inst.

Judge McCrary holds that it is not in the province of either party to declare the contract void. On the question of the effect of the foreclosure proceedings, Judge McCrary holds that the notification of the contract, and use of the line under it, bind the successors the same as the original railroad company. On the question of the exclusive privilege given the telegraph company of constructing and operating a line of telegraph along the railroad, he says he has little doubt that the clause referred to is valid, and if any [illegible] company so desires to construct a

mitter armature be moved or vibrated by sound, like sounds will be produced by the motion or vibration of the armature of the other telephone upon the circuit.

"Fifth. In a system of electric telegraph or telephony, consisting of transmitting and receiving instruments, such as are described in the fourth and fifth plans, united upon an electric circuit, I claim the combination in the armature of each receiving instrument of any given motion by subjecting said armature to an attraction varying in intensity, however such variation may be produced in the magnet; and hence I claim the production of any given sound or sounds from the armature of the receiving instruments, such as are above mentioned by subjecting said armature to an attraction varying in intensity in such manner as to throw the armature into the form of vibration which characterizes the given sound or sounds.

"Sixth. The combination, or the manner described in the fourth and fifth plans, of an electro-magnet with a plate of iron or steel, or other material capable of inductive action, which can be thrown into vibration by the movement of armature, or any of the armatures of a magnet.

"Seventh. In electric telephony the combination with the plate of a magnet having poles upon the end or ends of the magnet nearest the plate, substantially as described in the fourth and fifth plans.

"Eighth. In an electric telephone, the combination with a permanent magnet and plate armature of a soft iron pole piece forming the core for the coil, substantially as described in the fourth and fifth plans.

HIGGINS' IMPROVED PRINTING TELEGRAPH INSTRUMENT.

No class of telegraph instrument is, perhaps, more useful for the distribution of information to a large number of stations simultaneously than the kind which prints in Roman type the message transmitted; and in no class has more ingenuity been displayed in effecting improvements which have for their object the production of a compact and simple instrument which can run at a comparatively high speed, and be free from a liability to skip letters, and which, also, so that the error may not repeat itself beyond improved instrument seems to promise to be free from these particulars in a high degree, and is, therefore, well worthy of notice.

The object aimed at by Mr. Higgins is mainly the construction of a printing telegraph instrument which can be worked on a single wire without the aid of clockwork for driving the type wheel.

The instrument consists of the following parts :—

Either one or two type wheels fixed to a common axis and driven by a propellent, which is so constructed as to prevent the momentum of the type wheels carrying them beyond the desired point. For this purpose two pallets, carried by a rocking lever, act alternately on the top and bottom of a ratchet wheel on the axle of the type wheel, with pin stops for the pallets to come against at the end of their forward movement. An arrangement is also provided for bringing the type wheel to the zero point.

The armature which carries the pallets is composed of iron and brass, and is magnetised from a large fixed permanent magnet through the armor of which it forms a part.

The transmitter sends alternate currents; the currents pass through (or cause other currents to pass through) coils or electro-magnets which are placed on either side of the magnetised armature.

The printing is effected by the current being diverted by a magnetic switch which is made rather sluggish of movement, and only acts when the current is caused to flow for a slightly longer time than when the type wheels are being rotated.

The circuit of the type magnets is closed at such times, and in the whole force of the battery passes through the printing magnet, or a separate battery may be used for operating the printing.

The printing from one wheel or the other, when two are used, is controlled by an arrangement which traverses a shield to and fro to cover or uncover the paper below the wheel to be printed from, and at the same time brings a support below the printing paper and so locks it and unlocks the printing pad under the one not being printed from.

Where figures are not much required one type wheel and a narrower band of paper and lighter printing mechanism may be employed. The arrangement will continue the same, but a greater number of contacts per revolution of the type wheel will be required.

Sixty or more characters may be used, but for the distribution of general intelligence thirty-six will be sufficient with a corresponding saving in cost.

For long distances an escapement and train of clockwork are employed, the other arrangements remaining the same; but the shunting magnet puts in operation a local battery instead of diverting the main current.

The type wheel axis is connected to and obtains motion from the train by a light intermediate coiled spring; the pulsations are thus therefore sensibly felt by the train.

Any form of transmitter which sends alternate currents and can be stopped on either, and when no current is passing, may be employed, provided the motion be regular.

To detach the armature which controls the type wheel promptly from the electro-magnet to which it was last attracted two springs may be employed, which are of such tension that very little force is needed to repel it. The coils must be such that the armature may also be cut off, so as to concentrate the whole force of the current on the other. The inking roller is made of cloth covered with Utrecht velvet.

Fig. 1 shows a vertical section of the instrument; fig. 2 is a plan of the same; fig. 3 is an under side view ; and fig. 4 shows separately some of the parts in considerable connection with the type wheels.

A is the electro-magnet for actuating the propellent; it consists of four coils; they are arranged in pairs and are so wound that when excited by the passage of a current the poles facing each other are of opposite signs. Between each pair of poles there is a soft iron tongue a; the two tongues are both mounted upon an axis c, which is built up of iron and brass, the centre portions between the tongues being of brass to prevent magnetic connection between the two tongues. The outer ends of the axis, which are of iron, pass through the extremities of the permanent horse-shoe

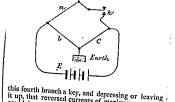
Tel Jour Mar 15 1875

A SINGLE CONTACT DOUBLE CURRENT KEY.

In every form of double current key hitherto in use, from two to four contacts have been employed in addition to the switch contacts which cut off the battery and the line wire through the receiving instrument to earth. Where four contacts are employed, as in the ordinary double current key the play of the lever is necessarily considerable, otherwise false signals are liable to be made. Again, in the latter form of key, the several currents must be of equal strength; and in the submarine keys, where not less than two contacts are employed, it is usual to have two batteries, one for sending a current in one direction and the other for giving a reversal. In the following arrangement, only one contact and one battery is employed for sending reversed currents; and, moreover, the relative strengths of these currents can be adjusted to a great nicety. The figure shows the method by which the result is arrived at. *a*, *b*, and *c* are three resistances forming the arms of a Wheatstone bridge, *e* is a battery, and *f* the line wire. The fourth arm of the bridge is formed by a single contact key, *k*. As is well known, if the fourth arm were of such a resistance *x*, that

$$x = \frac{a\,c}{b}$$

then no current would pass out to line; but if *x* were larger than this value, then a current would pass to line in one direction, and if *x* were smaller than $\frac{a\,c}{b}$ then a current would pass in the opposite direction. It is clear if *x* were made either *a* or *b* by making



this fourth branch a key, and depressing or leaving it up, that reversed currents of maximum strength could be sent out to line, and by adjusting the resistance *a*, *b* and *c*, the relative values of these currents could be altered at pleasure.

A priority in the arrangement consists in the fact that the reversal takes place without any break, and it might therefore prove of service as a "polo changer" in the quadruplex telegraph system, and, indeed, in any telegraphic apparatus where a multiplicity of contacts might be objectionable, and where an instantaneous reversal is required.

New Intaxonic Type Printing Telegraph.—Theoretically may be described as a combination of the Little and the Bonelli apparatus. The machine by means of which the transmitting strip is prepared consists of twenty-five cylindrical steel punches, each one-tenth of an inch in diameter and the same distance apart, arranged to form a square of five rows each way. A key-board, analogous to that of the House printer, is so arranged in connection with the punches, that when any particular key is depressed the proper punches for forming that corresponding Roman letter are selected and forced through the paper slip, perforating the paper with apertures arranged in the form of the letter. The letters, as perforated in the transmitting slip, are half an inch in height, the strip, after having been thus prepared, is passed at a rapid rate through a transmitter similar to that of the Little automatic, but provided with five circuit closers, side by side, corresponding precisely to the five horizontal ranges of punched apertures from which the letters are formed. A corresponding receiving instrument, running at an approximate speed, is provided with five pens or styles, arranged in a row transversely across the chemically prepared strip, which is made to pass beneath them. The Roman letters, as recorded upon this strip, are much smaller, and appear far more legible than upon the transmitting strip. Five lines of wire, of course, required to work it, although it is considered possible to be able to do the work with one. With five circuits the rate of speed with which messages may be recorded in plain Roman letters is from four to six hundred words per minute for the permanent printing, with an iron solution, and twelve to fifteen hundred words per minute with the fugitive iodine solution.

Tel Jour May 1, 1874

M. Mouzaour has called the attention of the French Academy to a new telegraph of his invention, in which both the transmitter and receiver consist of two ivory plates carrying the disconnected ends of an open part of the circuit. The sender places this continuous between his lips, and sends the message by talking or by closing the circuit by his lips, according to a code of signals. The receiver, holding the receiving apparatus similarly, interprets the message by the sensation he feels. This is an old idea, but may be cleverly worked out in this case. M. Mouzaour claims to become a competitor for the Volta prize with it.

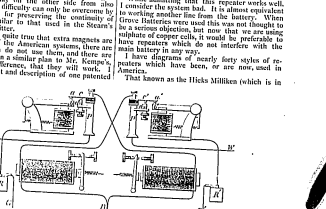
Electrical News Aug 15 1873

Improvements in electric apparatus. Frank Wirth, of the firm of Wirth and Co., patent agency, Frankfort-on-the-Main, Germany. (A communication from Josef Leiser, manufacturer, Vienna, Austria.) January 26, 1873.—No. 296. All batteries hitherto constructed, especially those which have to be transported, have the disadvantage that when they were charged they could not be hermetically closed, and that when the elements had to be lifted out a complicate mechanism was necessary. If such batteries were to be transported for some distance the several parts of them and the acid had to be packed in separate vessels. Elements that remain filled during the time when they are not employed consume metals and acids uselessly, and are readily spoiled. All these disadvantages are avoided with my apparatus. . . . . .

of Working by Translation on a Closed Circuit," he gives a diagram of a translator (or repeater as they are called here), which he says "is clearly applicable to the instruments in common use, and does not require any extra magnets, such as are used in the American systems."

Instruments arranged as in the diagram would not translate or repeat a single word on a closed circuit. It looks very well in theory, but in practice would be a complete failure. If Mr. Kempe had made an experiment before publishing the diagram he would have found that, during the instant while the relay armature is moving from the front to the back contact, there is nothing to prevent the relay on the other side from also so arrangement for preserving the continuity of the circuit, similar to that used in the Steam's Duplex Transmitter.

Although it is quite true that extra magnets are used in most of the American systems, there are repeaters which do not use them, and there are also repeaters on a similar plan to Mr. Kempe's, but with this difference, that they will work. I enclose you a cut and description of one patented



nearly ten years ago by Mr. B. B. Toye, Superintendent of the Montreal Telegraph Company in this city, and which has been in daily use ever since on a large number of lines. You will see that it would cost but a few shillings to make ordinary instruments available.

In the diagram M M' are the relay magnets of the eastern and western circuits respectively, S S' are the sounder magnets, which are connected with the relays and local batteries in the ordinary manner. These connections are omitted in the drawing to avoid confusion of lines. The flat springs, *a c* and *a' c'*, are supported by the standards F F', but are insulated from them by a piece of vulcanite rubber, as shown in the diagram.

E and E' are the eastern and western line wires, and B is the point of connection with the main battery and ground.

At E and E' is a "resistance," which should be adjusted so as to equal that of the main line as nearly as practicable.

In the diagram the operator on the eastern circuit is supposed to be working, and at this moment has his key open. The western main circuit is broken by the lever of the eastern sounder at the points *c' d'*, but the western relay, M, is kept closed by a branch circuit from the battery at B, established through the relay points, *a' b'*, the sounder, lever, and standard, the resistance, R', and ground at C', and from thence back to the battery.

Now, if the eastern circuit be closed, the lever of the eastern sounder, S, will close the western circuit at *c' d'*, at the same instant breaking the branch circuit at *a' b'*. If the western circuit is broken, the same action takes place on the opposite side of the apparatus.

If both circuits are closed, each is complete through its own relay and respective points, *c d* and *c' d'*."

While admitting that this repeater works well, I consider the system bad. It is almost equivalent to working another line from the battery. When Grove Batteries were used this was not thought to be a serious objection, but now that we are using sulphate of copper cells, it would be preferable to have repeaters which do not interfere with the main battery in any way.

I have diagrams of nearly forty styles of repeaters which have been, or are now, used in America.

That known as the Hicks Milliken (which is in use on the Western Union Lines) seems to be nearly perfect.

Yours truly,
HUGH NELSON.

DISTINCTIVE STAMPS FOR TELEGRAPH MESSAGES.—Such notice has been issued from the General Post Office to the effect that on and after Monday, the 1st of May, no postage stamps other than those embossed on the telegraph message forms still on hand, will be received in payment of telegrams.

THE Eastern Extension Australasia and China Telegraph Company (Limited) announce that their cable between Java and Australia is interrupted. Messages for Australia will be sent by post from Singapore on 1st May, from Java on 3rd May, or from Galle on 9th May.

PATENTS.

ABSTRACTS OF SPECIFICATIONS.

Improvements in electric telegraphs. George Allan, civil engineer, and James Wallace Brown, electrician, 18, Leadenhall Street, London. February 12, 1875. No. 553.—The main objectare (1), to record dots and dashes sent through submarine cables at a superior speed; (2), to translate or re-translate signals from one circuit to another at a superior speed; and (3), to relay or re-translate from land to submarine or land line without sending land line circuit through cable line or vice versa. The improvements consist:—First. In constructing what we call a conical, preferably of a metal bar provided with adjustable insulated platina steps or stops. The conical is mounted in bearings, and has to revolve by an armature. In bearings, and has to revolve in bearings, preferably on the armature above mentioned. Part of said disc serves as insulator and part as conductor; the conducting portion is provided with a local wire. The said disc bears against a metal surface also provided with a local wire. Various arrangements equivalent to the said disc may be used. Third. In the use of compensating springs in combination with our movable contact, sliding once against the other, and so adjusted as to maintain the armature of a relay or its equivalent in any required position. The springs and magnet act on the armature so as to compensate each other's action; one spring only may be used. Fourth. In connecting two circuits outside the relay or pecker, and connecting the armature of the relay or pecker to the line. The forward stop of the relay or pecker is connected through the right hand electro-magnet and to the battery, the back stop through the left hand electro-magnet, so that opposite poles of the battery, the centre of the said battery being carried to earth. Fifth. In connecting the receiving relay or pecker through its armature or equivalent to a receiving battery. The centre of such battery is connected to earth, and the extreme positive pole to the right hand stop of relay or pecker, and the extreme negative pole to the left hand stop, or vice versa. Sixth. In winding the relays differentially. Seventh. In using two arms pivoted one on each side of an armature or its equivalent, of a relay or pecker or the equivalent of a relay or pecker, the said arms being placed angularly in relation to the armature but in the same plane. The free ends of the said arms are connected together by a bar which passes freely through a hole or slot in the armature. The ends of the said bar serve as contact points, and a similar bar passes through the armature and has the ends working in the arms above described. Stops are provided and compensating springs are attached to the armature.

2378. *Printing Telegraph.* JOHN E. SMITH, New York, N.Y. Filed May 21, 1875.—Type wheel revolved both on make and break of circuit. One coil of printing magnet in a local circuit closed by escapement lever on prolonged closure of main circuit, other in a local ditto on momentary closure. Device applied to stop transmitter automatically at end of message. Printing telegraph the arrangement of one-half or portion of the type wheel of the printing magnets in one local circuit or branch of a local circuit, and the other half or portion of the type wheel of said magnets in another local circuit or branch of a local circuit, in combination with a circuit breaker that shall, by the rotation of the type wheel, to open and close the said circuit or circuits alternately through the two parts of the printing magnets, substantially as set forth. 2. In a printing telegraph, a printing magnet in a local circuit or circuits, a type wheel magnet in a main circuit, and an escapement wheel that allows the type wheel to advance a whole character at a single movement of the escapement pallet, in combination with a lever that serves the double purpose of liberating the type wheel and closing the local printing circuit, to effect an impression by either a prolonged opening or closing of the main circuit. 3. In a printing telegraph, the ratchet wheel *l* and the pawl *m*, in combination with the lever *f*, substantially as described. 4. The springs *e* and *e'*, in combination with an electromagnet C, pallet B, and wheels for being into an electric circuit a resistance of measurable or infinite. 5. The magnet C, pallet B, springs *e* and *e*, resistance *k*, lever *f*, ratchet wheel *l*, and pawl *m*, in combination with a train of wheels, substantially as set forth. 6. In the transmitter of a printing telegraph, the combination with a train of wheels of the arm F, and the loosely-fitted lever E, substantially as and for the purposes set forth. 7. The lever E, in combination with the lever H, substantially as set forth. 8. In printing telegraph apparatus, a self-locking transmitter, in combination with a self-locking reister.

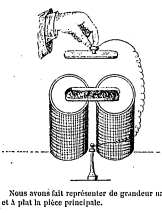
LE RELAIS À COMPRESSION DE CHARBON

DE M. EDISON

Comme nous l'avons promis dans notre dernier numéro, nous allons donner une description sommaire du relais à compression de charbon de M. Edison, dont l'Exposition universelle vient de s'enrichir.



Nous avons fait représenter de grandeur naturelle et à plat la pièce principale.

Elle se compose d'une petite auge en chonite dont les deux fonds, supérieur et inférieur, sont en fer doux : elle est placée au-dessus d'un électro-aimant et remplie de poussière de charbon.

Nous avons représenté un opérateur au moment où il ferme cette auge, après avoir placé dans l'intérieur la matière pulvérulente.

Le principe d'action est analogue à celui dont M. Edison a tiré à tant de reprises un parti si brillant.

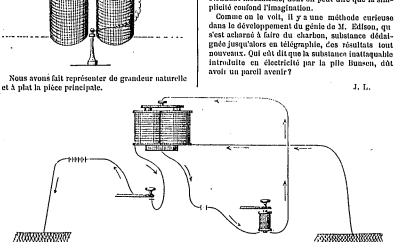
Quand on fait passer un courant dans l'électro-aimant, le fond supérieur, qui est mobile, se trouve attiré, magnétiquement, par le fond inférieur qui est fixe et la poussière de charbon est comprimée. Il en résulte que sa conductibilité est augmentée et qu'un courant local, qui passera du fond supérieur au fond inférieur, par l'intermédiaire du charbon, sera renforcé.

C'est cette différence de pression qui fait parler un marteau local.

Il suffit du dessin que nous donnons pour que chacun puisse se rendre compte de la marche de cet étonnant mécanisme, dont on peut dire que la simplicité confond l'imagination.

Comme on le voit, il y a une méthode curieuse dans le développement du génie de M. Edison, qu'est acharné à faire du charbon, substance délaissée jusqu'alors en téléphonie, ces résultats tout nouveaux. Qui eût dit que la substance inattaquable introduite en électricité par la pile Bunsen, dût avoir un pareil avenir?

J. L.



UNITED STATES.

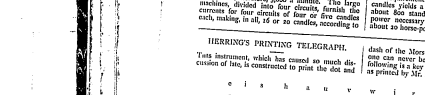
136,630. H. D. Rogers, Cincinnati, Ohio. *Printing and Dial Telegraph and Circuit.* Dated May 24, 1873 Places Morse sounder and a printing or dial telegraph in same circuit and on same line. Printing circuit thrown on automatically when in use, cut out when instrument is not in use. Morse sounder key and lever transmitter in one circuit breaker. The method of rotating the type wheel, by the circuit forming the alternators upon a flexible strip, which is then affixed to the type wheel frame.

140,143.—Adolphus A. Knudson, Brooklyn, N. Y. *Printing Telegraph.*—Application filed May 15, 1873. The operation of printing thereon in an extra pair of magnets, the spring of wheel armature furnishes in drawing up the armature, the motive power to revolve the type wheel.

is carried to 100 turns a minute, and the number of reversals is, therefore, 5,600 a minute. The large machines, divided into four circuits, furnish the currents for four circuits of four or five candles each, making, in all, 16 or 20 candles, according to the requirements of the locality. Each of these candles yields a light equal to 100 Carcel jets or about 800 standard sperm candles. The motive power necessary for producing these 20 lights is about 30 horse-power.

HERRING'S PRINTING TELEGRAPH.

THIS instrument, which has caused so much discussion of late, is constructed to print the dot and dash of the Morse alphabet in such a manner that one can never be mistaken for the other. The following is a key to the Postal Telegraph Alphabet, as printed by Mr. Herring's system—



This is effected by the use of two distinct levers —an arrangement which permits the dot and dash to be printed instantaneously instead of by continued pressure, thus saving the time of the operator and very considerably diminishing the length of the message slip. The coil of paper on which the message is received is made to travel by clockwork in the ordinary way. It passes directly over a thin metallic disc placed transversely to the course of the slip, revolving on an axis and dipping into an ink well. Over the paper is the lever terminating in a broad style, placed vertically above the disc so that the descent of the lever compresses the slip of paper between the disc and the style. The central portion of the lever carrying the central portion of the style can be acted upon either independently of the shared portions or together with them. In the one case only the narrow central portion of the style descends, and the slip of paper is pressed upon the inking disc at only a single point of contact, which produces a vertical dot, and in the other case the style descends as a whole, and having a convex edge it presses the paper into contact with the disc, thus producing a vertical dash. The pressure of the style stops for the moment the revolution of the inking disc upon the immediate recommencement of which the ink supply depends.

Mr. Herring has therefore placed upon the axis of the disc a box containing a spiral spring, so arranged that when the disc itself is checked, the power of the clockwork coils the spring. The moment the disc is released the coiled spring gives the necessary impulse to produce immediate revolution. Each lever also serves to clamp the paper at every impression, thus insuring perfect clearness and regularity in the signs.

The operator is furnished with two keys, one of which commands the central or dot portion of the lever and the lever as a whole.

Hence the dot and the other the dash, and no mistake can occur between the two except by the use of the wrong key. The printing is remarkably clear, distinct, and compact, and gives a legibility to the messages which no other modification of the Morse system has ever exhibited.

The utility of Mr. Herring's system in transmitting and recording messages may be partly perceived from the following comparison between it and the system of the Post Office.

On Mr. Herring's system a message would be recorded thus :—

an important communication.

On the Post Office system the same words would be recorded thus —

147,489. Thomas A. Edison, N. J. *Circuit for Printing Telegraph.* Application filed February 18, 1873. Two relays in main line circuit, central printing and type wheel circuits, form one local battery, the relays having polarized armatures and being so wound and connected that one is attracted while the other is repelled. One of the relays brought into action by reversal of current, in addition to the main magnets in a main circuit, in combination with two local circuits connections to the magnets of a printing instrument, and a mechanism for opening and closing the main circuit and reversing the polarity of the current.

2. The combination of the permanent magnet *a*, the electro-magnets *b b*, armature T, and lever F, substantially as the worm *c* working in the sector *e* substantially in the manner and for the purposes specified.

163,456.—ELECTRIC SIGNALING APPARATUS.—WM. H. SAWYER, Cleveland, O. Filed April 15, 1874.

EDISON & MURRAY,

10 and 12 WARD STREET,

NEWARK, N. J.

A New Relay.

This invention was patented by P. B. Delany, of New York, June 22, 1874. The inventor says in his specification that there is great difficulty on leaky lines in adjusting the retractile springs of relays at each station. If at a terminal station an operator adjusts his relay to get the writing from the other terminal the tension of his spring will be so great that when he transmits his own armature will not respond promptly but "drag." Way stations experience the same difficulty; different adjustments being necessary according to the distance and tension from each end.

If there is a battery at each end, as there usually is, the battery at the end receiving is constantly in connection with line wire, and whilst the line is interrupted at the other end there is a constant escaping from the battery through leaks, etc.; so strong even on some lines as to keep the inscriptions at way stations closed, especially those near the end receiving.

The object of this invention is to lessen if not entirely to obviate these difficulties. To accomplish this I dispense with the back yoke and place a pivoted armature at each end. These armatures have retractile springs of different tensions, so that a strong current will affect both and a weak current affect the armature, having a spring of slight tension.

The second part of my invention consists in placing the armature of a relay so constructed directly on main line circuit. The front and back stops of such armature are both connected to the main line, the path of the current being through the electro-magnet, the armature and one of its stops. It follows, then, that when the armature is moving from one stop to the other the main line is completely broken, thus giving notice to all stations, especially those whose magnets would be held closed by the current from leaks, etc., that the line is in use.

Fig. 2 shows this device. A is a relay magnet; the main line passes through the relay, back armature lever D and points either F or G, out to battery. B is a magnet in local circuit which attracts lever D and holds it on point F when line is open. C is the regular sounder. The momentum of lever D carries it from one point to the other and prevents vibration.

The inventor claims a relay having two armatures and two armature levers, capable of different adjustments substantially as and for the purpose set forth.

We have already alluded to Morse's successful completion of a telegraph line between Washington and Baltimore in 1844. In 1846, Royal E. House, of Vermont, patented an admirable long line printing apparatus, by which messages were sent in Roman capitals in lieu of dots and dashes. The next important improvement was that of Hughes, who patented a telegraph in which the feat of printing a letter with every impulse or wave of the electric current was accomplished. Two years later (U. S. Pledge, of Troy, N. Y., combined the most valuable portions of the inventions of Hughes in a combination instrument, which is considered the most perfect printing telegraph for long lines yet produced. To Mr. Cyrus W. Field is due the credit of suggesting the transatlantic cable; and through his persistent labors and energy that great undertaking was successfully accomplished.

Stearns' modification of the Gintl duplex telegraph system was the first practical solution of the problem of sending two messages at the same time on the same wire. Moses Farmer has also devised a way of sending two messages at the same time in opposite directions, by using two auxiliary batteries in combination with two principal batteries. The important researches of Thomas A. Edison have aided greatly in rendering the practical shape the system of quadruplex telegraphy; and the phonetic system of Gray and Bell aims to increase indefinitely the number of messages which can be sent simultaneously over a single wire, by using tuning forks moved by electromagnets, for sending and receiving the signals. Only one fork at the receiving station is in unison with a particular fork at the sending station, and responds to it. The first system of fire alarm telegraph was invented in 1852, by Channing and Farmer, and shortly after was adopted in Boston.

STANDARD MAIN LINE RELAY.—No. 1.

This is the most highly finished and beautiful Relay now in the market. The working parts are covered with a glass shade, and thus absolutely protected from rust or dirt. All the adjustments are arranged to work from the outside without removing the shade. Although recently introduced, this beautiful instrument has already become a great favorite.

Standard resistance 150 ohms. Any other resistance furnished to order at short notice. PRICE, $16 00.

Self-Starting Registers, of new design, protected by a Glass Shade, complete, with Paper Reel and Weights..... $40 00

Sounders, from..... $4 50 to $6 50

Electric Bells, single stroke or continuous ringing, from..... 5 00 to 8 00

Relays, from..... 9 50 to 16 00

Improved Switch Keys, from..... 2 00 to 2 50

☞ SEND FOR ILLUSTRATED CIRCULARS.

A new key is being put into the telegraph offices of the Pennsylvania railroad. Under the existing system a key and sounder are required for every wire that comes into the office. The new key can be operated by the same instrument, and requires only one sounder. The wires in turn, of local relays, attached to which, and projecting from the under surface, are a number of platina points, representing the number of wires which may enter the office, each one of which the key can be turned, and it can be discovered at a glance. This mode of connection, apart from its convenience, will enable the operators to obtain a difficulty familiar to those using the old system, the point of contact in the armature upon which it works, through the current is frequently weakened or interrupted by the clogging of the points.

NEW TELEGRAPH APPARATUS.—A new apparatus for telegraphic signalling has lately been brought before the Society of Arts. It is the invention of a Spanish gentleman, and its object is to provide a simple and inexpensive system by which any police-station—may be able to communicate with a central office, without interfering with one another. With any system of telegraphy now in use the number of persons can telegraph straightforward—that is, their messages are received at the central office in the order of their position, those nearest to the office being taken first. The signals transmitted are the movement of a pointer acted on a dial. The signals required are marked on the dial by lines, and is recorded at the central office. The receipt of the message is shown by the return of the hand to the zero point. The principal signals suggested are for giving an alarm of fire, summoning the police, or desiring the attendance of a doctor. Street accidents might also be arranged, from which a fireman or a police-constable might communicate with the central office.

Unparalleled Telegraphic Feat.—What the Phelps Motor Printer Did.

We have heretofore spoken of the most wonderful improvement in printing telegraph instruments yet developed—the Motor Printer, invented by Mr. G. M. PHELPS, the able and talented Superintendent of the Western Union Telegraph Company's extensive telegraphic shops in this city. This invention, and the ease, reliability and rapidity with which it works, has opened up a new and prosperous future for printing telegraphs, and will undoubtedly lead to its extensive reintroduction in practical telegraphic use in this country and Europe.

In order to give the Motor Printer a thorough trial, and demonstrate its speed and reliability on long circuits, an experiment in actual telegraph work on a Western Union line between Washington, D. C., and Boston, Mass., was made on Thursday evening, March 16th, the results of which were an unparalleled telegraphic feat, that astonished and delighted Printing and Morse operators, and all who were privileged to witness it.

It should be premised that the weather was unfavorable—a rain and sleetstorm having commenced in Washington in the morning, which gradually extended over the whole route—a test of the wires showing a considerable escape between the terminal points.

Mr. FRED. W. ROYCE was the operator at Washington, and Mr. C. S. NORTH at Boston. These gentlemen are known as among the best Printing Telegraph operators, their ability, to say the least, equalling that of any now or heretofore engaged in the service.

The matter sent was specials to Boston newspapers from their Washington correspondent—Mr. HOYCE sending and Mr. NORTH receiving. During the evening 4,324 words were sent and received, and during the whole time there were only three breaks. By actual count the lowest rate of speed in transmission was 84 words per minute, and from that up to 89 words per minute. It should be stated that the instruments were not geared up to the highest attainable speed, which is about 70 words per minute.

In fact, the only limit to the speed of transmission over these instruments is the ability of the operator to finger the keys.

By the arrangement for duplexing these printers, devised by Messrs. PHELPS and GRAHAM BELL, the capacity of a wire is actually doubled when these instruments are used, which is not the case when Morse instruments are duplexed.

All who witnessed this feat declared that it was unparalleled in telegraphic experience, and were enthusiastic in their commendation of Mr. PHELPS' beautiful and valuable improvement.

The Western Union Company have now in process of manufacture and nearly completed at their shop, a number of these Motor Printers, and they are to be put upon some of the principal circuits as soon as they are ready.

The circuit between Washington and Boston is the longest upon which they have yet been tried, but it is believed they can be successfully worked upon much longer circuits, and further experiments to determine this are soon to be made.

Per mile, discount from above rate for resistance with order.
Per No. 1 Cutlery, Manual, other wire and Chemicals, for Western Union.

LANNERT & BECKER,
Mf'g Electricians,
CLEVELAND, O.

The historical collections of telegraphic instruments are of great interest. Here is the original five-needle telegraph of Cooke and Wheatstone, 1838, with its large hexagon-shaped combined dial, and heavy pointers indicating the letters by the convergence respectively of the two of the needles, and we here also find the first attempt at the insulation of underground wires, the five metallic line wires required to carry the signals being inserted in grooves cut longitudinally in triangular pieces of wood, and filled in with a hard cement, paraffin and hot beeswax. Here are also the first electric telegraphy instrument constructed by Wheatstone, and Cooke and Wheatstone's early letter dial telegraph of 1846. Passing along the collection sent by Her Majesty's Postmaster-General, the attention is arrested by two large double-needle instruments in ivory mahogany cases, bearing brass inscription plates at their base. These two instruments, constructed by Issacs, Reid Brothers, were the means of bringing to justice Jewell, the murderer, and the Times of that date, 1854, observed, that "had it not been for the efficient aid of the electric telegraph, both at the Paddington and Slough stations, the greatest difficulty, as well as delay, would have been occasioned in the apprehension of the murderer." The Bain electro-magnetic machine, or "thunder-pump," has likewise an interest as marking an early form in the series of coils and needles employed in telegraph apparatus, shows the advance made by Selmin in 1848 from the above primitive notions of the Cooke and Wheatstone long 5-inch astatic needle combination. Equally instructive is the display of Bonelli's, which must not be a forgotten that the early line wires were at first insulated with goose quills. Special attention should also be directed to a rare early forms of apparatus, which have been the medium upon which have been built two of the most valuable and important of modern telegraphic apparatus. The first is that of Gauss and Weber's telegraph (1833), constituted by the German Telegraph Department. In this original electro-magnetic apparatus, motion is given to a bar-magnet, suspended by a fine fibre, by means of the directive influence of a multiplying coil of wire surrounding it, and in the centre of which the bar oscillates freely. A mirror is attached to the axis of rotation of the magnetic bar, so that if the bar turns to the right or left, the mirror moves with it. The second early form of apparatus upon which attention is directed is that of Sykes' Yardy telegraph (1845), in which the signals are produced by the effection of electro-dynamic coils, free to vibrate over the sides of a permanent magnet. It will be observed that the motor power in Sir William Thomson's syphon recording telegraph is obtained by the motion of a delicately suspended coil of fine silvering over a soft iron core placed between the poles of a powerful magnet, the motion of the coil being operated by the delicate marker or capillary tube, which registers the signals upon the advancing paper ribbon. The early chemical printing telegraph of Alexander Bain, 1849 accomplished, with its cumbersome wooden box and governor engagement, also marks an era. In the collection of modern recording telegraphs, the high speed automatic printing instruments of Wheatstone and the syphon recorder of Sir William Thomson are the most interesting.

Mr. Culley is to be congratulated on the completeness of Post-Office display, and the exhibition of the German Telegraph Department forms a very complete historical collection of apparatus, from the beginning, in the recently-made spoke-and-wheel instrument of Messrs. Siemens and Halske, of 1875. Of the ancient telegraphic apparatus, of which the diplomatic are most ancient, such as those and Weber's or Steinheil's apparatus, copies have been forwarded so exactly made as even spots of rust are represented. The automatic form recorders and letter-printing telegraphs of Messrs Siemens deserve most careful study. The automatic Morse inker transmitter is comparatively rare in this country, and combines three important elements in its construction: it separate and transmits the messages automatically in the case of a single apparatus, the sending of the message being accomplished by the depression of fingerkeys corresponding to the letters required, and it possesses great rapidity, transmitting upwards of 80 messages an hour of the ordinary length. his most important forms of magnets current generators for reducing the electric light are well represented.

The original collection of apparatus contain objects which any will be glad to see—the apparatus with which Faraday ained the magneto-electro spark and his apparatus for ecomposing electric induction, also a portion of the battery used Sir Humphrey Davy in decomposing the alkalies, and ach of Dr. Wilde's apparatus used by him both in his researches on passage of the induced current through rarefied ases, and first experiments in galvanic gilding.

Manufactory, 614, 616 and 618 Filbert Street.

WESTERN ELECTRIC MANF. CO.

220 Rinzie Street, Chicago, Ill.

POCKET RELAY,

PATENTED JULY 18th, 1871.

Our Patent Pocket Relay has an improved key, large enough to be durable and for practical work.

It has an independent circuit closer.

The sounding lever is supported by adjustable tension screws, and can be readily removed at any time, or adjusted as finely as a relay armature.

The adjustment spring is conveniently arranged, and can be repaired with ease.

The instrument gives a splendid sound.

The case is hard rubber and the same in length and width as the Celon Pocket Relay Case, and a trifle deeper.

It is pronounced the best finished and most serviceable Pocket Instrument made.

PRICE, $18.00.

Twenty per cent. discount when money is sent with order.

WESTERN ELECTRIC MANUFACTURING COMPANY.

An electro-magnetic sounder, recently described by M. Semonnis, in *L'Electricien*, has the following arrangement:—In a hollow metallic cylinder, closed at the top, open below, is suspended by a strong spiral spring, a plunger, with weight attached below. When the apparatus has been let down into the water below by a line, the weight strikes on the bottom, the plunger rises in the cylinder, and thereby closes a circuit formed by wires in the line, a battery and an alarm apparatus. At the same time a hook is caused to liberate a float, which rises to the surface, and indicates the distance travelled by the ship during the experiment. [illegible]

CENTENNIAL EXHIBITION AWARDS.

Phelps's Motor Printing Telegraph.

THE Western Union Telegraph Company exhibited at the Centennial Exhibition the Motor Printing Telegraph instrument, invented and patented by Mr. [illegible] Phelps. This instrument attracted much attention during the whole time of the Exhibition, and was kept busy printing specimens for the public, and demonstrating its practical advantages in actual operation.

It was carefully examined by Sir William Thomson, the Judges, in the electrical department, upon whose report the Company was awarded a diploma and medal for its excellence and superiority over other apparatus for similar purposes. The report of Sir William Thomson was approved by the Group Judges, Messrs. James C. Watson, H. K. Oliver, J. E. Hilgard, F. A. P. Barnard, J. Schiedmayer, Ed. Favre Perret, E. Lenssenz, Joseph Henry, and Charles E. Emery. It is as follows:

"This instrument, founded on the same principle of electromotric telegraphy as the original Hughes printing instrument and the old military teeth telegraph of the Greek General Xerxes, is a great advance on the instrument known as the "combination instrument," in which some of the peculiarities of the Hughes and Morse instruments were combined. On some points it goes back advantageously to the simple character of the original Hughes instrument, as, for instance, in dispensing with the plan of air pressure, introduced into the combination instrument, and performing the mechanical action by electro-magnetic power alone. It has the great advantage above all previous printing instruments of the electromotric class, of permitting groups of consecutive letters to be telegraphed by depressing simultaneously all the corresponding keys. Thus: if the keys A, B, are depressed simultaneously on the "combination instrument," the letters transmitted and printed are A F; if on the Phelps instrument, the fourth A B is correctly given. If all the letters of the alphabet are simultaneously depressed on the Phelps instrument, they are transmitted and printed in the order of the alphabet, and in the time of a single revolution of the type-wheel; and if any group of letters is simultaneously depressed, these letters are correctly transmitted and printed in the order in which they would be found in going through the alphabet in regular order. Thus, if the letters DAILY are simultaneously depressed, the result is daily; but to send the word "daily" correctly, all that is necessary is to first press the key D, then, as soon as it has marked, press "ally." The same manipulation would give this word correctly on the "combination instrument." But take the word "Defeat." On the combination instrument, to send this word, the key D must first be depressed; when it has made its signal, E must be pressed, and the type-wheel runs around the alphabet through Z, A and D to E, until it prints E; then F must be pressed, and the wheel runs around once more before making the fresh signal, then L and one more turn of the wheel, then ANT may be pressed simultaneously, and the word is completed, while the type-wheel runs direct from A to T. On the Phelps instrument DEFT may be pressed simultaneously, and these letters are printed while the type-wheel runs from A to I, and next ANT depressed simultaneously finishes the word as in the other instrument, while the wheel runs from A to T.

Considering the enormous gain on this one word, and the continual occurrence of words in which more or less of such gain is obtainable, I should expect to find that in practice the Phelps instrument would give an ordinary working speed quite as much as double that of the previous forms of instrument on the same electromotric principles, and I am not surprised to learn that, worked by expert operators, it can transmit from 60 to 70 words per minute.

The Phelps Electro-Motor (used also in the "Gold and Stock Transmitter," the subject of another award) is used to give the electromotric motions of the synchronous wheels of the transmitter and receiver in this instrument, and deserves special notice on account of the simplicity of the manner in which it gives the required degree of electromotric uniformity in virtue of its governor, a modification of Hebdomki's electro-magnetic governor."

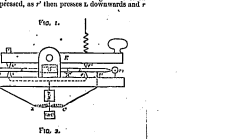
According to reports attributed to the officers of the Western Union Telegraph Company, where dynamic generators have been substituted for decomposition batteries for the generation of the current the cost of charging the wires with the dynamic current is about one-half what it was under the old system. Readers of THE TIMES will recall that some months ago, in a description of a system of telegraphy devised by one of our prominent electricians, in which the dynamic current was employed in place of that generated by decomposition, the reduction in the cost of charging was stated in figures closely corresponding to those developed by the experience of the Western Union Company. The statement was sharply taken up at the time by the partisans of the dynamic current in a series of communications, and some even went so far as to claim that the actual cost, with for volt, of electricity was about one-sixtieth of that produced by decomposition. This extraordinary assertion was based upon the fact that a pound of coal contains a certain amount of energy whose quantity is fairly accurately measured and determinable, and the amount of power in a pound of copper or zinc is also accurately determinable; and when these two factors of the problem alone are compared, and this comparison is made the basis of an estimate of cost, the relative ratio shows an advantage in favor of coal of between 45 and 60 to 1. The reasoning looked very plausible on paper, but, unfortunately, there were certain factors which the partisans of dynamic electricity did not take into account. In the use of the dynamic generator the number of thousands of energy contained in a pound of coal is one thing and the actual horse-power of that energy which appears in the circuit as electricity is quite another. In the first place, the imperfect combustion of the coal in the furnace must be regarded, and, although it may seem strange to the popular reader, in view of the great advances that science has made of late years, it is none the less a fact that not far from four-fifths of all the heat-forming energy contained in a pound of coal is wasted in the furnace through imperfect combustion; so that in operating a steam engine only about one-fifth of the actual energy of the fuel is converted into steam. This fact is so well verified that able engineers have already turned their attention to the construction of furnaces to produce perfect combustion, and the next step in the economical production of power will no doubt take the direction of better-constructed furnaces. In the second place, only about 40 per cent. of the energy transferred from the engine to the generator is actually converted into available current, and as three-fifths of the steam-power is lost before the transformation into current is completed. If, for example, the amount of energy contained in a pound of coal be placed at 100, 80 of this 100 will be lost by imperfect combustion, and 12 out of the remaining 20 will be sacrificed in the development of heat in the generator. The result is that only 8 per centum of the actual energy contained in a pound of coal is transformed into electricity in the use of the dynamic generator, while the larger proportion of the energy contained in the copper and zinc is converted, and this is the reason why the theoretical and the practical relations of the two methods are so at variance with each other, and why those who based their computations upon a mere comparison of foot-pounds of energy were so wide of the mark in their statements.

THE DOUBLE CURRENT TELEGRAPH KEY.

By P. THOMSON, of the Pontiac Gulf Telegraph.

FIG. 1 gives an elevation, and Fig. 2 a plan of the connections of this key.

In Fig. 1, E is an ordinary Morse key. t is a brass beam, the two halves of which are insulated from each other at A. This beam vibrates on an axis shown by the dotted lines between a a, from which it is insulated, and plays between the brass stops s and s'. s and s' are insulated from the key, over position it may be had thrown by the action of E, by the rollers r and r'. These two rollers work on springs which are so adjusted that when the beam t is in the position of rest, as shown in Fig. 1, r tends to press it downwards, and r' upwards. This order of things is reversed when E is depressed, as r then presses t downwards and r



presses it upwards. s and s' are two weak spiral springs by means of which the negative and positive poles of two batteries are maintained in connection with the back and front halves of t, respectively. They exercise no influence over the movements of t.

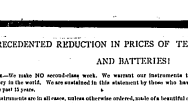
The back and front stops b and f are permanently in connection, and are to earth through the adjustable resistance marked "Shunt."

The action of the key is as follows:—Fig. 1 shows the key at rest. The switch (not shown in the diagram) being turned to "send," the negative current passes on to the beam t, at s, and at the stop b it divides between the shunt and line; if now t is depressed, t does not follow the movements immediately, being held in position by the spring s, but finally it is struck against by f, at which moment the full positive current passes to line, and then t, being pressed down until the stop f is reached, the shunt comes into play, carrying off a portion of the current. The negative half of t has in the same time been raised from contact with the back stop b, and now occupies the same position with respect to b and f as the positive half had previously occupied with regard to f and b—viz., touching neither. If E is allowed to fall back, similar movements take place; first, the full negative current is sent to line at the moment t, is struck, which continues until the position of rest is reached, when the reduced current flows. This arrangement has been worked satisfactorily through 500 miles of line, but from the incomplete details from Kerrebec to which comparison as regards nature of the apparatus no reliable comparison as regards speed with the ordinary "permanent" current keys have been obtained.—*Telegraphic Journal.*

UNPRECEDENTED REDUCTION IN PRICES OF TELEGRAPH INSTRUMENTS AND BATTERIES!

Secure.—We make NO second-class work. We warrant our Instruments to be more perfect than those of any other manufactory in the world. We are sustained in this statement by those who have had practical experience with our work during the past 12 years.

Our Instruments are in all cases, unless otherwise ordered, made of a beautiful quality of GOLD BRONZE METAL, which retains its lustre for years, and is without a doubt the best possible material of which to make Telegraph apparatus of proper durability and high finish.



Western Union Latest Standard Relay Reduced to $10.00.

Until further notice we will make a *discount of 33⅓ per cent.* from our catalogue prices on the following :

	Price.	Reduced to
No. 1 Dorsilene Spring Registers	$27 00	$18 00
No. 2 Weight Registers and Weights	37 50	25 00
No. 3 Register	47 00	31 46

WESTERN UNION IMPROVED PIN-SWITCHES.

33⅓ per cent. discount from Catalogue.

LIGHTNING ARRESTERS of all kinds constantly on hand.

STANDARD WESTERN UNION GRAVITY BATTERY

FOR MAIN LINE AND LOCAL USES.

No. 1	1 50	
No. 2 "	1 00	1 00
Glass, Copper, Jars and Elements for these sizes at same discount.	1 00	1 25

Quality maintained strictly first class as heretofore in all of our Telegraph Machinery and Supplies.

We are now furnishing at relatively low prices ALL MATERIALS used in the CONSTRUCTION and EQUIPMENT of TELEGRAPHIC LINES, LINE WIRE, INSULATORS, BRACKETS, PINS, TOOLS, etc., always on hand in any quantity required. Special low prices made on KERITE WIRE, OFFICE WIRE, CABLES, Etc., in any quantity.

50 PER CENT DISCOUNT.

We have a quantity of the well known HILLS PATENT LOCAL BATTERY, (size of Jars 6x8½) which we are now selling until further notice at the list prices $1.50 per cell and 50 per cent discount. We sell per cell.

L. G. TILLOTSON & CO.,

8 Day Street, New York.

1875, has produced the following results: it has brought the Danube considerably nearer to Vienna; the consolidation of the new banks prevents shifting of the current, and preserves a vast extent of fertile ground from being undone; the inundations which used to be so frequent are now entirely prevented. We shall in another article proceed to describe the execution of the work.

TELEGRAPHIC APPARATUS AT THE PARIS EXHIBITION.—No. V.

STILL keeping to the wall, the next stall past that of the "Société Anonyme Telephonos-Bell" is that of M. Jarrinet, the well-known electric bell-maker of the Rue de Morny, Paris. The bell-pulls and porcelain on view are very elegant in design. The tablet indicators are mounted on a base plate of different expansion on heating. Several also shows some very ornamental lightning rods. On this side of the hall there is less to interest the telegraph engineer than on the other; electric and pneumatic bells predominating here. After Jarrinet's come the stalls of M.M. Chauvin and Marin-Darbel, Bolvin (bells), Legay (wires and bells), De Cosse (bells), Cavedoues (pneumatic tubes and bells), Courtet (very small bells and speaking tubes), Deyrolle and Sire (bells). In the way of novelties M. Bolvin exhibits a patent electric target bell up at a distance electrically connected to a mark indicator, which can be placed beside the shooter. When a bullet strikes any particular section of the target it is forced back by the impact, and making contact completes an electric circuit, which registers the number of marks scored by the shot. M. de Cosse's battery exhibits a temperature alarm consisting of a mercury thermometer, horizontally balanced on a pivot, so that when the mercury column reaches a certain degree the balance is upset and an electric contact established which rings a bell, or otherwise gives warning. Proceeding onwards we pass in succession the smaller stalls of M.M. Müller, Tellier (bells), Pillifant, Nacke and Perin, Franche Comté (galvanised iron wires and brackets), Nastrer (who exhibits one of Reynier's electric lamps with carbon disc electrodes), Claffe (ordinary telegraphic battery), Legray (wires and bobbins), and Chenuet, the stall of M. Postel-Vinay, which comes next, we remark a well board containing a full set of the larger construction tools together with a leather knapsack of finer tools; a useful little instrument table of cut, comprising a needle instrument lightning protector, two relays and galvanoscopes; a handsome mirror speaking galvanometer cased in ebonite, with nickel plated dials and magnet. There is also on view here a Hughes and Breguet dial, a single dial on the same principle for printing twenty copies of one message locally. In the next stall are Digney and Desmarest, who, along with M. Breguet, rank as the best electrical mechanicians in France. They exhibit a variety of Morse instruments employed by the French Telegraph Administration, notably a small Morse adopted by the Administration since 1876 for service in the provinces. It is but 18 in. long by 6 in. high, and 5 in. wide, and the paper is pressed up against the working disc by the end of the armature, which is curved inward, and terminated in a triangular knife edge. This disc is made portable by being fitted into an oaken case, and provided with a belt or handle. A larger Morse, also used by the French Telegraph Administration on long circuits, and having a relay attached, is also on view. It can be fitted into a portable case with folding sides, and drawer for adjusting tools; about 18 in. long, 12 in. high, and 7 in. wide. These instruments are fully described. There is here also a solid telegraphic battery in the shape of a *manipulateur à cuvette*, as the electro-magnetic dial manipulator, formerly mentioned, is termed, with corresponding needle instrument, both having the alphabet in Roman, Turkish, and Arabic characters. It is designed for service in Algeria and other Mahomedan countries.

The firm of Dumoulin's battery, recently contrived by D'Ubigni, an Italian, is also exhibited by MM. Digney and Desmarest. The outer vessel of this cell may be described as an ample glass cylinder 4 in. wide, contrasted at its middle to contain the diaphragm, after the fashion of a sand-glass. The zinc pole, which is a flat cylinder, rests in the upper wide portion, the copper pole, which is a flat spiral ribbon, rests in the wide bottom part of the vessel, the electrode from it passing upward through a neutral bath cut in the zinc. Crystals of sulphate of copper strew the floor of the cell, and the blue solution surrounds the copper pole, but is prevented from diffusing upward to the zinc pole by the screen of porcelain. The sulphate of zinc solution surrounding the zinc pole therefore remains comparatively pure, and waste of zinc by local action is thereby saved.

The next and last stand still is that of M. E. Deschiens, who likewise exhibits a considerable variety of apparatus, including Hughes's instrument and Morse's.

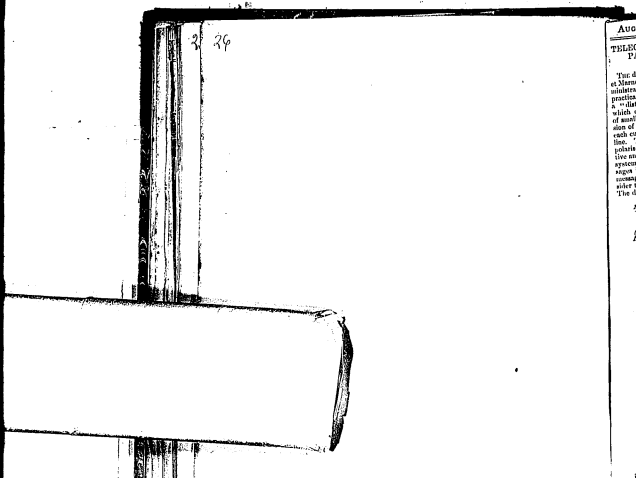
At the far end of the concave there are a number of small detached stalls in two groups, comprising exhibitions by the following makers: MM. Degoz, Tisserat, Tourrade, Dumbell, Callaud, Mouchel, Doneux, Dumet, Casanelle, Legu, Paris, Barbier, Lebourseau, Gerenot and Dubois, Bigeon, Delmasse, Vassalle, Guérin and Son, Cissaco, Pelech, Delaurier, and Guerot. Of these M. Vassalle exhibits a large number of specimens of prepared carbon and graphite for various purposes, including the electric light; and M. Gerot exhibits Delaurier's bichromate battery, which in France has gradually taken the place of Callaud's for electro-plating, by reason of its great economy, and the absence of deleterious fumes. The excellent consists of a zinc and two or more carbon plates enclosed in a porous pot; the exciting liquid being a solution of bichromate of potash, sulphate of soda, sulphate of iron, and sulphuric acid in water. It is contained in the porous vase or in the carbons, and water is placed in the outer vessel around the zinc. It is known that water charged with only thirteen one-hundredths of its weight of bichromate of potash; but in presence of the other salts it dissolves many, because the sulphuric acid being in excess, the more soluble salts, bichromate of soda and persulphate of iron, are formed. In order to prevent the current falling off by a deposit of oxide of chrome on the plates, the proportions of chemicals are so calculated as to permit the oxide to be dissolved in proportions as it is produced. According to Count Du Moncel, the electromotive force of this bichromate element works for five consecutive days through 40,000 Ω, of telegraph wire averaged 2.054, taking the Daniell element as unity. On first charging, the electromotive force has been equivalent to 2.102 Daniells, and slightly hoarsather the trial in question it had recovered the value of 2.130 Daniells. The resistance of the element on first charging is equal to the resistance of 2201 Ω, and it falls on being worked to that of 1920 Ω.

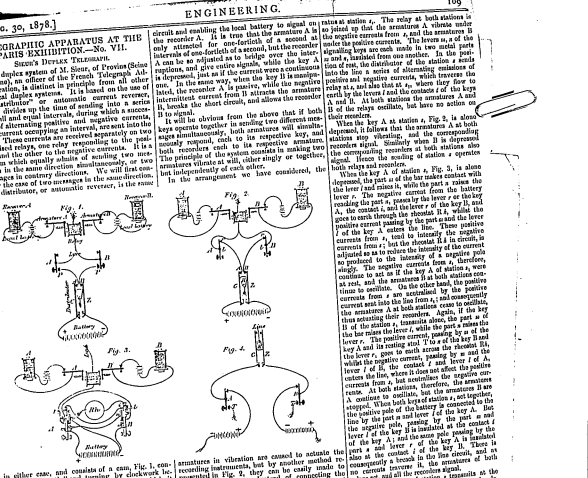
Besides these small stalls there are in this part of the hall four large stalls in groups of two, namely, those of M. Walker and M. Hattier and Son, and those of MM. Coupil-Lemaout and Fellinger, and M. Walker exhibits some fine electric clocks and other apparatus; MM. Coupil and Fellinger, a complete pneumatic despatch apparatus. The neighbouring stalls of Berset and of Meslier exhibit examples of india-rubber and gutta-percha insulated wires and cables, insulators, battery jars, and other works in classic—the display of Meslier being especially fine. The specimens of cable are also dressed at the ends so to show the different layers of material. Several specimens of the Paris india-rubber gravel wire are to be seen here. It is formed of a seven-wire copper strand insulated with gutta-percha. Over the latter is wound a cotton tape steeped in a solution of copper-solution and dried, to preserve it. Over the cotton is laid a layer of tanned hemp, then a wrapping of tarred yarn, then another layer of tanned hemp, then tarred tape again, and, lastly, the whole is enclosed in a lead pipe. In another form the lead pipe is overlaid with steel wires and a protecting compound. The lead pipes are soldered

TELEGRAPHIC APPARATUS AT THE PARIS EXHIBITION.—No. VII.

Siemen's Duplex Telegraph.

The duplex system of M. Siemens, of Prussian (Selasia et Mansa), an officer of the French Telegraph Administration, is distinct in principle from all other practical duplex systems. It is based on the use of a "distributor" or automatic current reverser, which divides up the line of sending into a series of small and equal intervals, during which a succession of alternating positive and negative currents, each current occupying an interval, are sent into the line. These currents are received separately on two polarised relays, one relay responding to the positive and the other to the negative currents. It is a system which equally admits of sending two messages in the same direction simultaneously, or two messages in contrary directions. We will first consider the case of two messages in the same direction. The distributor, or automatic reverser, is the same





circuit and enabling the local battery to signal on the receiver A. It is true that the armature A is only attracted for one-fortieth of a second, but the recorder instruments of one-fortieth of a second, but the recorder A can be so put as to bridge over the interval, and give entire signals, while the key A remains depressed, just as if the current were a continuous one. In the same way, when the key B is manipulated, the recorder A is passive, while the negative latch, the recorder A is passive, while the negative latch, the recorder A is passive, while the negative intermittent current from B attracts the armature B, breaks the short circuit, and allows the recorder B to signal.

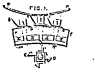
It will be obvious from the above that if both keys operate together in sending two different messages simultaneously, both armatures will simultaneously respond, each to its respective armature, both recorders each to its respective armature. The principle of the system consists in making two armatures vibrate at will, either singly or together, but independently of each other.

In the arrangement we have considered, the armatures in vibration are caused to actuate the recording instruments, but by another method recording instruments, but by another method recording instruments, but by another method

G. GRABNER'S QUADRUPLEX TYPE-PRINTER.

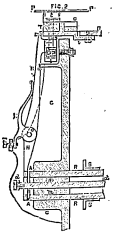
…s instrument, which is distinguished by a peculiar contriv… for printing, was patented on December 30, 1873, for …tents. Here the 60 types *t* (Figs. 2 and 3) of minimal size, …ly disposed in the compass of a type-plate T so as to shift …dily near the type-plate T is a contact-plate C, and both, …dulated by a ring *l*, are screwed on to the contact cylinder B. …a special axle above the type-plate is the paper-cylinder P, …ich is made hollow and as light as possible, and has to take up …l paper to be printed in telegraph form. Both ends of the …er are passed through a narrow slit in the convex surface of …paper-cylinder, and are stretched and firmly pressed by means …wedge. The ground surfaces of the paper-cylinder consist …o plates, and their moves endwise, as in matrices, the firmly …ected axle, a male screw, the height of whose section exceeds

FIG. 1.



…t of the types by the interval between the lines. Then, as the …linder revolves the breadth of a letter with each imprint, the …et of paper becomes printed like any ordinary printed matter. …the nave of the paper-cylinder plates is adjusted a …interposite to equalise any possible eccentric position of the …tre of gravity, and at the same time to regulate the turning …e each printing of a letter by firmly bracing the nave to the …ocket. Near the deepest part of the type-plate is an ordinary …-roller, by which the colouring matter is applied to the types. …he type-plate T, together with contact plate C and contact …inder, revolves with its axle set in motion by a weight, with …aid of several cog-wheels. But, inside the type-plate T, in …uppermost part of the plummer-block G, is an axle *a*, to which …adjusted *n* small, light wheel *b*. The four springs *e* attached

FIG. 2



…e thus wheel lie with their ends within reach of the lower ends *s* …f the types *t*; hence, while the type-plate revolves in the direc…tion of the arrow, the wheel *b* is carried along by the ends *s* so …long as no obstacle is opposed to its motion. But as soon as the …further turning of *b* is prevented, which happens at the indicated …place of wheel *b* in fig. 2, the next type *t* with its end *s* is forced …up to the spring *e*, whereupon this type is printed off on the …paper. With the upward motion of the type the spring *e* curves …upwards, and, tapering above, becomes pressed to the paper …cylinder P, which it turns round the required piece just before …the printing taken place; but, this done, as soon as it has passed …over *s*, the spring *e* again presses the type *t* down to its resting …position.

The special axle of contact plate B, of the type-plate T and contact-plate C, forms a steel magnet, to the extremity of which is screwed an iron tube R, which is thus continuously magnetised by the steel magnet. The electro-magnetic spool S is further passed over the tube R, one end of the winding connecting with the contact-plate C, the other through the line battery with the earth over the pin *d* lying within tube R, and by *n* insulated from it. The pole at *d* of the battery in question is at the same time connected with one wave of the contact-cylinder B, so that the currents may by the latter be conducted to the line when a telegram is being sent off; but, when a message arrives, the line currents come, on the contrary, from contact-lever to the contact-plate, and pass to earth through the electro-magnet. But the arriving current is so directed in the electro-magnet S that the tube R, serving as a core and magnetically induced by the steel axle, becomes unmagnetised. Hence, whereas hitherto the tube R retained the ring A (serving as anchor) attracted to the lever H revolving round axle *o*, the powerful spring K, to be correspondingly strained by means of the screw *r*, is now enabled to detach the anchor and place a wedge-shaped adjustment at the upper end of the lever H resting on a stopper before a leaf fly of the small wheel *b* and in the arresting place *u*, thus causing the just inverted types to be printed off. When this is completed, the nearest of the cams *x* (see fig. 1) immediately below the type-plate T acts on the upper end of the anchor lever H, and again places the anchor A on the tube-shaped core R.

FIG. 4.

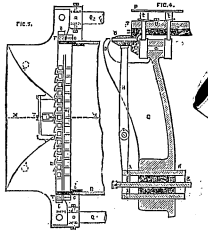


FIG. 3.

In the arrangement of the printing apparatus represented in fig. 4, and differing somewhat from the above, the anchor-lever A, which falls down through the action of the spring at the arrival of the line current, ought to press a double-cutted little wheel D into the space between the conic indented flange Z of the type-plate T, and a small conic wheel E adjusted to the shaft *a*, and thereby transfer the motion of the flange to the cam-shaft *a*, whose cams drive the types *t* towards P. Although the teeth of D and E still remain dovetailed together, the double-cutted wheel D and the cog-shaft *a* are at once stopped at the recoil of the anchor-lever, because the former with the cylindrical portion between both cones becomes pressed into the arresting place at a firmly-fixed arm *p* of the pillar block G. The types move in the same direction as the cogs. In first contrivance each type is raised with the fourth of a revolution of the small spring wheel *b*. With a 3-mm. breadth of the type-pin, with a 100-mm. diameter of the pitch-circle of the type-plate, and 1·5 revolution per second, the printing itself will require $1 : 3 (100 \times 3 \cdot 14 \times 1 \cdot 5)$, or

$$\frac{1}{300}$$

that is almost exactly $\frac{1}{300}$ second.

Now, if four such type-printers be connected with a quadruplex telegraph, each of the four contact-plates C, and each of the four contact-cylinders B, must receive 60 contact pins for 60 types. But, instead of arranging each of the four apparatus quite independently one of the other, they are joined together two-and-two in a double apparatus. Then there will not be required four

TELEGRAPHIC APPARATUS AT THE PARIS EXHIBITION.—No. X.

LEBLANC'S ELECTRIC FIRE TELL-TALE.

It is the nature of a fire to spring from the most insignificant origin, or a vast conflagration may be kindled by a spark, and its growth increases in an accumulating ratio far exceeding the compound interest law. It, therefore, becomes of the utmost importance to give quick warning of the outbreak of a fire, so that the firemen may be on the spot to commence their extinguishing operations against it as soon after its beginning as possible, for time saved then is of great value. The letter to effect this several different systems of conveying fire alarms by electricity have within the last few years been developed, and also applied, particularly in America, where fires in towns are usually of a more dangerous character than in England, by reason of the quantity of timber used in construction, and the extreme dryness of the climate in most parts. Some of these public fire-alarm systems are beginning to be adopted in this country. Glasgow, for example, has taken the question seriously in hand, and, before long, we trust that London will be supplied with street fire-alarms communicating with the fire-stations situated along the main thoroughfares, as the pillar letter-boxes are now, so that a citizen or watchman may, at a few moments' notice, send intelligence of the outbreak of a fire to the nearest fire-brigade. These systems, however, are designed for calling help after the fire has been detected; but there are, as is well known, auxiliary contrivances for automatically announcing the origin of a fire to the inmates of a building or the watchmen on duty. Thirty years ago Alexander Bain patented a means of doing this by electricity, in which a column of mercury in a thermometer completed a battery circuit and sounded an alarm, when the temperature of the locality in which it was placed rose to a certain degree. This was among the first, if not, the very first, example of this species of fire-alarm, and it is one still largely employed in warehouses, and in the holds of ships, or other stores containing inflammable goods, or other cargoes liable to fires. In France, we believe, the first fire tell-tales date from the year 1855. Many different devices have been devised to effect the same purpose, such as fusible thermostatic threads and strings passing through apertures, the explosion of bombs, and the dilatation of wires or bars of alloys by increase of temperature, the expansion of air, or some other gas, in a vessel having an elastic wall, and other more or less complex mechanisms. In 1859 the Count du Moncel invented an electro-automatic thermometer similar to Bain's, but it was only intended to maintain the temperature of rooms or workshops beneath a certain fixed degree, and not to be a fire tell-tale, although it might have been easily modified for that purpose.

All these plans, however, including that of Bain and Du Moncel, were designed only to be a fire alarm when a certain definite temperature, decided upon beforehand, had been reached. It is obvious that such tell-tales with fixed maxima are open to some objection, since in order to prevent false alarms it is necessary to know the maximum temperature which the apartment ordinarily acquires, and from the fact that a fire might have broken out and made considerable headway in some part of the place before the fixed maximum temperature was reached on the tell-tale. The fire-tale of M. Jules Leblanc, a manufacturer, of Tourcoing, France, which was exhibited amongst the telegraph apparatus at the Paris Exhibition is, therefore, an improvement upon the foregoing methods, inasmuch as it signals all sudden elevations of temperature whatever. This system has been considered so satisfactory by the Société Industrielle du Nord de la France that they have awarded a medal to M. Leblanc.

As one of the weak points in the older inventions, M. Leblanc has aimed at producing a tell-tale which will automatically follow or adjust itself to the *normal* variations of temperature, however high they may be, in the room in which it is placed, but which under the influence of a sudden and abnormally rapid rise of temperature will actuate an alarm signal. It is based upon the property which certain materials, such as felt, thick woollens, &c., possess of behaving as good conductors of heat when the heat varies by insensible degrees like that emitted by the sun or stoves, but as bad conductors when the variation in question is sudden and accidental. It is, in fact, a kind of differential thermometer, regulated automatically. The part sensitive to heat is constructed of zinc, which is one of the metals whose coefficient of expansion is the highest. Fig. 1 represents an elevation of the entire apparatus, and Fig. 2 an orthographic projection, on a larger scale, of the most important details; the indicating letters being the same in both diagrams. D is a hose of wood little liable to expand and warp under heat;

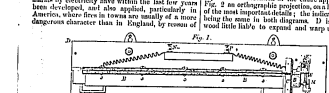

Fig. 1.

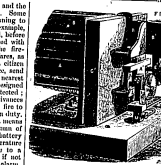

FIG. 2

C and C' two upright metal supports bolted to the base. A and B are two expansible plates of sheet zinc about 60 centimetres long and 0.05 centimetres thick, set from the same piece so as to be isometric, or having an equal expansion. They are doubled into a gutter shape, so as to be more rigid, and are rigidly fixed at one end to the support C, while being free to move at the other end through openings in the support C'. One of these plates, B, is covered with a wrapper of cloth or felt, which retards the effect of sudden changes of temperature on the metal within it; the plate A, on the contrary, is bare, and susceptible to the surrounding changes of temperature. Of exactly the same length and of similar quality these two plates give sensibly the same linear dilatation for each degree. B' is a square bar soldered to the extremity of the plate B, and F' is a small bar fixed to the box B', but isolated from it, and carrying an adjustable contact screw E. By means of this screw the range of the tell-tale is regulated. The head is milled with 120 teeth, and each tooth represents a quarter of a degree of temperature, so that an interval from a fraction of a degree to several degrees Centigrade may be at will adjusted between the contact point of the screw and the spring platinum contact F, attached to the free end of the lever zinc A, according to the degree of sensibility required in the apparatus. The zinc A carries at its extremity a metal piece A' which bears two spring contacts F F', which are intended to make contact with the screws E and M when the plate A expands far enough. M is a small insulating bar supported by the base board D and carrying the second regulating screw M. The latter screw can, if need be, be added to the apparatus as a second tell-tale of the old sort, namely, with a fixed maximum, determined beforehand. It has 50 teeth round its head, each representing a degree Centigrade. The two screws E and M are connected by wire with the terminal P to which is led one pole of a battery, and the fixed ends of the zinc plates are also connected by wire to the terminal N, to which is led the other pole of the battery. It will be seen that when the plate A expands sufficiently far to carry the spring F into contact with the screw E the battery circuit would be completed, and a local gong, bell, or other alarm in the circuit would be sounded. F' and M'' are small spring ratchets gearing in the teeth of the screws E and M and holding the latter in their adjusted positions. All the contact points are faced with platinum, to avoid the evil effects of oxidation, and the whole is enclosed in a protecting case to exclude the dust of even the finest atmosphere. After the description we have given the action of the instrument will be readily understood, and as we suppose that it is properly installed in an apartment, and that the screw E is adjusted so as to leave an interval of one degree between 18° and the contact spring F. Now, so long as the variations of temperature in the room are sluggish, the faucet or felt round the zinc plate B which carries the screw, will not interfere with the successiveness of the plots it covers, and both plates, the covered as well as the bare, will keep pace to each other in their expansion. The relative distance of the two contacts will therefore be preserved with very little alteration, since the screw is carried by one plate and the spring by the other. But, if there is a sudden rise of temperature due to any cause, such as the outbreak of a fire, the bare plate will first feel its effects, and expand so rapidly in proportion to the plate swathed in flannel, that the spring contact will be carried forward into connection with the screw contact, the electric circuit will be completed, and the alarm will be sounded.

The case of a sudden rise of temperature which we have hitherto assumed, is without doubt that to be most frequently anticipated; but nevertheless there might be fires which take their rise in a fashion so slow and gradual as to prevent the closing of the circuit in the manner described, and defeat the object of the tell-tale. M. Leblanc has also provided against this contingency, by adding to this differential sensitive arrangement the auxiliary contact which takes place at a fixed maximum temperature. Any device in the proper operation of the former arrangement is thus made up for in the end by the latter. The best site for the tell-tale is, naturally, near the ceiling of the apartment it is applied to, as in some place where heat tends to accumulate under the action of air currents determined by the disposition of the doors and windows.

M. Leblanc's tell-tale has been in use for several years past, and given very satisfactory results. It is easily readily regulated to begin with, and when once it is set up it requires no further care. They have been subjected to sudden changes of temperature, even to the extent of placing them in stoves or in iced water, and, by all accounts, appeared to have fully sustained their good character. Experiments have been made with them before various of the learned societies of France, which demonstrated that they are able to signal any sudden outbreak of fire in two or three minutes afterwards, let the gradual range of temperature be what it may within the limits of the fixed standard here for a day. At one of these trials, which took place at the Brussels International Exhibition of Hygiene in 1876, there were five tell-tales from different countries pitted against each other. They were tested in a large *salle* of 11 lineal by 23 ft. wide, and 14 ft. high, well lighted by large windows and very well ventilated, a circumstance rendering it more difficult to heat up. The heat was produced by supplying a light to a small gas cooking-ring box soaked with alcohol. All the apparatus were placed at one extremity of the hall, while the fire was stationed at the other extremity at a distance of 42 ft. After the alcohol had been lit for a quarter of an hour, M. Leblanc, of which there were three, sounded their alarm, and all the other tell-tales tried remained silent. M. Leblanc's own instrument regulated for use in warehouses, libraries, docks, and warehouses, signalled after the interval of 35 seconds; his second, regulated for places where the temperature is more variable, such as concerts, workshops, &c., after two minutes; and his third, regulated for industrial establishments, in which the temperature is extremely variable, such as in wool and linen factories, after two minutes and ten seconds. As some of the other instruments tried gave way indications at all, the burning time was placed beneath them at the distance of a few metres, and even in this advantageous position, only two fulfilled its function and died after an interval of 15 minutes. The jury, therefore, awarded to M. Leblanc the medal at their disposal.

THE TELEGRAPHIC JOURNAL AND ELECTRICAL REVIEW.

VOL. VII.—NO. 143.

MR. HERRING'S INSTRUMENT.

The letter from a correspondent which we publish in the present number of the Journal contains remarks which have much truth in them. They are evidently the opinions of a skilled practical telegraphist, who from long experience is well qualified to know the value of any improvements that may be suggested in the existing forms of telegraph instruments. The opinion of the writer of the letter is not, of course, necessarily a strictly correct one, though the arguments seem plausible in the main. In the case of Mr. Herring's printing telegraph which we described in our issue for Dec. 15, we have had opinions as to its merits expressed by men who are well known as eminent scientific experts, and whose names are household words in the electrical world, and now we also have the opinion of a practical telegraphist, which, as we desire only to be fair, we would recommend to the notice of our readers. The general public and probably also inventors give their verdict on this question on the side of the eminent scientific authorities who have been invoked. But a mere blind following of the opinion of scientific experts and men of name is not to be upheld. The judgment of such men on particular points is practically law, and correctly so; and their opinion on subjects which, to a certain extent, lie outside their own sphere of work, in many cases is also extremely valuable, simply from the fact that their natural astuteness enables them in many cases to see clearly at first sight the exact facts of the matters connected with their profession on all one. A man may be a perfect oracle, but it does not therefore follow that he is competent to say whether a violinist handles his bow properly, or whether a new form of bow is more suitable for the purpose than those previously used. In order to determine that matter it is absolutely necessary for him to possess a knowledge of the requirement in question. So it is in telegraphy; a thorough knowledge of the systems, that are being attempted to be improved, is absolutely necessary before a correct opinion can be arrived at, and this can only be obtained by lengthened experience. We do not mean to say that it is useless therefore to attempt to introduce improvements into systems of which a thorough knowledge is not possessed, but there is perhaps, a certain tendency in inventors to feel convinced that they know much better what improvements are wanted than those who have had to deal with the object which the inventor is desirous of remodelling or superseding. On the other hand, there is equally a tendency the other way, viz.: for those in authority to reject any proffered aid from outsiders, a natural inertia to suffer change; and perhaps also a feeling of wounded professional egotism because the improvement in question did not originate with them. Now, the fact that these discordant tendencies exist on both sides, seems to us to call for a competent and independent third party which would mediate between inventors and telegraph officials. We have already advocated such a course in pointing attention to the Commission of experts appointed to recommend inventions to the authorities, in France and other Continental countries, and it still appears to us to be the link required for the harmonious interaction of outside inventors and the Government telegraph service of England.

MR. HERRING'S INSTRUMENT.

SIR,—For the sake of your non-telegraphic readers, I appeare to me very desirable that the recent article ...understood to Mr. Herring's device should not be allowed to pass without a remark or two, suggested as much by practical experience as by long consideration of the subject. At one time, indeed, I must have owned to a certain bias in favour of Mr. Herring, having myself met, under somewhat similar circumstances, with what I regarded as scant justice from the ate engineer-in-chief of the Post Office; but increased knowledge has long since convinced me that the "eternal fitness of things," and not the Postal Telegraph authorities, is the real enemy with which Mr. Herring has to contend. One is truly at a loss whether to admire most that gentleman's "dogged resolution," or deplore his apparent lack of practical familiarity with current telegraphic requirements, whereby he remains, as it were, for ever whirling round and round in the back-water of invention.

Had he been content to apply his system to needles, bright's bells, and similarly-worked instruments, the question would lie within very narrow limits; but when, n place of the universal Morse Alphabet and Varley's monopoly "Double Current," he proposes to introduce a new peculiar "tongs and sheets," worked by slight ...ent reversals, we may well enquire whether the proposal is likely to result in aught else than abortive ...ments. Mr. Herring evidently talks and legislates ...oriental dot and dash, and does not appear to be mistaken one for another; but the fact is—as ninety-nine clerks out of a hundred would tell him—that "land speaking," and not imperfect dots or dashes, come most trouble and prove ...re by far the largest number of mistakes.

A B C D E F G H I

...I cannot digress to such an extent as would enable ...e to satisfactorily account for this failing, interesting ...the point is, but simply enquire, will Mr. Herring's system be less free from the same defect? Presuming the use of "tapper keys" for sending, I fear, the evil would be increased rather than diminished. For instance, look at the enclosed specimen "slip" taken in a somewhat similar manner to Mr. Herring's, except that the marks are horizontal, and are produced by the parallel printing discs one or both of which act as the left or right key is depressed at the sending station. This being my own device, and constantly joined up in "Bell" circuit, might be always "turned on," but is not. Why? Because the attendant labour of even winding up the machine, let alone paper, tear and wear, &c., would not justify the possible gain of, perhaps, tearing by it two or three errors in a twelvemonth. The whole question is, clearly enough, one of expediency. The Postal Telegraphic authorities find they can get on very well without these recorders, and it is, therefore, a thankless thing to put in their way what they don't want.

The retention of visual systems will, to some slight extent depart from automatic working, be unavoidable; but it is to the *ear* and not the eye that we now principally trust, and daily experience proves that our confidence is not misplaced. With sounders, receiving clerks are obviously obliged to "keep up" with the senders, and in the case of moderately sized offices, Postmasters or Superintendents are never at a loss to know what is going on, while as regards "calling," and liability to inattention, the voice of the sounder is not a thing to be ignored, its very importunity compelling attention.

With all respect, therefore, to Mr. Herring, I cannot help thinking that more quick garnier service he can render to practical telegraphy by "rising sounds," working out "his printing division," and betaking himself, heart

MR. HERRING AND THE POST OFFICE.

SIR,—You are quite right in maintaining the necessity for a "third party to mediate between inventors and telegraph officials." The letter of your correspondent "E" simply furnishes additional reasons for such necessity. He ignores my complaint altogether, and because I have resolved not to submit any further invention to the Telegraph department until the authorities have dealt with such complaint, he "deplores the apparent lack of practical familiarity with current telegraphic requirements," and asks me to "betake myself heart and hand to the improvement of sounders" in order to "win his admiration."

May allow me to inform your correspondent that an agreement exists between the Post Office and myself to refer to a third party all questions to Sir William Thomson; Professor Fleeming Jenkin, Mr. Latimer Clark, and Mr. Forde, and that until these eminent gentlemen have been called together and all the facts necessary for a full and fair trial of my system have been submitted to them as the official referees, it is not my intention to hold any discussion with anonymous correspondents. At present the Post Office has broken faith with me in regard to points: It promised that there should be a full and fair trial of my system. It invited me to make costly preparations for such trial. It induced me to engage and to pay two eminent scientific gentlemen to attend and act at the trial. It arranged and signed terms of reference. It promised to adopt my system if the trial proved satisfactory. It obtained possession of my instruments under a written promise to proceed with the trial. It broke all these promises. It has given no reason for doing so. It has never appointed a meeting of the referees. It has not replied to my application to be reimbursed for the consequent loss of my time and my money. It has neglected to deal with my petition for redress although such petition has been referred to by the Crown. What more can your correspondent "E" desire? Is this a satisfactory state of the Government Telegraph Department of England in which such proceedings are impossible, be they then rely upon my hearty co-operation in every endeavour to improve telegraphy. As a matter of fact, however, I do not like the Morse system at all, and Sir William Thomson and Professor Jenkin in a recent report state:

"We are far from believing that the present Morse system can be regarded as final. This opinion is also shared by the highest authorities in the working of land lines, Mr. Latimer Clark. Your correspondent "E," therefore, must be prepared for any difference of opinion which I may therefore express as to the policy of extending the use of his favourite Morse sounder. Many telegrams contain the pith of private matters which the sounder discloses to waiting ears. Even the Morse transmitting key, in a quiet suburban office, gives no unnecessary sound to a practised listener. I know several offices to which my remarks apply, where either under the pretence of waiting for an omnibus or preparing a telegram, secret information might easily be acquired either from a Morse key in sending or a Morse sounder in receiving.

RICHARD HERRING.

January 24, 1879.

[W. L., F. D. and F. J. S.—Your letters will appear in our next.—Ed. T. J.]

TÉLÉGRAPHIE ÉLECTRIQUE

Télégraphe imprimeur de M. Phelps

Les télégraphes imprimeurs, dont l'invention remonte à l'année 1837, n'ont été regardés pendant longtemps que comme des appareils curieux et on croyait qu'ils n'étaient pas susceptibles d'être appliqués dans la pratique. Dans l'origine, ils fonctionnaient très-lentement, ils étaient très-compliqués de construction et se dérangeaient tellement facilement qu'il aurait fallu que les employés fussent eux-mêmes mécaniciens pour en obtenir un service régulier. Cependant, grâce aux perfectionnements que leur apporta M. Hughes, on put acquérir la preuve que c'étaient les appareils télégraphiques les plus rapides et les plus commodes pour les dépêches privées, car elles sortaient de l'appareil imprimées en caractères romains et pouvaient être livrées au public sans transcription. Aujourd'hui, ces appareils sont employés dans tous les pays, et bien que leur usage se soit ralenti depuis la mise en pratique des télégraphes à transmissions automatiques et des systèmes duplex et quadruplex, ils occupent encore une place très-importante dans la télégraphie, et nous en avons la preuve dans le télégraphe de M. Phelps qui, malgré la répugnance des administrations américaines à employer ce genre de télégraphes, a reçu néanmoins d'elles un bon accueil.

Les télégraphes imprimeurs peuvent être classés en deux grandes catégories : les télégraphes à échappement et les télégraphes à mouvements synchroniques. Dans les premiers, la roue des types qui porte les caractères en relief ne tourne que sous l'influence d'échappements électriques successifs déterminés par un manipulateur mis en action à la station de transmission et qui font arriver devant un mécanisme après imprimeur, celui des caractères de cette roue qui doit être imprimé. Alors une action particulière déterminée soit par le fait même de l'arrêt de cette roue, soit par un renversement du sens du courant, soit par une interruption de celui-ci, soit par tout autre moyen, provoque l'impression de la lettre sur une bande de papier qui avance en même temps de l'espace convenable pour la succession des lettres de la dépêche. Ce système, comme on le comprend facilement, a l'inconvénient très-fort. Dans l'autre système, les deux mécanismes télégraphiques marchent synchroniquement aux deux stations en correspondance et les différentes lettres des deux roues des types peuvent de cette manière se présenter en même temps devant le mécanisme imprimeur; de sorte que, si à un moment donné un courant électrique est envoyé à travers les deux appareils, on peut obtenir une réaction électro-magnétique ayant pour effet d'imprimer aux deux stations la lettre qui se trouve alors à portée. Avant M. Hughes, il fallait, pour obtenir cette impression, arrêter le mécanisme, ce qui détruisait un peu le synchronisme de mouvement des appareils; mais M. Hughes, par une conception hardie et qui a réussi, est parvenu à imprimer en quelque sorte les lettres au vol sans arrêter les mouvements; et pour corriger les retards qui pouvaient résulter de cette réaction, il imagina sa roue correctrice qui non-seulement a résolu ce problème, mais encore a fait que plus les signaux envoyés se succèdent rapidement, plus la transmission de la dépêche est correcte. Toutefois, en raison de cette impression au vol, on ne peut imprimer beaucoup de lettres par chaque tour de la roue des types, et nous avons vu dans un article que nous avons publié dans ce journal que, pour augmenter sous ce rapport le rendement du télégraphe imprimeur, M. Olsen avait été obligé de le compliquer de certaines combinaisons mécaniques. M. Phelps a résolu le problème plus complétement en combinant, dans son appareil les deux systèmes que nous avons exposés précédemment. Comme dans l'appareil Hughes, cet appareil, est soumis en effet à une marche synchronique des deux instruments en correspondance, et chaque lettre s'imprime sous l'influence d'une seule émission de courant; mais, comme dans les systèmes à échappement, le mouvement de la roue des types est arrêté pendant l'impression de chaque lettre et relâché automatiquement à l'instant où l'impression a été effectuée, et il paraît que de cette manière on peut obtenir pour la rotation de la roue des types une vitesse beaucoup plus grande que celle qu'on pourrait atteindre au moyen d'un mouvement à échappement. Or, avec ce système on a l'avantage que les lettres qui se présentent successivement sur le clavier peuvent s'imprimer dans une même révolution. De cette manière, un employé habitué a pu obtenir, d'après M. Prescott, une vitesse de transmission dépassant tout ce qui, jusqu'à présent, a été regardé comme possible. L'appareil est, d'un autre côté, plus portatif que celui de M. Hughes, et il est beaucoup moins fatigant à faire manœuvrer, car c'est un électro-moteur qui fait les frais du mouvement et on n'a pas un poids assez lourd à remonter sans cesse.

En somme, l'appareil se compose d'une boîte plate en fonte assez large (46 c. sur 38 c.), qui est munie sur l'un de ses côtés d'un clavier semblable à celui du télégraphe Hughes et qui porte à sa partie supérieure les différents mécanismes lesquels sont adaptés sur trois colonnes distinctes. Sur la première, qui est le plus en avant, est monté le système transmetteur; sur la seconde, à droite, est fixé le mécanisme imprimeur, et sur la troisième, à gauche, le système moteur.

Les différentes touches du clavier sont mises en rapport par des tiges articulées qui s'élèvent verticalement dans la colonne du transmetteur avec des doigts d'arrêt rangés circulairement autour d'une sorte de collier à roue dentée mise en mouvement par le moteur avec une vitesse de 240 tours par minute. Le mouvement de ce collier est soumis à l'action d'un régulateur qui permet de l'uniformiser et de le synchroniser avec celui de l'appareil correspondant, et il est disposé lui-même de manière à pouvoir être arrêté par le doigt de la touche abaissée, mais sans pour cela déterminer l'arrêt du mécanisme moteur. Il résulte toutefois de cet arrêt une action mécanique qui a pour effet de soulever une tige agissant sur un interrupteur de courant, et ayant pour effet de faire réagir le mécanisme imprimeur. Un système de cames, disposé en conséquence, fait d'ailleurs en sorte qu'aussitôt l'action sur l'interrupteur accomplie le doigt qui avait provoqué l'arrêt se trouve dégagé et permet au collier de reprendre sa course avec le système moteur jusqu'à ce qu'une autre touche abaissée ait provoqué un nouvel arrêt.

Lors donc qu'une touche est abaissée, aucune action ne peut avoir lieu jusqu'au moment où le doigt en rapport avec la tige abaissée vient se présenter devant le collier et l'arrête, et ce collier reste ainsi arrêté pendant un quart de sa révolution, après quoi il se trouve dégagé; mais pendant son arrêt la tige commandant le jeu de l'interrupteur s'est élevée et a fourni un contact d'une durée de 1/28 de seconde qui réagit sur le mécanisme imprimeur de la station correspondante.

Le mécanisme imprimeur est disposé de manière que la roue des types marche synchroniquement avec le collier déterminant le jeu de l'interrupteur et que l'arrêt de celui-ci provoque celui de la roue des types; cette action est produite par une roue à encoches qui sous l'action d'un électro-aimant remplit la quadruple fonction d'arrêter la roue des types au moment précis où une lettre doit s'imprimer, de presser promptement la bande de papier contre le

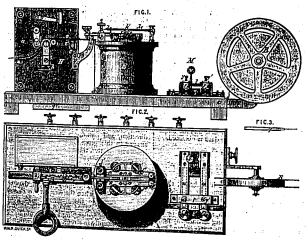
BRAUN'S TELEGRAPH INSTRUMENT.

This apparatus, the invention of M. Braun, telegraphist to the Austrian Government, has been in use for some considerable time on the Austrian railways. It is a step-by-step dial instrument, and is shown in elevation and plan by figs. 1 and 2 in the accompanying illustration. The transmitting apparatus is worked by the hand of the operator, and consists of the handle *a*, which is attached to the axle *b*, which terminates in a pinion *c*, gearing into the wheel *d*, which is fixed on the axle *e*, which carries the contact-wheel *f*, and the pinion *g*, gearing into the wheel *h*, which is fixed on the axle *i*, which carries the contact-wheel *k*. The contact-wheels *f* and *k* are insulated from each other, and from the rest of the apparatus, by being made of hard wood, pierced through with holes, and fitted with metal pins, which project on both sides of the wheel. The pins on the wheel *f* are connected with the line-wire, and those on the wheel *k* with the earth-wire. The pins on the wheel *f* are arranged in a single circle, while those on the wheel *k* are arranged in two concentric circles, and at the same time connected with each other in pairs, as shown in the figure. The pins on the wheel *k* are also connected in the ordinary manner with the pins on the wheel *f*, so that the pins on the outer circle of the wheel *k* are connected with the pins on the inner circle of the wheel *f*, and the pins on the inner circle of the wheel *k* are connected with the pins on the outer circle of the wheel *f*. The pins on the wheel *k* are also connected with the pins on the wheel *f* in such a manner that the pins on the outer circle of the wheel *k* are connected with the pins on the inner circle of the wheel *f*, and the pins on the inner circle of the wheel *k* are connected with the pins on the outer circle of the wheel *f*. The pins on the wheel *k* are also connected with the pins on the wheel *f* in such a manner that the pins on the outer circle of the wheel *k* are connected with the pins on the inner circle of the wheel *f*, and the pins on the inner circle of the wheel *k* are connected with the pins on the outer circle of the wheel *f*.

through at an average speed of 50 centimetres per minute. The paper is wound on the wheel R. After having this wheel the paper band passes through the opening *c d* formed in the base of the apparatus, rises in the plate *c*, and passes between the rollers *k B*.

The plate *c* acted upon by the spring *e*, presses the band lightly against the lower surface of the piece *f*, and places it on the receiving plane; the force of the spring *e* is determined by the screw *e'*. The lever *g* may occupy two positions, one raised and the other lowered; in the latter position it stops the clockwork mechanism and removes the band from the receiving plane simultaneously.

The electro-magnetic apparatus it is composed of an ordinary electro-magnet and a strong magnetic bar bent twice at right angles.



The poles *n n* of the magnet and the poles *p p'* of the electro-magnet are in the same plane, and are respectively placed at the extremities of two perpendicular diameters. These poles, divided in two in the direction of the circumference, freely contain the armature $a^1 a^2, r^1 r^2$ composed of two semicircles of cast iron $a^1 a^2, r^1 r^2$; these two semicircles are united by a copper cross *t* to an axis or arbor *s* in the centre of the apparatus.

The levers $f f^1$, figs. 1 and 2, are moveable in their axis $f \cdot f^{(1)}$, and by yielding to the action of springs $f^{(2)} f^{(3)}$ acting in contrary directions transmit, each on its own side, the action of these springs to the appendage *b* of the armature; this action is limited on both sides by the piece b^1, which by its lateral play, enables it to cause the direction which the levers $f f^1$ give to the appendage *b* to coincide with the position of repose of the armature. In case this does not happen this position corresponds to the moment when the extremities $a^1 a^2, a^3 a^4$ are arranged identically in relation to the poles $p p^1$ of the electro-magnet. The screws $f f^1$, at equal distances from the appendages *b*, limit each in its own direction the full movement of the armature. The appendage *b* is terminated by a holder or claw which supports the inker *m*, formed of a funnel-shaped cup, in which printing ink is poured. The buttons or knobs $e e^1$ partly regulate the tension of the contrary springs $f^{(2)} f^{(3)}$.

The manipulator or manipulating piece *M*, figs. 1 and 3, comprises two flexible springs $x x^1$, four contact pieces $l l^1, u^{(2)} u^{(3)}$, a commutator *v* furnished with two springs $u u^1$, and a pin or peg v^1.

The ends of the springs $x u^1$ of the commutator press against two insulated pieces which are fixed on the under surfaces of the blades $x x^1$.

The two blades are ordinarily in contact with the screws $x \cdot x^1$ of the piece *l*, and are consequently removed from the contacts of the piece l^1; the same separation also exists between the extremities of the springs $u u^1$ and the contacts of the pieces $u^2 u^3$.

When the spring *x* is pressed down the contacts of *x* with l^1 and of *u* with u^3 are simultaneously established; when the blade x^1 is lowered the contacts of x^1 with l^2 and of u^1 with u^2 are established in the same manner.

The screws $x \cdot x^1$, in constituting the contacts of the pieces *l* also serve to regulate the full movements of the springs $x x^1$. The pin or peg *v* serves to put the commutator *v* into metallic connection with the springs *x* or with the spring x^1 according to the side on which it is placed.

The spring *s* is a small picker for clearing out the orifice in the ink cup should it become clogged from disuse.

The following is the action of the apparatus:—

Supposing the regulator of the clockwork mechanism and the plate *c* free from the action of the lever *g*, which occurs when the latter is raised, the band unrolls uniformly in the receiving plane, and receives a continuous line or stroke from the very fine orifice of the inker *m*.

According to the movements of the armature, and consequently the displacements of the inker, this stroke or line is converted through the influence of the currents into angles to the right and bars or lines to the left; the signals produced in fact are very similar to those obtained by means of Thomson's Siphon Recorder.

In practice, if as in the "Morse" system a single manipulating key is used, the apparatus is precisely under the same conditions as the apparatus generally employed, the signals appearing on one or the other side of the line of repose, according to the direction of the current with which the apparatus is worked.

If the two keys are employed at the same time, but in such manner that each reproduces complete signals, the "Morse" alphabet may be reduced to 30 combinations for each side, which produces the 60 signals constituting this alphabet, without having to use combinations of more than four elements or emissions of current.

By using two keys, but so as to produce only elements of short emissions of current, the angle to the right in substitution of the dot, and the angle to the left in substitution of the dash is obtained.

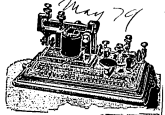
JEROME REDDING & CO.,

No. 30 Hanover Street, Boston, Mass.

Manufacturers of

ELECTRICAL SUPPLIES OF EVERY DESCRIPTION.



No. 1 Private Line Instrument. (Size of Base, 7 in. x 10 in.)

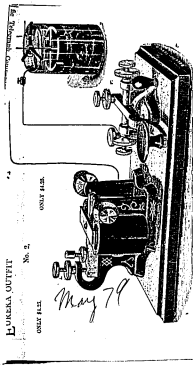
We are now selling our improved Learners' Instrument, consisting of a full sized Sounder and Curved Lever Key, well finished, and mounted on a Japanned Iron, or polished Mahogany Base at the following low prices, O.B.B., or money is always refunded.

No. 1 Outfit including Instrument, one cell Callaud Battery, Chemicals, roll of Office Wire, and an excellent Book of Instructions.....$5.00
" " Instrument, alone.....5.00
"Home" Learners' Complete Outfit.....4.00
" " Instrument without battery.....3.00

Also, Telegraph Instruments, Office Wire, Line Wire, Insulators, Brackets and all material used in the construction of Telegraph and Telephone Lines, at a GREAT REDUCTION FROM FORMER PRICES.

Send Stamp for our new Catalogue, just issued.

New Invention! H. O. F. Lodge exhibited his new invention of Insulated Wire at work, which is perfectly to the ordinary kind as giving a high insulation, small capacity, and not requiring the hand to approach close to it to work it. It consists of two insulated wires, arranged in pairs, crossing each other; each pair crossing between the other two; one wire of are the terminals and parallel pieces of the bar. The middle pair are supported by an endless silk thread, which runs on two pulleys, one of which is filled with a handle. On turning the handle to right or left, the two middle wires are brought into contact with one or other of the two outer wires, and the current reversed as well. The whole is inclosed in a metal box.—*Physical Society, London.*



LUCERA OUTFIT

ONE PACKAGE BLUE VITRIOL, ONE ROLL INSULATED OFFICE WIRE, ONE INSTRUCTION BOOK.

The above Outfit and material all complete sent on receipt of $4.25.
Two Cells Callaud Battery, Chemicals, Wire, Book and Instructions to work same.
Parties sending three dollars will receive Outfit and Instrument to work same.
Send Stamp for circular. Address

M. A. BUELL & SONS,
76 Frankfort Street, CLEVELAND, OHIO.

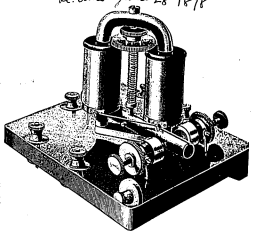
A New Electric Current Breaker.—A simple form of current breaker is described by Dr. F. Niemöller. To the axle of a fan, rotated horizontally by clockwork or similar power, which touches the mercury at every half a revolution, is fixed a platinum wire, which at every half revolution of the fan, when the current passes when all the apparatus is in normal state is a small magnet. This magnet, acting on the current, causes vibrations in the circuit so breaks and makes contact. The number of vibrations can be readily rectified by changing the length of the platinum wire. The number of breaks per second can be obtained. By passing an intermittent current over the wire, it can be set in vibration without the intervention of mechanical means. This happens when the fundamental note of the string is in unison with the pitch of the breaker.

A NEW SOUNDER.

The accompanying illustration represents a sounder for direct working or translation, and of which over one hun-

Sc. Amer. June 26 1875



A NEW FORM OF SOUNDER.

speed at dred have been constructed for the telegraph lines in India.

It differs from an ordinary sounder in the arrangement of the armature, which is supported by a vertical spiral spring. This spring serves to restore the position of the armature when the current ceases, as well as to relieve the lower bearing of nearly all friction. The prolongation of the armature acts as the beam, and plays between the two stops shown in the engraving.

To insure very good insulation for damp climates, the coils are rendered solid by repeated immersions in a compound of resin and beeswax (for hot climates, ten parts of resin and

one of wax answers well). The range of the instrument is shown by its working without fresh adjustment, either with one Daniell's cell through 6,000 ohms, or with 20 through 0. When very delicately adjusted, one Daniell's cell through 31,000 ohms is just able to work the instrument if the stops be extremely close together.—*H. Dickers, in Journal of the Society of Telegraph Engineers.*

Electric transmitter
Earliest date found 1880

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It has occurred to me that a vast amount of battery power is employed to produce comparatively trivial results. Why not do away with batteries altogether for telegraphic purposes, and rely on magnetic electricity for the transmission of signals? The labour expended in depressing a Morse key is surely capable of producing a magnetic current sufficiently strong to give a signal at a considerable distance. The suggestion may seem very unorthodox; but allow me, Sir, to explain more definitely what I mean. A magnetic current is generated in a coil of wire by bringing a permanent magnet near the coil. If, therefore, a number of magnets were to be brought simultaneously near a number of coils in one circuit, a strong current would be produced; and if a delicately balanced lever were constructed with a key at one end and a number of bar-shaped magnets at the other, the power required to move such a lever would be small. If then, say, fifty magnets were to be simultaneously withdrawn from the centres of fifty coils, each of considerable length, I venture to think that a sufficiently strong current would be generated in the coils to send a telegraphic signal from Land's End to John o'Groat's Land, or even further. Perhaps it would be advisable to complete the electric circuit only at the moment when the key was down in order to get the full effect of the magnetic current, and to prevent a second current being sent in the opposite direction when the key sprang back.—I am, &c.,

CHARLES STEWART, M.A.

59, Cadebrooke-row, N., 31st January, 1880.

1870 Cowpering, Telegraphing, and Recording Secret Telegrams,
E. J. Hobbins.—Dated 19 May, 1870.—(4 communications.) 5d.

The repetition consists of several alphabets or signs arranged in concentric circles on a transmitting or recording dial, on which circle the required letter is brought opposite a fixed point by means of a hand or governor key, the key being composed of as many letters of figures as there are sets of the alphabets employed, and their letters arranged in the order of the alphabets. Use is made of a combination of the Morse and Roberts systems of a dotted alphabet.

1871 Electric Telegraphs.—

Multiplex Telegraphs.—A company pursues to acquire and work the patented inventions of Frank Winfield Pancoast for "improvements in multiplex telegraphs for transmitting and receiving signals on slips of paper, and for other purposes." It was registered 30th ult., with a capital of £20,000 in £1 shares.

ELECTRICIAN

the condenser is moved by clockwork which causes it to act every five minutes, so that every hour twelve throws are observed on each galvanometer. At the end of every hour the ship reverses the battery so that the direction of the throws is changed.

In order to enable the ship to communicate with the shore, instructions are given that if at the end of the hour the throws do not become reversed, or if they become reversed before the expiration of the hour, it is a sign that the ship wishes to communicate with the shore; in this case, then, the shore disconnects the cable from the clock lever and connects it with the speaking apparatus, and at the ship does the same, the necessary communications can be carried on. If, on the other hand, the shore wishes to call the attention of the ship he can do so by moving a lever corresponding to the clock lever two or three times quickly by hand: the ship then observing that the throws on her galvanometer take place quickly, instead of at intervals of five minutes, immediately joins up her speaking apparatus, and thus communicates with the shore.

As it is advisable that the operation of disconnecting the cable from the clock lever contact and connecting it to the hand-worked lever shall be done without difficulty, the arrangement of the apparatus is such that this can be performed with great facility.

The whole of the arrangement is shown by fig. 3.

A is a brass tongue, whose normal position, while the clock-work is in operation, is on contact plate B; this plate is connected with the plate C, which plate is also connected by a small spiral spring with the lever L, L. D is a contact plate which is free while the clock is working. E, E is a brass tongue which in its normal position is in contact with the piece G. To the contact plate F the cable end is attached, and to G the condenser is connected. The lever L, worked by a ratchet-toothed wheel connected to a clock, makes contact every fifth minute on the contact at F, returning, after making this contact, to G. H' is a cam on the end of a hand lever, which is used for moving the tongue A from its normal position on B to the contact at K, thus switching out the connection with the lever L when signals are to be given by hand. H is a cam on the end of a second hand lever; this is used for giving signals by hand (when the clockwork and the lever are cut out), by pressing the tongue E down on the plate F, to which the cable is attached. When the clock is at work the current passes from F to lever L, on to plate C, and thence *viâ* B and A to condenser. When hand signals are given, the current passes from F to E, D and A, and thence to condenser. When E returns to normal position at G the condenser is discharged.

In order to render the motion of the lever, to or from a contact, quick and decided, the best spring on the plate C is provided; this has a conical piece at its end which presses against a pin on the lever; as the lever moves under the action of the clock wheel, the pin acts against the inclined side of the conical piece, and moves it until the apex is reached and passed, when the action of the spring immediately drives the lever over sharply against its contact. A similar action takes place when the lever moves in the reverse direction. The amount of play given to the springs at the end of the lever L is such that they do not break contact from F or G, as the case may be, until the point is passed at which the lever is thrown sharply over.

TELEGRAPHIC APPARATUS IN USE IN THE BRITISH POSTAL TELEGRAPH DEPARTMENT.

Telegraphic Journal
Jour. Society of Telegraph Engineers

Sir W. Henley's Direct Instrument.

This form of instrument was patented by Mr. C. Bright (now Sir Charles Bright) in 1863, and was almost exclusively used by the "Magnetic" Company, it having superseded the Magnetic Needle instrument of Henley and Foster.

The instrument is an "acoustic" one, that is to say, it gives signals by sound, like the single needle instrument fitted with the Noble acoustic dial. To this latter form of apparatus indeed it is closely allied, inasmuch as the two forms are worked and read from in identically the same manner.

The apparatus consists of three parts, viz., "the Tappers," "the Relay," and "the Bells."

"THE TAPPERS."

Either of the two forms of tappers which are used in the "Single needle" instrument and which are fully described in Articles I. and II., can be used with the Bell instrument; the way, however, in which they are connected up to the apparatus differs slightly from the method employed with the single needles.

In the latter form of instrument the portion of the apparatus from which the signals are read, that is to say, the "Dial," is equally affected by the outgoing and the incoming signals; in the Bell instrument only the incoming signals or currents work the acoustic signalling apparatus, the outgoing signals pass direct to line without working the latter.

The way in which the connections are made in order to effect this result is shown by fig. 14, which represents the ordinary form of tapper keys joined up in circuit with the rest of the apparatus. Referring to this figure, it will be seen that in the key the terminals X and Y, which for the single needle instrument are kept connected together by means of a brass strap (seen in fig. 1, Art. I.), are in the Bell instrument connected to the B and U, that is, the "Down" and "Up" line, terminals of the receiving portion of the apparatus; the strap being of course disconnected from X and Y. The other connections are precisely similar to those shown in fig. 2 (Art. I.), which represented the connections for the single needle instrument; that is to say, the battery is connected to terminals Z and C, the "Up" line is connected to A, and the "Down" line is connected to Y through a single needle dial, S S, which dial is now attached to all of the Bell instruments, in order to enable the signals to be read visually if necessary.

Action of the tapper.

As regards the transmission of signals the action of the tapper and the course of the current is identical with that in the case of the single needle instrument, viz., when the left-hand pedal is depressed, then the Zinc pole of the battery becomes connected to the block, A, and thence by the end of the spring, Y, to the earth, / thence to terminal A and on to the "Up" line of the circuit. The Copper pole of the battery being in connection with the block supporting the spring, X, *F*, becomes con-

nous permettre de communiquer en peu de minutes entre le Nouveau Monde et l'Ancien Continent, se doutait-il qu'il avait été deviné ou plutôt annoncé dès l'an 1762?

plates, between which the hammer of the instrument plays, the upper plate corresponding to the upper screw stop, and the lower plate to the lower screw stop of the ordinary Sounder.

The connections of the instrument possess no peculiarities, being similar to those of an ordinary relay-worked circuit. The resistance of the relay is about 400 ohms; the local Bell has a resistance of 20 ohms.

The tongue of the relay being pivotted between two pointed screws, care should be taken that the upper one of the two is screwed sufficiently down to allow only a very slight amount of up and down movement or "end shake" of the tongue. If the play allowed is too great it will cause the contacts, and, consequently the signals, to be irregular. If, on the contrary, the screw be screwed down too tight, the tongue will be jammed and will not

FIG. 41.

respond at all. The lock-screw securing the upper screw should always be kept tight.

DOUBLE CURRENT SYSTEM.

Single Current working, with Relay, from its simplicity, is very useful for lines which are beyond the range of direct working; but which, at the same time, are not of an excessive length. Now, in the Single Current system, as has been pointed out, the line current has to work against a magnetic pull, or bias, which is of a fixed and unvariable strength, unless altered by turning the regulating screw, consequently variations in the line current have to be allowed for by changing the adjustment. On long lines, which are much and continually affected by climatic changes, the need of this continual alteration would prove very troublesome; besides, even if the current did continue constant for any length of time, it would often be too weak to work the tongue of the relay against the necessary bias; on such lines, therefore, the "Double Current" system is adopted. In this system the relay tongue is set neutral, or very nearly so, and the key, on returning to its back position, sends a reverse current, which carries the tongue back to the "spacing" side. To enable

Mr. W. T. Henley is manufacturing a 3-inch cable for the Montreal Telegraph Company. The dielectric of this cable is formed of an ozokerit compound.

According to some experiments made by M. Zloff, the magnetic co-efficient of an aqueous solution of perchloride of iron varies with the magnetising force.

Mr. James Sivewright, general manager of the telegraph between the Cape of Good Hope and Natal, has been gazetted to the most distinguished Order of St. Michael and St. George, for services rendered in South Africa during the late war.

The catalogue of the Ronald's library has been completed by Mr. A. J. Frost, and will shortly be ready for publication. The catalogue will be something more than a mere list of the works contained in the library, as many valuable notes have been compiled and printed in the volume.

A course of lectures on "Electrical Testing as applied to Telegraphy" is now been delivered by Professor W. C. Adams, at King's College, London. The series commenced on Friday, 23rd inst.

The report that the Western Union Telegraph Company have paid Mr. Edison 100,000 dollars for the sole right to use his electromotograph in connection with telegraphy, is stated to be incorrect. The company having paid only a nominal sum down, the remainder being conditional on their working the patent, which they are not likely to do.

MM. Leblanc and Loiseau have invented an automatic electrical railway block telegraph instrument. The apparatus consists of a lever or pedal, placed close to the railway metals, so that it can be moved by the action of the wheels. The movement of the lever sets upon a relaxing arrangement, which in its turn works a commutator. Thus the apparatus serves to put a battery in communication with an electric bell at the signal station. A peculiarity in the arrangement lies in the fact that the lever is moved by the action of the first wheel of the train, and then remains moved away to permit the last carriage has passed, thus the lever is not subjected to the hammering of each wheel as it passes, meanwhile would result in the disarrangement of the apparatus. In the position shown, the apparatus is ready for receiving signals. Supposing the current to come in from the "Down" line, its course is as follows:—From line, through the galvanometer, G, to terminal 3, from thence to lever l_1, and contact point 4_1, thence to terminal 4; and from there to terminal U of the relay, and through the latter to terminal U_2 and the "Up" line.

When it is required to send, by means of the key, the switch s_1 and consequently the levers l_1, l_2, connected to it, are moved to the positions indicated by the dotted lines. On depressing the key, the Zinc pole of the battery becomes connected to a_1, through z coming in contact with a; from a the current passes to lever l_1 through contact point d_{11}, and from thence to terminal 7 and the "Up" line. The "Copper" pole of the battery comes into connection with l_1 through contact point c_{11}, and the spring s_{11}, and thence through l_2 and l_1 with terminal 3 and the "Down" line.

The connections shown are those for an "Intermediate" station. If the apparatus is at an "Up" station, then terminal 7 of the key or terminal U_2 of

ENGINEERING.
FRIDAY, MAY 7, 1880.

VISUAL TELEGRAPHY.

WHEN the telephone became an accomplished fact, and persons were enabled to speak and hear by electricity, it did not require a great effort of imagination to predict the time when light as well as sound would be transmitted to a distance by wire, and images as well as words despatched by telegraph. To transmute into electricity and electricity again into light became the next great scientific problem. Recent rumours from America announce the invention of an apparatus whereby this feat has been performed in America, with all the real prodigies of ingenuity, is yet a hotbed of many abandoneries and "bogus" inventions, we are constrained to take these reports with all reserve. It is stated in the New York papers that a certain Dr. H. E. Ives, of Bethlehem, Pennsylvania, has invented an instrument called the "disphote," which has the power of showing, in a mirror at one end, the image of any object placed in front of a corresponding mirror at either end. These mirrors are composed, the one of selenium and chromium, the other of selenium and cells of silver—selenium is very sensitive to light and heat. Each mirror is, moreover, built up of a number of small plates, and the corresponding couples are connected by separate wires. The receiving mirror is placed in a camera, and receives from a lens the pictures of any desired object. The varying gradations of light and form falling on the plates of the mirror set up variations in the electrical currents traversing the connecting wires. These variations cause changes in the plates composing the reproducing mirror, which thereupon exhibits an image of the object. A public exhibition of the instrument is said to have been held at Reading, in the United States, and the images of various simple objects, such as a penknife, an apple, a watch, a collar, a printed handbill, and letter still, the head of a live kitten, were transmitted from a room below to the hall above, where they were rendered visible to an enthusiastic audience.

This rumour—and we do not require to be told that all the rumours of the New York papers are not to be taken as literal truth—has it appears some foundation in the fact that Professor Graham Bell, the famous inventor of the earliest speaking telephone, despatched some time ago with the Franklin Institute, U.S., a sealed packet containing a description of a new apparatus which has to do with the problem in question. Professor Bell's results are said to be due to his work in England during his visit here in 1878, so that our own country both is providing the men and the scene of his labours, will be fully entitled to the honour of the discovery whatever it may be, although it is first published in America.

The gossip about Professor Bell has called into publicity several theoretical plans and experimental attempts which have been recently devised and carried out by English men of science. One of these, originated a few years ago by Professor Perry and Ayrton, takes advantage of the well-known photo-electric properties of selenium. It was we believe first demonstrated by Professor Adams and Mr. Day that when a ray of light falls upon a piece of crystalline selenium a current of electricity is set up in the metal; and this effect has been closely studied by Mr. Willoughby Smith and Mr. R. Sabine. The transmitter of Messrs. Perry and Ayrton, based upon this fact, consists of a mirror made up of a mosaic of little squares of selenium, insulated from each other, and each connected with a separate telegraph wire. An image of the object to be "telephoted" is focussed on the mirror by means of a lens, and the resulting current started in each square of the mirror by the portion of the image falling on it is transmitted by the corresponding wire to the distant station. Here it is made to pass through a coil of wire and deflect a magnetic needle, the motion of which opens or closes an aperture allowing light to fall on the back of a sheet of frosted glass. There are supposed to be as many illuminated squares at the receiving station as there are selenium cells at the transmitting station, and the amount of light admitted to each square of glass is to be proportional to the strength of current, which in turn is proportional to the intensity of the light falling on the corresponding square of selenium. Thus the illuminated image at the receiving station would be to a certain extent a reproduction of the original image.

Professors Perry and Ayrton also suggest an application of Mr. Kerr's experiments on the distortion of the plane of polarised light by reflection from the polished poles of a magnet. The cousins in making the receiving mirror a mosaic of soft iron pieces, silvered, and causing the current from each selenium square to flow in a fine coil round each piece so as to magnetise it. This mirror is to be illuminated by a beam of light polarised by reflection from glass, and after being reflected from the mirror, the beam is to be received again on a glass mosaic corresponding to each selenium square by magnetising the corresponding soft iron square, rotates the beam of polarised light, and alters the intensity of the analysed light to an extent proportional to its strength. Here again, then, we have a mode of reproducing an imitation of the original image.

Both of these plans, though undoubtedly ingenious, and to a certain extent theoretically feasible, are yet too elaborate and expensive to be practicable. Moreover, the reproduced image would at best be but a clumsy sketch of the original one. Professor Bell's plan is probably much simpler, if we may judge by the simple means with which he effected the electric transmission of speech, and the scientific world will now await with great interest the publication of it.

One way of simplifying the problem would be to find out a way of transforming electricity directly back into light again, by the principle of reproduction which operates in nature and has been so extensively applied of late in the construction of scientific apparatus. If a beam of light falling on a mirror of selenium is transformed into electricity, why should not that electricity be as simply turned back again into light by a polyscope, not a mechanical process. A means of doing this would get rid of the necessity for complex receiving instruments like that of Professore Ayrton and Perry. Has any one ever tried to evoke light from selenium by an action the very contrary to that by which electricity is set up in it under light? This is another experiment well worthy of trial.

Another plan for transmitting light is that proposed by Mr. H. Middleton at a meeting of the Cambridge Philosophical Society on March 8. It is based on thermo-electric effects. The image to be sent is thrown by a lens on a mirror enclosed in a camera. This mirror consists of thermo-electric pairs, polished on their front surfaces and connected by separate wires to a second thermo-pile similar to the first at the receiving station. The image sets up thermo-electric currents in the mosaic of pairs, and these are reconverted into a similar image on the face of the receiving pile. Moreover, according to the manner in which the elements of the plates are arranged with respect to each other we can get a "positive" or "negative" photograph or image. The images thus produced may further be viewed directly, projected on a screen, or rendered permanent by photography. Full details of Mr. Middleton's method will, we believe, appear in an early number of the Cambridge Philosophical Society's proceedings.

The particulars of still another step in this direction of research were communicated to the Physical Society at its late meeting on Saturday, April 24th. For two years Professor Mitchin has been engaged in the transmission of light by means of the electric current produced by the action of light on certain sensitive photographic salts. Professor Mitchin prepares a small photo-chemical cell of two silver-foil plates immersed in a conducting solution of salt and water. One plate is rendered sensitive to light by coating it with an emulsion composed of chloride of silver. When a beam of magnesium light is allowed to fall on the sensitised plate of this cell, a current of electricity is observed to flow through the cell from the uncoated plate to the coated one. Bromide of silver was also used for the sensitive salt with like effect; the conducting liquid in the cell being in that case a solution of bromide of potassium.

The current thus set up is due to the photo-chemical action of the light on the sensitive plate; and Professor Mitchin also demonstrated that it could be made to effect a corresponding photo-chemical action on a second plate in a second receiving cell at a distance, but in circuit with the first or transmitting cell. He conducted the current thus obtained by means of wires to a second chloride of silver cell kept in the dark, and on developing the sensitive plate of the latter by means of pyrogallic acid, found it to exhibit a darkened surface due to the transmitted light. Professor Mitchin is still prosecuting these researches, and has procured a number of cells for the purpose, as well as a cabin containing a corresponding number of metallic conductors to isolate them from each other, to convey the currents from the separate cells. The currents originated by the photo-chemical action is considerable; the weak light from a match being sufficient to produce a decided deflection on a mirror galvanometer. Professor Mitchin's experiments are only on the threshold of the subject yet; but they are to be depended upon as far as they go, and are no mere theoretical schemes; moreover, the photographic method would have the advantage of yielding permanent portraits.

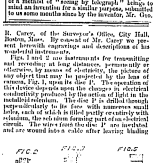
Guy Mitchin

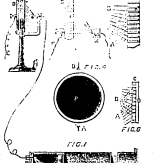
SEEING BY ELECTRICITY.

THE art of telephoning has already reached a point at which electric engineers is now at hand, the same state of advancement that the art of telegraphing by telephone had attained in 1876, and it remains to be seen whether it will develop as rapidly and successfully as the art of telephony. Professor Graham Bell deposited a sealed packet at the Franklin Institute a sealed description of a method of "seeing by telegraph." Extracts are sealed an invention for a similar purpose, submitted to us some months since by the inventor, Mr. Cox.

R. Cover, of the Surveyor's Office, City Hall, Boston, Mass. By means of Mr. Cover we yesterday received drawings and descriptions of his wonderful instruments.

Figs. 1 and 2 are instruments for transmitting and receiving at long distances, permanently or otherwise, by means of electricity, the picture of any object that may be projected by the lens of camera, Fig. 1, upon the disc P. The operation of the instrument depends upon the variations in conductivity produced by the action of light in the metallic selenium. The disc P is drilled through perpendicularly to its face with numerous small holes, each of which is filled pretty accurately with selenium, the whole then forming part of an electrical circuit. The wires from the disc P are insulated and are wound into a cable after leaving binding





screw B. These wires pass through disc C (Fig. 8, in the receiving instrument at a distant point, and are arranged in the same relative position as in disc P (Fig. 1).

A chemically-prepared paper is placed between discs C and P, and the image of any object presented to the camera is thrown upon the paper (Fig. 3 is a sectional view of Fig. 5, showing wires and the chemically-prepared paper).

Fig. 6 is a sectional view of disc P (Fig. 1) showing platinum points and conducting wires.

Fig. 4 is a sectional view of another receiving instrument, in which the chemically-prepared paper is dispensed with, there being a vacuum between glass disc D and insulating plate or disc C.

Note.—Points are numbered inconsistently in the

Teléfonos.—Se encuentran entre nosotros los señores W. F. Clark y José D. Husbande, directores de la compañía Telefónica de los Estados Unidos de Norte América.

El objeto de su venida es el procurar establecer algunas líneas telegráficas.

Anoche se hizo un ensayo del teléfono, comunicando el cuartel jeneral de bomberos, situado en la calle del Puente, con el de la 5.ª compañía, Arturo Prat, que está situado en la Alameda, donde un mesón de vino.

Este ensayo se hizo a presencia de numerosas personas, reuniéndose tanto en el cuartel jeneral como en el de la 5.ª compañía.

Se conversó y se cantó, el tocó una corneta en este último lugar, reproduciéndose en el cuartel jeneral la voz y los sonidos de la manera mas perceptible aun para las personas colocadas a mayor distancia del teléfono.

Esperamos ver muy luego planteado entre nosotros esta útil invención, adoptada ya por el comercio de Valparaíso y que la trae tan oportunos y rápidos resultados.—(NUEVA ERA.)

El teléfono.—Hemos tenido ocasion de presenciar anoche una nueva ensayo de este asombroso descubrimiento de la ciencia moderna.

La oficina central trabajando [illegible] de esta ciudad, puesta en comunicacion con [illegible] oficina correspondiente de Santiago, fué el lúcido [illegible]

Asistieron esas personas, entre las cuales estaba el señor ministro de los Estados Unidos.

El señor Husbande, ajente de la sociedad telefónica, se hallaba en la oficina de Santiago, a donde habia ido con el objeto de practicar el grandioso esperimento.

Puestas en juego ambas oficinas por unos cinco minutos, se oyeron [illegible] los esperimentos con singulares peculiaridades, pues, segun se habia de oir, el tono de la música era perfectamente recojido.

El señor Bolton, jefe de la oficina de Valparaíso, habló con el jefe de la oficina de Santiago. Al oir las primeras palabras que este le dirijió, reconoció su voz y le hizo notar que estaba ronco; a lo que le contestó el colega que efectivamente hacia dias que se hallaba resfriado. Habló despues con los demas, y todos lo reconocieron por el dueño de su voz.

Dijo Valparaíso: «Oigo una pequeña orquesta de música, y de Santiago contestaron que no oia tan siquiera un solo.»

Santiago cantó el señor Husbande una bonita canzoneta, y en Valparaíso fué oida perfectamente.

Puesta en correspondencia la oficina de Valparaíso con la central, se comunicaron con la mayor claridad. Una señora cantó el himno del *Invador* en esta oficina, y todos los concurrentes de la Trasandina pudieron gozar con asombro de esta dulce melodía.

En una palabra, el ensayo ha sido completo, y no cabe duda alguna acerca de la perfección de los aparatos, de la electricidad, el inventor Edison, y también [illegible] propagador el señor Husbande, a quien Chile debe un voto de gracias por la introduccion de tan maravillosa [illegible]

[illegible] [illegible] [illegible] [

Teléfonos.—Se encuentran entre nosotros los señores W. F. Clark y José D. Hoskinsha, directores de la compañía Telefónica de los Estados Unidos de Norte América.

El objeto de su venida es el procurar establecer algunas líneas telegráficas.

Anoche, en vista un ensayo del teléfono, comunicando el cuartel jeneral de bomberos, situado en la calle del Puente, con el de la 5.ª compañía, Arturo Prat, que está situado en la Alameda, donde un ensayo semejante.

Este ensayo no hizo a pesarnos de numerosos personas, reunidas tanto en el cuartel jeneral como en el de la 5.ª compañía.

Se conversó y se cantó, si todo una concreta en este último lugar, reproduciéndose en el cuartel jeneral la voz y los sonidos de la manera mas perceptible una para las personas colocadas a mayor distancia del teléfono.

Esperamos ver muy luego planteada entre nosotros esta útil invención, adoptada ya por el comercio de Valparaíso y que la dado tan ventajosos y deseos resultados.—(NOVEDADES.)

El teléfono.—Hemos tenido ocasion de presenciar anoche un nuevo ensayo de este admirable descubrimiento de la ciencia moderna.

La oficina central telegráfica compañías de esta ciudad, puesta en comunicación telefónica con la oficina telegráfica de Santiago, fué el lugar designado para el ensayo.

Asistieron como personas, entre las cuales se encontraban el señor Bolton, jefe de la oficina de Valparaíso, el señor Hosbando, inventor del teléfono, el ayudante de la oficina de Santiago, a donde habia ido con el objeto de presenciar el grandioso esperimento.

Puestas en juego ambas oficinas por una hora de cuatro ochenta millas, empezaron los esperimentos con singulares resultados. Se oyó perfectamente la palabra de cada uno de los interlocutores; la música con perfecta claridad.

El señor Bolton, jefe de la oficina de Valparaíso, habló con el jefe de la oficina de Santiago; al oir las primeras palabras que este le dirijió, creyendo oir ver la voz de Hosbando que estaba cerca, rozó a lo que le contestó su colega que efectivamente hacia dias que era de nuestra residencia. Habló despues con los empleados, y tambien lo reconocieron por el dueño de su voz.

D. de Valparaíso se cantó una pequeña copla de mitico, y de Santiago contestaron que se oia una toda claridad. Desde Santiago cantó el señor Hosbando una bailadora perfectamente.

Puesta en comunicación la oficina de Valparaíso con la central, se comunicaron con la mayor claridad. Una señora cantó el vaterre del Trovador en esta oficina y todos los concurrentes de la Tesorería pudieron gozar con aquella dulce melodía.

En una palabra, el ensayo ha sido completísimo, con resultados dignos para el mas grande entusiasmo por el teléfono, de la electricidad, el inventor Edison, y tambien para los americanos, especialmente el señor Hosbando, a quien Chile debe un voto de gracias por la introducción de tan maravilloso descubrimiento.

Ya se encuentra concluido por los señores Clark y Hosbando, el contrato celebrado con el gobierno de Chile, para establecer líneas telegráficas entre Santiago, Valparaíso, Mendoza y los Andes y demás ciudades intermedias.

Debemos advertir que el Norte no se halla particularmente dotado, a causa de los innumerables accidentes que ofrecen sus líneas telegráficas, y que mas inmediatamente nos interesa, por ser nuestro centro de relaciones comerciales.

Lo veremos a repetir: el señor Hosbando, cuyo entusiasmo por su noble profesion es sino con la mas completa satisfaccion para con el público que lo reconoce, merece un voto de aplauso.

Es la flor de los yankees: sabe que es portador de un gran elemento de civilizacion, y no escatima en los gastos para difundirlo en su pais que el oro digan donde a la gran nacion! Es menos de dos y medio la colocacion en Valparaiso ciento, cuatro aparatos telefónicos, y ahora la oficina de Santiago, Quillota, Limache, Viña del Mar, Quilpue, Casablanca, Melipilla, Talagante, Isla de Maipo, con la seguridad de que la capital no quedará en zaga de Valparaiso.

De desear seria que, no satisfecho el enviado del señor Intendente, para que publicase palabras las ventajas que reportará el buen servicio público que el palacio presidencial esta hace en comunicacion telefónica con la correspondencia. A cualquiera hora del dia o de la noche podria el gobierno dar o recibir noticias, ordenes, instrucciones, pudiendo por consiguiente mayor ajilio que el que podrian obtenerse en un telégrafo diario.

Teatro

Ayer ha sido firmado el contrato por el cual el señor Bolton, jefe de la oficina de la república, el privilejio exclusivo concedido al señor don José D'Hosbando, director representante de Edison, de Estados Unidos i autor i dueño del descubrimiento del teléfono.

Pronto se establecerá en Santiago una oficina para atender a los muchos pedidos de colocacion de teléfonos que el comercio de la capital tiene hechos al director, pues creemos con tanto el gobierno como los particulares se apresurarán a utilizar, tan útil i valiosos descubrimiento que está llamado a revolucionar en el telégrafo i a operar un trascurso favorable a las rápidas comunicaciones en los centros comerciales de la república.

feneral to. They had no doubt whatever on the subject themselves, that it would be for the mutual advantage of both companies, and they hoped by this means that they would command all the telephones known and patents, or the most important of them, in the new United Country all their property and the shareholders to give their assent to the resolution. Mr. Crisp (the secretary) would explain the agreement. It was a novel kind of resolution. The enterprise of that kind of having unity of administration was the importance in an undertaking. He had in themselves very valuable elements—most valuable to them. The Board, especially the chairman, had devoted considerable time and energy to the consideration of the agreement, and they believed they had made a bargain which was fair to all, and to be satisfactory to both sides, inasmuch as it was a fair one, and recognised the value of the property of both companies. He believed they were unanimous in recommending it to the cordial approval of the shareholders.

Mr. Crisp said he might state that the general effect of the agreement was that the Bell Company on the one hand and the Edison Company on the other would amalgamate in the new United Company all their property and assets with one exception, which he would afterwards mention, for the following consideration—that the Bell Company would receive £625,000 in fully paid up shares of the capital of the United Company, and the Edison Company would receive £125,000, also in shares of the United Company. Each company sold its entire assets with this exception—that is effectively that each now in the possession of either company, or any debts due to them, or any moneys in bank or loan calls would not be sold. In the case of the Bell Company there was a considerable sum in their hands which would be applicable either for dividend or for dealing with hereafter. He then explained in general terms such clauses in the agreement, observing in the course of his remarks that the companies which had been formed in connection with Edison now would not have the benefit of the Edison name in agreement with transfer. The new company would take the liability, as the result of the costs of the suits of the action between the Post Office and the two old companies. The Bill of Sale was the day on which the matter was to be completed, but the agreement was to take effect as from the 1st May last. If the matter were not completed before the 30th of June it would fall to the ground. The agreement might be modified from time to time on the Boards of the two companies might decide.

Mr. Hubbard, the late president of the American Bell Company, said that the proportion on which the transfer was to be effected was in the present case 200 to 175. In America the Edison patents were held by the Edison United Telephone Company, who received 20 per cent. of the net profits earned, and stood in the right to use the telephones for their telegraphing business. He explained the manner in which that relationship had arisen and the same in the present case in those on which the Edison Company was taken over in America by the American Company. At night and that in America the telephone was considered as a necessity adjunct to the telegraph system, not as forming part of the telegraph system but as separate and entirely independent, though connected to it.

The Chairman, in reply to further questions, said that no arrangements were made with the Post Office. Negotiations with the Post Office—there was no notice pending with all the telephone companies. A great many negotiations were entered into respecting the subject, and they were continued from month to month, but they had not arrived at what they now saw. They could not accept the terms of the Post Office, as they thought they would "kill" them.

Mr. Carey, also in reply, stated that they were advised that the Post Office had no jurisdiction for their claim. It was provided that whatever arrangement was entered between the Bell Company and district companies, that no action would be taken ége by the United Company.

In answer to Mr. Galsworthy,

The Chairman said that by the amalgamation the subscribers would get the advantage of being able to use both instruments if they chose, and to talk to a great many more people for no more money.

Mr. Galsworthy thought that the whole of the details ought to left in the hands of the Board, who, he felt sure, must have given a great deal of time and attention to the matter. So long as they were not diminishing companies working with apparently the same object but with different means, so long did they prevent the public from deriving benefit from adopting either company, and when there was simply one to come, then in thought the number of subscribers would naturally be immensely increased. He regretted the resolution.

The Chairman, in answer to a shareholder, said that the matter would be brought before the Board if they had given the Edison Company £200,000, and they themselves have only received £125,000. The local was on the other foot. It took some degree of time to work out the matter, but he thought there was room to give the other side the larger sum. The intention as to the new company was to offer the first capital to the shareholders in the old Company and to the subscribers to the central system—the general existences. He then put the motion, and it was carried unanimously.

On the motion of Mr. Galsworthy, seconded by Mr. J. A. Gower, a vote of thanks was passed to the chairman and directors.

The Chairman, in reply, said he, on behalf himself, expressed his acknowledgements, and said that it had not been without difficulty and trouble that all these negotiations had been brought to an end; but the amalgamation of the two companies had been successful, and they would feel themselves amply repaid for their trouble.

Mr. Crisp, in reply to a question, said that a confirmation meeting would not be necessary.

The proceedings then terminated.

THE EDISON TELEPHONE COMPANY OF LONDON (LIMITED).

An extraordinary general meeting was held on the 1st inst. at the offices of Messrs. Price, Waterhouse and Co., Gresham-buildings, E.C., when a resolution agreeing to sell the business, goodwill, and property of this company to the United Telephone Company (Limited), and to empower the directors to carry such sale into effect, was considered.

[The resolution was similar to that referred to in another column as discussed at the meeting of the Bell Company's shareholders.]

two hundredths of a millimetre; the feed, therefore, is practically continuous and causes the light to be proportionally steady.

The pinion into which the wheel, n, gears is not fixed to the wheel, c, but is connected to the latter by a ratchet wheel, so that the rod, x_1, can be drawn up when it is required to insert a new carbon, without turning all the wheels in the train.

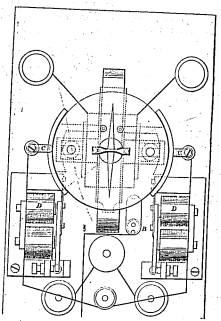
The course of the current through the electro-magnet and carbons is quite simple; thus, the current entering at w_1, passes through the electro-magnet, y_1, direct, thence to the frame of the apparatus and the upper carbon, and from there to the lower carbon and back to the dynamo machine.

The screw, s', when screwed down presses the strap, r, against the brake-wheel, s, and prevents it from turning; this is only required for security during transport.

Telegraphic Journal Dec. 15 1880

ROGERS' PATENT NEEDLE SOUNDER.

This invention is intended to afford a ready means of converting the ordinary single-needle instrument into a sound-reader at will. A reference to the accompanying illustration will explain the simple and inexpensive way in which this is effected. The local battery terminal is in metallic connection with the pillar, n, which makes a rubbing contact with the dial plate. The ivory pins controlling the play of the needle are removed and replaced by



platinum or silver pins soldered to brass strips at the back of the dial plate, but insulated from it by ebonite or waxed paper, and these strips are in

AN ELECTRICAL SPEED INDICATOR.*

By H. R. KEMPE.

May 15 1880

THE design of a Speed Indicator has often been attempted by various mechanicians, and many ingenious devices have been the result. One of the simplest forms of apparatus for the purpose is constructed on the principle of the governor of a steam engine, in which the angular deviation of the weighted arms represents the speed at which the instrument is turning. Such an instrument has been designed by Messrs. Elliott Brothers. Another form of instrument consists of a vertical glass tube partly filled with oil or coloured liquid, and which is rotated on its axis; the action causes the liquid to rise in the tube, the height to which it ascends representing the velocity.

The scales for such instruments are graduated by trial, and are not always correct under all conditions, as they are dependent to some extent upon variable quantities. It is also necessary that the indications be read at the place where the speed to be measured takes place.

In the instrument which I have to show you this evening the indications given are absolutely accurate under all conditions, as the apparatus is regulated by means of a clock, and, moreover, the instrument can be placed at any distance from the engine or apparatus whose speed it is required to indicate.

It would be impossible without elaborate diagrams to explain the action of the apparatus, but I will point out that the indicating hand points at every minute to the number of revolutions which the machine to which it is electrically connected has made during that minute, and the hand remains stationary at that indication till the next minute, when it advances or recedes according as the speed has increased or decreased during that minute. The apparatus is worked by a step by step motion, which moves a ratchet wheel forward one tooth at a time at each revolution made by the engine, the latter sending a current at each revolution. At the end of a minute the indicating hand is unlocked, and moves through the same angle which the ratchet has been turned through; the hand is then again locked, and the ratchet wheel allowed to run back to zero, when the same action is again gone through.

To prevent errors which may arise from the engine sending currents whilst the indicating hand is being set by means of the clock, an "accumulator" is employed which accumulates all the currents received from the engine during the time the clock is setting the hand; and then, when the latter action is completed and the ratchet wheel returned to zero, the amount accumulated is given

* Read before the Society of Telegraph Engineers, May 12th.

By this device, it happens that the sum of all the indications observed on the dial at each minute, during a number of minutes, will always equal the total number of revolutions given by the engine during that number of minutes."

By fixing a small grooved wheel on the axle of the indicating hand with a cord round it to which a pencil is attached, a record can be made of the speed. The size of the sheet of paper on which the indications are drawn can be made without difficulty of convenient dimensions. It need not exceed a size of about two feet by one foot, for indications given during twenty-four hours. On this diagram a line will be traced which will be straight if the engine is working uniformly, and wavy if the speed is irregular, the amount of the deviation showing at once the rate of increase or decrease in the speed.

The uses to which the apparatus, which is shown in front and back view by figs. 1 and 2, can be applied, are obviously numerous. It can be used for indicating the rate at which the paying-out drum of a cable ship is turning, the indicator being placed in the engineer's cabin; the rate at which the ship's engines are working can similarly be indicated.

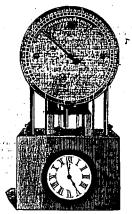


FIG. 1.

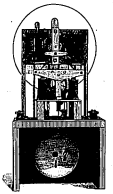

FIG. 2.

The lines of telegraph in the United States are reported as rapidly that it is difficult, even for their owners, to state the aggregate quantities at any particular time.

The best information, however, which can be obtained is that on the 1st of January, 1880, there were 112,642 miles of telegraph lines in the United States, and 280,858 miles of wire, without counting those lines specially used by the Gold and Stock Telegraph, and the District, the Fire Alarm and Burglar Alarm Telegraphs in the various cities.

One telegraph company alone, the "Western Union," had, in June, 1879, 8,501 offices, from which were sent and received 29,070,108 messages during the preceding year.

Equally prompt has been the application of the telephone, which, looked upon doubtfully, or only as a toy, when it was first shown by Professor Bell at our Centennial Exhibition four years ago, has so rapidly become a necessity, that there are now in this country 121,000 instruments at work, connecting our business places and dwellings with each other, and with the central offices, by means of which we are almost instantly brought within speaking distance of the persons miles away, with whom we have to transact our business.

You are so familiar, however, with the telegraph and telephone, that it may be more interesting to you to call your attention to some of the house uses of electricity which are becoming part of our common life. Within the last few years we have been introducing electricity into our houses, and virtually make of it a new domestic servant, by what are called the burglar and fire alarm systems; not only does it ring bells, and summon the other servants (and in recent appliances, keep these bells ringing until the summons are answered), but as a burglar alarm, it is on the watch at night. Thus a house properly fitted with these contrivances, the whole or any part of which may be attached or detached at pleasure. The windows may be left partly open at top or bottom for ventilation, if desired; and when the servants have turned on, any attempt to alter their position, or to effect an entrance from the outside, causes an alarm, which can be stopped only by the person in charge. A glance at the annunciator determines the position of the burglar, or by pressing a knob at the instrument, it shows what doors or windows are open. To accommodate late comers, the front door can be disconnected, or with a special key it may be opened without causing an alarm. In the absence of the family the bell may be made to ring outside, or in a neighbor's house, or at the Police Headquarters; while the clock that calls the servants in the morning, at any hour desired, disconnects such parts of the house they are allowed to use, so as not to disturb the rest of the family.

Applied to safes in counting houses, or to stores containing valuable goods, the burglar alarm rings the bell at Police Headquarters, and at the same time indicates the point of attack. In a recent case in New York, the burglars, who had broken into a silk house, so promptly set off the alarm that they were surrounded by the police and captured as they were taking the goods down from the shelves. The system is being rapidly introduced in stores, counting and banking houses, and in connection with time locks on the safes, affords such good protection as to make watchmen almost superfluous.

Applied to fire alarm, electricity renders still more important domestic service; not only does it advise all the fire engines located in a particular district, whenever an alarm is sounded from a street corner, but it sets machinery at work which unbitches the horses from their stalls, wakes up the firemen (and tumbles them out of bed in some cities), harnesses the horse, lights and fires, and opens the doors of the engine house, so that the machine is ready to start in eleven or twelve seconds after the alarm is sounded; but the fire alarm is also extended to private houses, and there presents itself in the shape of three unobtrusive knobs. Push the first and you summon the fire department; touch the second and a police officer makes his appearance; press the third and a messenger comes to run your errands. Moreover, by means of the pyrostat, should a fire break out during your absence, the expansion of a metallic bar makes an electrical connection which sets off the alarm and summons the fire engine.—*O. Chanute.*

PRINTING TELEGRAPH INSTRUMENTS ON LONG CABLE CIRCUITS.

By R. G. Brown,

Engineer and Electrician Societe Generale des Telephones, Paris, France.

The accompanying diagram represents something new in the way of working printers on long cable circuits which may prove interesting. I saw the system in operation a short time since while stopping at Marseilles. It is the invention of the late Mr. Allhand, formerly Inspector General of Telegraphs at Marseilles. The French Telegraph administration have been experimenting in the matter between Marseilles and Algeria for the past two years, and the present arrangement, although not perfect (it being about two sensitive) is considered the best that has yet been tried.

Polarized relays and Hughes's printers are used in connection with a transmitter formed of a revolving arm and metallic segments, as shown at H in the diagram. The arm, which consists of a steel spring, is joined to the shaft of the printing apparatus so as to revolve with it, and is thus made to press one after the other against each of the five divisions into which the disk is cut. The portion a is connected to a callend battery of 8 or 10 cells, b to a negative battery of 6 or 7 cells, and l is insulated. The segment d makes metallic communication with earth through the resistance R, E is joined to a sensitive galvanometer also to earth. The printer shaft makes one revolution for each signal, bringing the arm successively in contact with each of the divisions. By this means a positive current of a certain strength is first sent into the cable. This is immediately followed by a negative current somewhat weaker.

the party proceeded to Chester Park, where Mr. George N. Stone had the famous Vanderbilt Mansion, brought out and exercised for the entertainment. After the exhibition Captain Stone led the party into the Chester Park Club House, where additional refreshments were had, when they again took their carriages and were driven through Clifton, Walnut Hills, and other suburbs, finally entering Eden Park. After being driven through those beautiful grounds they arrived at the Island House.

Here a meeting was organized with Mr. James Hoyt, of New York, as Chairman, and Mr. F. Lovejoy, of Cincinnati, as Secretary. After speeches by Messrs. Reid and Armstrong, the meeting proceeded to business, Col. L. C. Waltz making the motion that a committee of five be appointed to consider and report a plan for forming a permanent organization. The motion prevailed, and Col. Cleevey, of Dixie, was made Chairman of the committee, with the following named gentlemen as members: Superintendent E. P. Wright, of Cleveland, Superintendent Booth, of Mansfield, Superintendent J. J. Dyer, of Chicago, and Col. L. C. Weir, of Cincinnati.

The committee consisting of J. H. Logan, of Grit, corresponding secretary of G. M. Dugan, of Memphis, Tenn., G. Matteson, of Meridien, Miss., S. B. Shaw, of Nashville, J. W. Tillingham, of Buffalo, N. Y., R. Booth, of Evansville, Ind., H. E. Doolittle, of Dayton, Ind., J. F. Wallick, of Indianapolis, Ind., A. Burnett, of Buffalo, N. Y., W. O. Fuller, of Indianapolis, Ohio, W. W. Kelchner, of Springfield, Ohio, T. M. Keenan, of Seymour, and Charles Wilson, of Memphis, Tenn., were appointed to draft suitable resolutions thanking the Cincinnati Press Club, the press, and their friends for the hospitable manner in which the old time telegraphers had been received and entertained. Both committees were instructed to report at an adjourned meeting to be held at half past seven o'clock in the evening.

The party then returned to the city to prepare for the banquet.

Shortly before eight o'clock P. M., the party reassembled in parlor 12 of the Burnett House, and was called to order by Mr. J. D. Reid.

Mr. Clowry, of Chicago, presented a resolution that a committee of three be appointed to prepare a constitution and Code of By-Laws for the Society, to be known as the "Old Time Telegraphers' Association." This was adopted, and Messrs. R. G. Clowry, "J. S. Wilson and E. P. Wright, the Committee on Permanent Organization, submitted their report as follows:

"Cincinnati, September 7, 1880.

Mr. J. D. Reid, Chairman Old Time Telegraphers' Association: Your Committee on Permanent Organization has the honor to report for the consideration of the meeting the names of the following gentlemen for permanent officers of the "Old Time Telegraphers' Association": For President, R. Booth, of Mansfield, Ohio; for Vice-President, George M. Dugan, of Jackson, Tenn.; for Secretary, G. Matteson, of Cincinnati, Ohio; for Treasurer, J. Armstrong, of Cincinnati, Ohio."

This was with unanimous approval, and Mr. Reid was escorted to the chair, which he accepted in a few appropriate remarks. He at once appointed Messrs.

IRON WIRE FOR TELEGRAPHS.*

In the very early and palmy days of electric telegraphs materials for the construction of the lines were bought regardless of cost, but of the best quality; foreign timber was used in poles, and charcoal iron wire for the conductors. As competition arose prices were reduced rather recklessly, without any careful specification. The consequence was that wire of such inferior mechanical quality crept into use that it would not stand the strain caused by snowstorms. The wire, tightened by the contraction from low temperature and loaded by snow, broke the last straw put on its back when a gale of wind occurred. In writing the specification for the mechanical qualities, experiments were made on the conductivity of different qualities of wire, and it was found that considerable difference existed in this respect, a foot which, as regards copper - had been previously found out and provided for. Careless welds, too, were found to be a great source of breakage. The specification of the wire for the Post Office Telegraphs is now a somewhat elaborate affair. The wire must gauge within 2½ per cent. of the specified gauge, must be made from charcoal puddled bars, must stand so many twists in six inches before breaking, must have a certain tensile strength, be of a certain length without any weld, and not give more than a certain electrical resistance per statute mile. A regular table, stating the amounts of each of these qualities for the different gauges employed, is given in the printed specification.

In the same way the Indian Government has a special specification for the wire required for the Indian telegraphs. This specification, up to within about a year and a half ago, though very stringent as regards mechanical qualities, did not specify the electrical resistance, but this was at about that date supplied. The price now paid, therefore, for telegraph wire for those Government land lines is very much greater than it was before those rigorous specifications were issued, and the cost is about the same now as it was for the earliest lines, whilst at one time, intermediate between those periods, wire, cheap and bad, was supplied for about half the present cost.

The colonial telegraphs, where extensions are rapid, consume a great deal of wire, and most of the colonies follow the Post Office specifications. The English railway companies require a little wire yearly for repairs and extensions, but their specifications are not generally as rigorous as that of the Government.

For the external covering or armour of submarine telegraph cables a large quantity of wire is yearly consumed by the manufacturers, such as the Telegraph Construction Company, the India Rubber, Gutta Percha, and Telegraph Works Company, Messrs. Siemens Brothers, and Henley's Telegraph Works Company. The Telegraph Construction Company alone in one year made about 6,000 miles of telegraph cable, which would probably represent about 7,000 tons of wire.

For submarine cable wire a very different class of wire is used from that used for land lines. For deep sea work the wire known as homogeneous iron is largely used, and for the types of cable known as intermediate and shore ends iron wire known in the trade as "BB" is used. The engineers who draw up the specification for the telegraph companies specify the breaking strain of the homogeneous wire, but scarcely ever give any other specification for the wire than the very rough one of "BB." No tensile strength or twists to prove ductibility or elongation are mentioned for this wire. The manufacturers themselves make a few tests, but their principal test in practice is the time that the covering machines will run without a wire breaking. For this wire foreign competition has for a considerable time interfered largely with our Lancashire wire drawers. Thousands of tons come yearly from Germany to the banks of the Thames at a price which it is impossible for our English firms to quote. This is partly due to the cheaper labour in Germany, but also to the price which it is required to pay in this country for the wire can be brought from Cologne to the Thames for about ten shillings per ton cheaper than from Manchester or Warrington. It is also a curious fact that the carriage for wire from Lancashire to London for export is about half the price that it is for wire brought to London for manufacture, and it would appear to us that if it is the interest of the railway companies to bring wire cheap to London for export, it should also be their interest to bring it cheap to the banks of the Thames for manufacture into an article which is exported as soon as it is made. If the price of carriage was thus reduced, it would be, perhaps, possible for our English firms to compete with the Germans, and the railway companies would obtain the carriage of thousands of tons of wire from Lancashire to London which they at present lose. As it is, the wire trade is leaving the country, so far as the submarine cable business is concerned, and this forms a considerable item in the whole trade.

IRON WIRE FOR TELEGRAPHS.*

In the very early and palmy days of electric telegraphs materials for the construction of the lines were bought regardless of cost, but of the best quality; foreign timber was used in poles, and charcoal iron wire for the conductors. As competition arose prices were reduced rather recklessly, without any careful specification. The consequence was that wire of such inferior mechanical quality crept into use that it would not stand the strain caused by snowstorms. The wire, tightened by the contraction from low temperature and loaded by snow, broke the last straw put on its back when a gale of wind occurred. In writing the specification for the mechanical qualities, experiments were made on the conductivity of different qualities of wire, and it was found that considerable difference existed in this respect, a foot which, as regards copper - had been previously found out and provided for. Careless welds, too, were found to be a great source of breakage. The specification of the wire for the Post Office Telegraphs is now a somewhat elaborate affair. The wire must gauge within 2½ per cent. of the specified gauge, must be made from charcoal puddled bars, must stand so many twists in six inches before breaking, must have a certain tensile strength, be of a certain length without any weld, and not give more than a certain electrical resistance per statute mile. A regular table, stating the amounts of each of these qualities for the different gauges employed, is given in the printed specification.

In the same way the Indian Government has a special specification for the wire required for the Indian telegraphs. This specification, up to within about a year and a half ago, though very stringent as regards mechanical qualities, did not specify the electrical resistance, but this was at about that date supplied. The price now paid, therefore, for telegraph wire for those Government land lines is very much greater than it was before those rigorous specifications were issued, and the cost is about the same now as it was for the earliest lines, whilst at one time, intermediate between those periods, wire, cheap and bad, was supplied for about half the present cost.

PRINTING TELEGRAPH INSTRUMENTS ON LONG CABLE CIRCUITS.

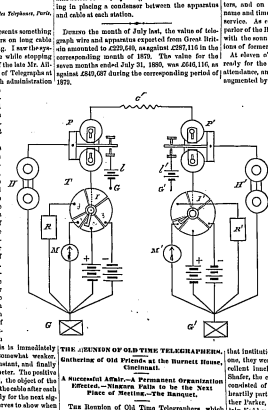
By R. G. Brown,

Engineer and Electrician Société Générale des Téléphones, Paris, France.

The accompanying diagram represents something new in the way of working printers on long cable circuits which may prove interesting. I saw the system in operation a short time since while stopping at Marseilles. It is the invention of the late Mr. Abband, formerly Inspector General of Telegraphs at Marseilles. The French Telegraph administration have been experimenting in the matter between Marseilles and Algeria for the past two years, and the present arrangement, although not perfect (it being most too sensitive) is considered the best that has yet been tried.

Polarized relays and Hughes's printers are used in connection with a transmitter formed of a revolving arm and metallic segments, as shown at T in the diagram. The arm, which consists of a steel spring, is joined to the shaft of the printing apparatus so as to revolve with it, and is thus made to press one after the other against each of the five divisions into which the disk is cut. The portion a is connected to a called battery of 9 or 10 cells, b to a negative battery of 6 or 7 cells, and 1 is insulated. The segment 2 makes a positive connexion with earth through the resistance R. 3 is joined to a mirror galvanometer also to earth. The printer shaft makes one revolution for each signal, bringing the arm successively in contact with each of the divisions. By this means a positive current of a certain strength is first sent into the cable. This is immediately followed by a negative current somewhat weaker. The cable is then insulated an instant, and finally put to earth through the galvanometer. The positive battery alone produces the signal, the object of the negative being simply to clear out the cable after each positive impulse, and leave it ready for the next signal. The mirror galvanometer serves to show when the clearing has been properly done. If it marks the presence of a current, one or the other battery, or the resistance R, must be changed until the needle is no longer deflected when the compensation is known to be right. The connections are so arranged that the polarized relay at the home station is not affected by the sending current, but responds promptly to the received current from distant station. It is said that a battery of low resistance is required.

More recent experiments have been attended with still better results, by a slight modification consisting in placing a condenser between the apparatus and cable at each station.



During the month of July last, the value of telegraph wire and apparatus exported from Great Britain amounted to £220,540, as against £287,116 in the corresponding month of 1879. The value for the seven months ended July 31, 1880, was £956,116, as against £849,687 during the corresponding period of 1879.

THE REUNION OF OLD TIME TELEGRAPHERS.

Gathering of Old Friends at the Burnett House, Cincinnati.

A Successful Affair.—A Permanent Organization Effected.—Niagara Falls to be the Next Place of Meeting.—The Banquet.

The Reunion of Old Time Telegraphers, which has occupied the attention of past and present members of the telegraphic fraternity for some months, took place at Cincinnati, Ohio, on the 7th inst., and was highly successful in every respect. Many who were expected, and who intended to be present, through the exigencies of business were compelled to be absent, but notwithstanding, the gathering was a notable one, and all who were so fortunate as to participate felt that it was good to be there.

The morning was cool and refreshing. Delegates were present from all sections of the country. The Burnett House had been selected as the headquarters, and on arrival each delegate registered his name and time and place of entering the telegraphic service. As early as eight o'clock A. M. the large parlor of the Burnett House was well filled and lively with the sound of fraternal greeting as the company, sons of former years met and saluted each other.

At eleven o'clock A.M., when the carriages were ready for the drive, seventy-five delegates were in attendance, and later in the day this number was augmented by the arrival of some fifty others. The services of fifteen carriages and the immense coach "Highland Chief" barely sufficed to furnish needed accommodations for the company.

After leaving the Burnett House the visitors and local representatives, under the polite and skillful guidance of Col. L. G. Weir, hiring self an old time telegraphist, now Superintendent of Adams Express, were driven up Vine Street. Passing the Western Union telegraph office, they were enthusiastically saluted by their younger telegraph brethren and sisters, always at every door and window in the huge five story building being occupied. Proceeding up Vine to Fifth, thence to Race Street, the party was driven to Mosebach's brewery, and were shown through the establishment, after which they resumed their journey. Walking up the Bellevue Incline Plane, bowing the carriages at the foot, they soon found themselves of the opportunity to view the city from the platforms surrounding the buildings.

Descending, the party were driven to the Work-house. After inspecting the various departments of that institution, with director Parker as their cicerone, they were escorted to the chapel, where an excellent lunch had been prepared by Miss Mary Shafer, the competent Matron. The lunch, which consisted of a large variety of good things, was heartily partaken of by all of the party. Mr. Luther Parker, director, assisted by Col. Morgan, Captain Kudd and Secretary Thompson, entertained the visitors handsomely, and courteously guided the party through the different departments of the great building. It was curious that at such a place the delegates found in an ample load of blooming roses the means of adding a fresh decoration to the handsome badges they wore.

After bidding their hosts at the Work-house farewell, the party returned to the Burnett House, and at 6 P. M. sat down to the banquet, which was a most elaborate affair, and reflected great credit upon the management of the house. The tables were arranged in the form of a horseshoe, and were loaded down with the choicest viands that the market could afford. Mr. Thomas Clark, of Cincinnati, presided, and at his right sat Mr. Thomas T. Eckert, President of the Western Union Telegraph Company, and at his left Mr. Norvin Green, President of the American Union Telegraph Company. Among the guests at the table were Mr. Jay Gould, Mr. Russell Sage, Mr. Wm. H. Vanderbilt, Mr. Frank Work, Mr. Wm. Orton, Mr. Edward Lauterbach, Mr. Wm. Walter Phelps, Mr. Wm. H. Baker, Mr. Wm. Dowd, Mr. Wm. Wheeler, Mr. Wm. Barnes, Mr. Wm. Hamilton, Mr. Wm. Hoffman, Mr. Wm. Bingham, Mr. Wm. Hunter, Mr. Wm. Bliss, Mr. Wm. Bowen, Mr. Wm. Bell, Mr. Wm. Bruce, Mr. Wm. Cary, Mr. Wm. Cook, Mr. Wm. Cowan, Mr. Wm. Cowper, Mr. Wm. Crane, Mr. Wm. Culver, Mr. Wm. Dickson, Mr. Wm. Dinsmore, Mr. Wm. Dunn, Mr. Wm. Eaton, Mr. Wm. Edwards, Mr. Wm. Ellis, Mr. Wm. Fisher, Mr. Wm. Foster, Mr. Wm. Gamble, Mr. Wm. Gilbert, Mr. Wm. Gilmore, Mr. Wm. Gray, Mr. Wm. Green, Mr. Wm. Hall, Mr. Wm. Hamilton, Mr. Wm. Hanna, Mr. Wm. Hardy, Mr. Wm. Harris, Mr. Wm. Hart, Mr. Wm. Hayes, Mr. Wm. Hedges, Mr. Wm. Hill, Mr. Wm. Hoffman, Mr. Wm. Hopkins, Mr. Wm. Howard, Mr. Wm. Hunter, Mr. Wm. Jackson, Mr. Wm. Jones, Mr. Wm. Kelly, Mr. Wm. Kennedy, Mr. Wm. Kerr, Mr. Wm. Kimball, Mr. Wm. Lamb, Mr. Wm. Lee, Mr. Wm. Lewis, Mr. Wm. Lindsay, Mr. Wm. Lloyd, Mr. Wm. Long, Mr. Wm. Lowe, Mr. Wm. Lyon, Mr. Wm. Mackey, Mr. Wm. Mann, Mr. Wm. Marsh, Mr. Wm. Martin, Mr. Wm. Mason, Mr. Wm. Matthews, Mr. Wm. Maxwell, Mr. Wm. Miller, Mr. Wm. Mills, Mr. Wm. Moore, Mr. Wm. Morgan, Mr. Wm. Morris, Mr. Wm. Morrison, Mr. Wm. Murphy, Mr. Wm. Nelson, Mr. Wm. Nichols, Mr. Wm. Norris, Mr. Wm. Norton, Mr. Wm. Oliver, Mr. Wm. Owens, Mr. Wm. Parker, Mr. Wm. Parsons, Mr. Wm. Patterson, Mr. Wm. Peck, Mr. Wm. Perkins, Mr. Wm. Phillips, Mr. Wm. Pierce, Mr. Wm. Porter, Mr. Wm. Price, Mr. Wm. Quinn, Mr. Wm. Reed, Mr. Wm. Reid, Mr. Wm. Rice, Mr. Wm. Richards, Mr. Wm. Richardson, Mr. Wm. Roberts, Mr. Wm. Robertson, Mr. Wm. Robinson, Mr. Wm. Rogers, Mr. Wm. Ross, Mr. Wm. Russell, Mr. Wm. Sanders, Mr. Wm. Scott, Mr. Wm. Shaw, Mr. Wm. Shepherd, Mr. Wm. Simpson, Mr. Wm. Smith, Mr. Wm. Stanley, Mr. Wm. Stevens, Mr. Wm. Stewart, Mr. Wm. Stone, Mr. Wm. Taylor, Mr. Wm. Thomas, Mr. Wm. Thompson, Mr. Wm. Tilden, Mr. Wm. Tracy, Mr. Wm. Turner, Mr. Wm. Vance, Mr. Wm. Wallace, Mr. Wm. Ward, Mr. Wm. Watson, Mr. Wm. Webb, Mr. Wm. Wells, Mr. Wm. West, Mr. Wm. Wheeler, Mr. Wm. White, Mr. Wm. Williams, Mr. Wm. Wilson, Mr. Wm. Wood, Mr. Wm. Woods, Mr. Wm. Wright, Mr. Wm. Young, Mr. Wm. Zimmerman, Mr. Wm. Zinn, Mr. Wm. Zoller, Mr. Wm. Zook, Mr. Wm. Zumbro, Mr. Wm. Zwick, Mr. Wm. Zwicker, Mr. Wm. Zwinger, Mr. Wm. Zwirner, Mr. Wm. Zwolle, Mr. Wm. Zwoyer, Mr. Wm. Zwyer, Mr. Wm. Zyck, Mr. Wm. Zyer, Mr. Wm. Zyerly, Mr. Wm. Zyers, Mr. Wm. Zyerson, Mr. Wm. Zyerton, Mr. Wm. Zyertown, Mr. Wm. Zyerville, Mr. Wm. Zyerville, Mr. Wm. Zyerville

the party proceeded to Chester Park, where
th George N. Stone had the famous Vanderbilt
, Maud S., brought out and exercised for their
tainment. After the exhibition Captain Stone
ed the party into the Chester Park Club House,
a additional refreshments were had, when the
' again took their carriages and were driven
gh Clifton, Walnut Hills, and other suburbs,
by entering Eden Park. After being driven
ugh those beautiful grounds they arrived at the
stand House.

ere a meeting was organized with Mr. James D.
, of New York, as Chairman, and Mr. F. A.
sterup, of Cincinnati, as Secretary. After
re for Messrs. Reid and Armstrong, the meeting
eeded to business, Col. L. G. Weir making a
on that a committee of five be appointed to de-
a plan for forming a permanent organization.
motion prevailed, and Col. Cleary, of Chicago,
made Chairman of the committee, with the fol-
ng named gentlemen as members: Superinten-
E. P. Wright, of Cleveland, Superintendent
I. Booth, of Mansfield, Superintendent J. J. S.
on, of Chicago, and Col. L. G. Weir, of Cin-
ati.

committee consisting of J. H. Logan, of Griffin,
, G. H. Dugan, of Memphis, Tenn., G. W.
man, of Meridian, Miss., R. B. Shaw, of New
, J. W. Tillinghast, of Buffalo, N. Y., N. R.
h, of Evansville, Ind., H. B. Doolittle, of La-
ite, Ind., J. F. Wallick, of Indianapolis, Ind.,
. A. Burnett, of Buffalo, N. Y., W. G. Fuller, of
ipolis, Ohio, W. W. Kelchner, of Springfield,
T. M. Keenan, of Seymour, and Charles A.
ise, of Memphis, Tenn., were appointed to draft
able resolutions thanking the Cincinnati indi-
ists, the press, and their friends for the hos-
ble manner in which the Old Time telegraphists
been received and entertained. Both commit-
were instructed to report at an adjourned meet-
to be held at half past seven o'clock in the even-

he party then returned to the city to prepare for
banquet.

portly before eight o'clock P. M., the party re-
mbled in parlor 31 of the Burnett House, and
called to order by Mr. J. D. Reid.

r. Cleary, of Chicago, presented a resolution
a committee of three be appointed to prepare a
stitution and Code of By-Laws for the Society,
e known as the "Old Time Telegraphers' Associa-
n." This was adopted, and Messrs. D. C. Clow-
, J. S. Wilson and E. P. Wright, the Committee
Permanent Organization, submitted their report,
llows:

"CINCINNATI, *September* 7, 1880.

'Mr. J. D. Reid, Chairman: Your Committee
Permanent Organization has the honor to report
the consideration of the meeting the names of the
owing gentlemen for permanent officers of the
d Time Telegraphers' Association': For President,
II. Booth, of Mansfield, Ohio; for Vice-President,
gus M. Dugan, of Tennessee, Texas; for Secretary,
C. Mattoon, of Cincinnati, Ohio; for Treasurer,
A. Armstrong, of Cincinnati, Ohio."

is name with unanimous approval, and Mr. Booth
s escorted to the chair, which he accepted in a few
propriate remarks. He at once appointed Messrs.
R. Pliem, of Chicago, Col. R. C. Clowry, of Chi-
o, and E. P. Wright, of Cleveland, as the Com-
ttee on Constitution and By-Laws. The matter
the time and place of the next meeting was then
nsidered, entailing considerable discussion. It
s finally decided to be held on the third Wednes-
y of September, 1881. Nominations for place
re made and Niagara Falls, Cincinnati, Chicago,
Atlanta, Utica, Louisville, Cleveland, and Jeffersonville, Ind., were named. The last fell to Niagara Falls by a vote of twenty-nine. The other cities ranged in this wise: Atlanta, 2; Chicago, 8; Cincinnati, 6; Cleveland, 5; Louisville, 3; Utica, 2; and Jeffersonville, 1.

The question of the eligibility of membership came up, and it elicited quite a warm discussion. Right at the outset the inquiry was made, What was the object of the gathering? Was it a mooting of pleasure, or was it a society the members of which could be continually renewed from the youthful ranks? The general feeling seemed to be in favor of limiting the membership to those who had been engaged in the telegraphing business previous to 1850, and this, it is understood, includes the ladies so engaged. And it was further resolved that all the names on the registration book be the charter membership of the society.

A committee was appointed to attend to the arrangements of the next reunion—J. W. Tillinghast, S. B. Gifford, and E. P. Wright.

Col. L. G. Weir was appointed a committee of one to see after securing the photographs of present and prospective members.

The following resolutions were adopted:

Resolved, That the thanks of the Old Timers assembled on the occasion of their first reunion in Cincinnati, are due and hereby tendered to the local committee of Cincinnati for their untiring energy and perseverance in making the reunion the success it is.

The committee do not wish to individualize, but deem it proper to make special mention of George T. Williams and John C. Mattoon, who have been particularly instrumental in perfecting all necessary arrangements to entertain the Old Timers.

Resolved, That we tender a vote of thanks to the press of Cincinnati—*Enquirer*, *Gazette*, *Commercial*, *Star-Times*—for complimentary notices and other gratuitous advertising, and we also extend our thanks to Luther W. Parker and Col. James C. Morgan, of the Work-house, and to the Burnett House for courtesies extended to the visitors.

A complimentary resolution was also tendered to Capt. Bates for his exhibition of Mond S. at Chester Park.

A picture of Prof. S. F. B. Morse, taken at the time he brought out his telegraph system, was silenced at one end of the parlor, attracted much attention. It is the property of Col. J. J. S. Wilson, of Chicago, and the fact that there are but three instances of the kind in existence was incidentally mentioned.

At the conclusion of the proceedings in the parlor the company adjourned to the dining-room, where the banquet had been prepared.

A superb floral piece graced the dining room, the gift of Adams Express Company. It followed the popular fancy for realistic flower work, and it has rarely been better illustrated. Upon a solid bed of rich blue blossoms eight feet long and four feet wide were placed two railway stations, rails, walls and roads, of sacred flowers, white immortelles for the floors and windows framed by scarlet balsams. Connecting these stations across the silver waves of the W. U. Telegraph, and the keynotes dropped from the wires. In pendant blossoms were the words: "Welcome, Old Timers."

This pretty conceit was due to Mr. Alfred Gaither and Col. Weir.

Following are the names of those present, the date of their entry into service, and their present occupation:

Gen. A. Burnett, 1852, telegrapher.
J. H. Logan, 1849, editor.
J. W. Chaplin, 1849, lineman.
Chas. B. Billings, 1850, operator.
M. J. Waldron, 1848, operator.
A. Heywood, 1851, Superintendent O. & M. Railway.
N. Hecker, 1847, manager.
O. H. Booth, 1852, Superintendent.
Jas. D. Reid, 1845, Superintendent.
E. C. Bush, 1847, broker.
W. G. Fuller, 1858.
S. B. Shaw, 1855, Superintendent N. Y., P. & O. Railroad.
W. H. Mendell, 1857, constructor American Fire Alarm Telegraph.
John Bayld, 1848, operator and railroad agent.
John H. Parnell, 1852, manager.
E. P. Wright, about 1850, Superintendent.
John A. Townsend, 1852, manager.
J. H. Tinker, 1852, Clerk United States Court, Waco, Texas.
Wm. C. Long, 1852, night manager.
James Fenwick, 1852, manufacturer of telegraph instruments.
Gen. T. Williams, 1852, Superintendent.
G. F. Stamm, 1852, chief operator.
C. P. Hammond, 1852, superintendent.
J. C. Hall, 1867, manager.
W. H. Allison, Superintendent of telegraph of L. & N. R. R.
E. W. McKenna, Superintendent of telegraph of Pittsburgh, Ft. Wayne & Chicago.
Phil. Renner, 1865, M. O. T. U. & P. Railroad.
John F. Wallick, 1851, Superintendent.
Dan. G. Hendeles, 1861, chief clerk W. U. T. Co.
L. A. Eaglebee, 1853, division manager of J. M. & I. railroad.
T. W. Keenan, 1853, train dispatcher, O. & M. R. R.
J. C. Wilson, 1852, manager at Union Depot, Indianapolis.
W. H. Marble, 1849, assistant chief operator.
E. N. Smith, 1849, operator.
M. Patten, 1851, manager.
D. H. Bingham, 1852, manager.
John E. Clarke, 1852, operator.
C. D. Thomas, 1858, operator.
Geo. T. Irwin, 1851, assistant chief operator.
W. H. Armstrong, 1850, second assistant bookkeeper.
C. W. McClain, 1852, railroad clerk and operator.
Chas. A. Cromwell, 1852, operator.
W. H. Corey, 1853, manager.
D. J. Willis, 1857, manager.
George Gilliland, 1853, journalist.
J. A. Mattoon, 1851, operator.
L. C. Witt, 1853, superintendent.
C. A. Tinsley, 1853, train manager.
E. H. Gordon, 1854, operator.
T. W. Coolidge, 1859, Superintendent Telegraph Central Southern Railroad.
R. C. Clowry, 1852, General Superintendent.
J. J. S. Wilson, 1852, District Superintendent.
H. B. Doolittle, 1851, manager.
Wm. Rockey, 1853, Superintendent Telegraph.
E. P. Nottnkles, 1851, manager.
E. L. Norrcross, 1855, manager.
Frank C. Jones, 1850, operator.
W. B. Dunn, 1852, operator.
J. F. Mellwain, 1853, operator and railroad agent.
Jas. Gallagher, 1853, operator.
Gen. H. Dugan, 1852, Superintendent Telegraph C., St. L. & N. O. Railroad.
Chas. A. Gwinn, 1860, railroad operator Mississippi Central Railroad.
E. J. Lane, 1853, manager.
Gen. E. Allen, 1847, manager.
E. L. Ryder, 1853, manager.
J. A. Armstrong, 1853, manager.
D. Hudnut, 1853, Superintendent Construction.
B. H. Johnson, 1860, chief operator.
W. H. Russell, 1864, ticket agent.
Jas. H. Cox, 1853, railroad agent and operator.
E. C. Johnson, 1859, Superintendent Police Telegraph.
W. B. Higgins, 1866, Superintendent Telegraph.
A. T. Sewell, 1861, night manager.
W. W. Smith, 1853, manager telephone exchange.
W. H. Johnson, 1866, Superintendent manufacturing.
J. Gus Fuller, 1858, night chief.
Leighton Brooke, 1855, operator.
L. D. Boyles, 1853.
Thomas Whalen, 1854, chief repairer.
W. H. Gardner, 1851.
Geo. J. Goulding, 1850, operator.
Wm. Brown, 1851, operator.
A. S. Ayres, 1855, night manager.
Jules J. Gutridge, 1855, operator.

author of "The Telegraph in America," while
e right was O. H. Booth, Superintendent of the
, & St. L. system of telegraph lines. There were
at 150 gentlemen at the table. During the ser-
of the bill of fare excellent music was furnished
the Cincinnati Orchestra.

llow is the bill of fare:

Sorbette.

Larded Fillet of beef, with Mushrooms.

Champagne.

at Prairie Chicken.

Saratoga Fried Potatoes.

ie. Assorted Cake.

Ice Cream. Cigars.

Coffee.

ad before 11 o'clock the chairman, Col. Weir,
d the gathering to order. Letters of regret were
from a number of leading telegraphers, stating
inability to attend, among them being a very
cross communication from Mr. Chas. Osborne,
d of the Western Associated Press at St. Louis.
Weir then stated that but one regular toast—
egraphy as it was"—had been chosen, it being
ght that it would be too much of an infliction to
ivery one present give his reminiscences of tel-
phy. He then introduced Mr. James D. Reid
e responder.

r. Reid made a very happy response. His
ch at times was intensely humorous, and elicited
of laughter. In an impressive manner he re-
d to the significance of this national reunion of
raphers. They had come from the North, the
h, the West, and the East (at least from as far
Buffalo, if not from New York). They had come
d each other "good-night" After the lapse of
ber year they would meet again at the great
, and, finally, when all earthly reunions were
hey would be hoped, gather on the "immi-
hors" to part nevermore. As he recalled the
of his youth the speaker grew strong in his pa-
but now, he said, his aim was declining low-
the west; his career was nearly run. Still it
great pleasure to him to bring back the days
early experience. The trials he underwent as
intendent years ago were forcibly portrayed,
sketches were given of telegraphers who have
e prominent both locally and nationally. Al-
g to Prof. S. F. B. Morse, he said that he
ed it as one of the honors of his life that he
able to speak of him as his friend. Several
s of illustrious telegraphers were mentioned,
great enthusiasm was aroused by the name of
ran Orton. Said he, "Among the men who did
to elevate telegraphy to its present high stan-
the name of William Orton must always occu-
distinguished place. His is a name no man
an afford easily to forget. His life was a sacri-
e to work to which he gave only success and
tion."

present were greatly affected at the pathos of
Reid's concluding remarks.

e Chairman, after Mr. Reid had finished, feelingly remarked that as the Poet had the last reputation, it was in order to give the Exit "the big
of the horn." He, therefore, called upon Mr. Flanagan, of the *Utica Herald*, to explain how
e that his hair had turned gray.

Flanagan was equal to the occasion. He said
one of his gray hairs could tell a tale, and he

would tell the tale were he sure that the young men present would take warning thereby. Anyhow, he retorted, gray hairs at the meeting were no more prominent than bald heads.

Mr. N. Hecker, of Buffalo, and E. B. Wright, of Cleveland, made short speeches.

W. W. Smith, despite his native modesty, was forced, through the raillery of the Chairman, to make a speech. He, in response, gave some interesting reminiscences of telegraphy, paying a glowing tribute to that eminent telegrapher, now dead, James P. Leonard, of Louisville.

The memory of Mr. Leonard was dwelt in silence.

J. C. Mattoon, of Cincinnati, paid the compliment to Mr. C. Taylor, of Frankfort, Ky., as having originated the idea of the present reunion. A telegram was read from that gentleman expressing his regret at his inability to attend on account of family afflictions. In his telegram Mr. Taylor asked that the deceased old time telegraphers be remembered at the gathering. Mr. Mattoon offered a resolution expressing regret at the enforced absence of Mr. Taylor, which was adopted unanimously.

E. R. Gorton, of Cincinnati, gave a review of the history of the Western Union Telegraph Company. He gave also a humorous description of I. R. Elwood, otherwise and better known as "Uncle Ira."

The rest of the speeches were of an informal character, but all very interesting to those present as illustrating the difference between telegraphy of the present and of the old days.

The assemblage did not adjourn until an early hour in the morning.

The reunion in its entirety was a grand success, and the local Committee are entitled to great praise for their management.

a ready index of the commercial prosperity or otherwise of any country or even locality. It is usually the first affected whether for good or bad. The annual report of the New Zealand Telegraph Department, which, for the present occasion, covers a period of nine months only, owing to the termination of the financial year having changed from the 30th of June to the 31st of March, correspanding with that of the home Government, shows that whereas the revenue for the year was estimated at 80,000l. the nine months' receipts have produced but 53,314l. The value of Government telegrams transmitted during the year amounted to 10,797l. This with subsidies for special wires, private lines, and incidental receipts, brings the total earnings of the department up to 77,767l.

The gross earnings of the department for the year ending 30th March, 1879, were 112,832l. comparing this with the total receipts for the nine months of the present year, a falling off of something more than 20 per cent. is visible. This, it is remarked, is only to be expected during the commercial depression which has so strongly felt throughout the colony. It is, however satisfactory to note that the revenue is again on the increase, showing a revival of trade.

The total number of messages of all codes transmitted during the nine months was 1,058,909, being a proportional decrease, in comparison with the previous year, of 188,432.

For the first time for many years, expenditure of the department exceeds the revenue by 2382—not a very large sum, but still sufficient to mark the extent to which the general depression has affected trade. As this failure in revenue has, however, been very justly regarded as of a temporary character, it has not been thought desirable to in any way reduce the operations of the department, and consequently no change has been made in the office arrangements.

Comparing the number of telegrams transmitted with the number of letters posted during the same period, it appears that the proportion of telegrams to every 100 letters was 14.27 as against 19.64 for the previous year.

The number of money order telegrams dealt with during the nine months was 11,691, representing a value of 46,425l., again showing a slight proportional decrease in comparison with the preceding year, both in messages and value. Wellington stands first as having issued the largest number of orders; then Auckland, Dunedin, and Christchurch in the order named. Referring to a letter which appeared some time since in the London *Times*, describing the facilities afforded by the New Zealand Telegraph Department for the transmission of money, and suggesting that a similar system should be adopted by the English telegraph offices, it is observed in the report that "there is no reason why it should not be adopted wherever a telegraph system exists, nor is there any reason why the same facilities should not be afforded between foreign countries, or between colony and colony. There is no doubt that great advantage would be taken of such a system, while it would prove highly remunerative to the various telegraphic administrations." We fully endorse Dr. Lemon's observations on this subject. Why the British postal department should ignore the advantages of a system of money telegrams is inexplicable. There is no system better qualified for the transaction of such a business, and we hope soon to see it in operation. It is clear that its introduction would be an additional source of revenue to the Telegraph Department, whilst the slight loss which the Post Office Department would incur would be almost inappreciable. In the end it would prove a means of additional revenue to the State, and a great advantage to the mercantile community.

The railway telegraph system connected with the Middle Island railways, a department formerly independent of the Public Telegraph Department, has now been taken over by the Government department.

The system of "urgent" and "delayed" codes, adopted by the New Zealand colonies, now, some two years since, continues to increase in public favour. "The former is taken great advantage of during business hours by the commercial branch of the community, while the latter is made a circulating medium for advices by travellers and trade representatives, and for other matters where a night's delay is of no importance."

Since the 1st of April the word rate on all international telegrams has been introduced into New Zealand and on the Australian cable, but this system does not apply to the messages sent to spare places within the colony, nor to messages between New Zealand and the Australian colonies. During the year, 79 miles of line carrying 83 miles of wire were erected, together with some 800 miles of wire on previously erected poles. The total mileage of line is thus increased to 3038, and of wire to 3933. The number of stations open on the 31st of March was 214. The cost of maintenance per mile of line was 4l. 3s. 1d. for the nine months, against 4l. 9s. 9d. for the preceding year. The nominal strength of the department was 342, against 301 for the previous year. This increase is stated to be owing to the additional stations which have been opened chiefly in the North Island and eleven in the new cadetship, and to the enrolment of cadets, who are being trained for future service in the department. The duplex continues to work with increasing success, and is in use on No. 1 and No. 4 cables, 46 miles each; Wellington to Napier, 231 miles; Napier to Auckland, 349 miles; Wellington to Auckland, 640 miles; Christchurch to Dunedin, 215 miles; with other wires of less length. The new cable from Wanganui to Wakapuaka (the New Zealand terminal station of the Australian cable) was successfully laid and completed on the 13th of February. The total length of this cable is 105.09 knots, and the contract price 24,500l.

Sanitary Amendment Act, 1880

Alarm Telephones.

A Chicago police officer suggests the addition of telephone boxes to the system of alarm telegraphs in use in our cities. In connection with the alarm a reserve force is to be maintained at the stations with wagons and ambulances, and all the paraphernalia necessary for riot or accident. Should a fire, a murder, robbery, or any other crime, the perpetrators of which have escaped, the alarm is to be given to every man in the district by sounding a large bell, which is to be placed upon the roof of the station. Upon hearing this, every officer on duty is to run to the nearest telephone box and correspond with the station; and it is also proposed that they report by the same means every hour, whether anything occurs on their beats or not.

Sanitary Amendment Act, 1880

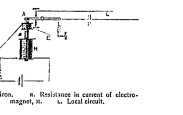
COLONIAL TELEGRAPHS.

The extent to which the recent depression in trade has proceeded may be judged by the fact that in New Zealand, business as exemplified by the telegraph service of that colony, has been affected fully as much as in England. The telegraph service in

VYLE'S RELAY.

To the Editor of THE TELEGRAPHIC JOURNAL.

SIR,—In your last issue, November 15th, a description is given of a new form of relay, invented by Mr. C. C. Vyle, of the Postal Telegraph Department, the idea conveyed being that this form is quite original. Will you allow me to point out that this is scarcely correct, as two years ago I constructed a relay on the same



A. Soft iron. B. Resistance in current of electro-magnet, 80. C. Local circuit.

principles, and worked it on two circuits of 300 and 500 miles respectively, where, for a roughly-made apparatus, it worked exceedingly well, both single and double current. I may mention that the receiving coil was a small one of not more than 20 ohms resistance, showing the extreme sensitiveness of this system. I beg to attach sectional view of the relay, the only distinction between this and Mr. Vyle's being the substitution of electro for permanent magnet.

I am, Sir,
Yours truly,
W. BOLTON.

22, Athelstane Road,
N. Bow, E.

GILBERT'S NEW TELEGRAPH WIRE BINDER.

THE main objects of this Wire Binder, the invention of Mr. Gilbert, of the Dundee and Arbroath Joint Railway, are:—

1st. To facilitate the erection and taking down of telegraph wires.

2nd. To reduce friction at the insulators, and the consequent breakages of the wires which occur with the ordinary wire binder.

3rd. To reduce surface contact of wires with insulators, and thereby to diminish the leakage of current in damp weather.

As will be seen from figs. 1 and 2, which represent respectively the elevation and plan of an insulator with the new binder attached, the latter is of a bow shape. It is constructed of malleable iron, and has its free ends hooked so as to embrace or grip the wire some inches on each side of the insulator. It can be applied to any insulator having a side groove, and by the most inexperienced workman in a few seconds.

M. Wilde a fait usage d'une disposition qui avait été déjà proposée et dont le principe a été appliqué sous diverses formes pour des relais de courant; je ne sais trop quel en est le premier auteur, mais je sais au moins certain que M. Tommasi l'a utilisée presque sous la même forme que M. Wilde dans le relais qu'il a combiné il y a quelque temps. Elle consiste essentiellement en une aiguille aimantée, mobile sur un axe entre les deux pôles contraires d'un électro-aimant, assez-el ayant une dimension aussi grande que la longueur de l'aiguille. Cet agencement avec la disposition que lui a donnée M. Wilde est représenté ci-contre figure 2 en élévation et plan. En regardant le plan on voit que, en supposant que le pôle A de l'aiguille soit Nord et le pôle B de l'électro-aimant Sud, l'aiguille a quatre raisons pour occuper la position AB. Le pôle A est attiré par R, repoussé par S, le pôle B est repoussé par R et attiré par S. Si les pôles de l'électro-aimant viennent à changer, sous l'action de quatre forces analogues, l'aiguille prendra la position CD. Or, les courants qui viennent des bobines d'induction et que la chef Morse envoie dans la ligne étant sans cesse inversés, il s'ensuit que l'aiguille pendant leur passage est animée d'un frémissement qui donne lieu à un bruit très-distinct. Les signaux employés suivant l'alphabet Morse, c'est-à-dire composés de points et de traits, sont donc transmis sous forme de bruits continus, de durée différente, très-faciles à reconnaître.

A bien étudier ce système, on trouve quelques objections qui ne sont pas sans importance, celle-ci par exemple : en supposant au poste central disposé comme il vient d'être dit, comment fera pour répondre le poste correspondant qui ne possède pas de machine génératrice? Il y a des moyens sans doute; il peut répondre avec les courants même de poste central; il peut faire usage d'une bobine de Ruhmkorff, etc.; ces questions accessoires demandent un complément d'étude; mais on peut reconnaître dès à présent au système des qualités très-intéressantes; la disposition est nouvelle, au moins comme réalisation, car je ne sais pas sûr que l'idée n'ait pas été émise déjà. (Mais quelle idée n'a pas été émise depuis quelque temps?) Il y a là un emploi divisé d'une force unique qui semble susceptible d'être très-utile, et cela à l'aide de moyens excessivement simples et peu coûteux.

Je n'espère pas beaucoup voir le système essayé en France où tout serait perdu si l'employé et non l'appareil écrivait les dépêches sous la dictée de l'électricité, mais nous le verrons peut-être appliqué ailleurs avec succès.

FRANK GERALDY.

L'ÉLECTRICITÉ A LA GUERRE

2e article (voir le numéro du 15 septembre 1880).

Les applications de l'électricité à la marine qui me restent à citer sont de moindre importance que celles que j'ai énumérées et d'ailleurs moins strictement limitées à l'action militaire.

C'est d'abord le système entier des sémaphores, stations installées sur le rivage en des points élevés et susceptibles de communiquer par des signaux visibles avec les navires en mer et par des fils télégraphiques avec les ports voisins. Ce réseau actuellement fort utile à la marine marchande, a été dans l'origine constitué afin de pouvoir correspondre sans cesse avec les navires de guerre chargés de croiser le long des côtes.

Je cite particulièrement le sélénitère électrique permettant de déterminer constamment de la terre la position d'un navire en marche; c'est un organe indispensable dans la défense des côtes, spécialement avec les torpilles. Plusieurs systèmes sont employés dans les divers pays. La *Lumière électrique* (1er janvier 1880) en a décrit en très-bons termes dû à M. Legaz-ary de Tromelin.

Il est bon de discuter ici un emploi en projet qu'on a proposé des appareils électriques pour le soulage (il y en a plusieurs systèmes dus à MM. Heidein, Siemens), pour la mesure de la vitesse d'un navire en marche (loch électrique de MM. Leupe et Koch de Legeazeau, etc.) pour le lancement des navires. Toutes ces applications sont aussi utiles dans la paix que dans la guerre et je ne dirai pas un mot ici à leur sujet. Pour la même raison je n'insiste pas sur l'emploi de la lumière électrique dans les travaux sous-marins et sur l'application qu'on en a faite pour rendre lumineuses les boules placées en mer.

Je dirai quelques mots de l'essai du téléphone qui a été fait à Cherbourg. On l'a employé pour mettre en correspondance la digue et les divers forts isolés en mer avec la terre ferme; les résultats ont été très-satisfaisants et si je suis bien informé la communication subsiste, et reste en usage. On a proposé de se servir du même moyen pour relier entre eux les navires d'une escadre au mouillage; mal douté que le procédé ne réussisse si l'on juge utile de l'employer.

Je laisse complètement à part la question de l'éclairage électrique des phares, elle ne tient que de loin à la guerre et, d'ailleurs, elle vaut une étude moins rapide.

Les applications de l'électricité dans l'art de la guerre terrestre sont peut-être moins nombreuses, mais elles sont d'une sérieuse importance.

Pour simplifier, je passe d'abord en revue celles qui ont le moins d'intérêt.

Comme dans la marine, on a employé l'électricité pour produire l'inflammation de la poudre, mais avec moins de suite et de généralité. La précision absolue dans l'envoi d'un coup de canon ou de fusil n'a pas la même importance sur terre que sur un navire sans cesse en mouvement; d'autre part, il est extrêmement incommode et difficile de charger les soldats d'un matériel électrique compliqué, tandis que, sur mer, un cela du navire peut le tenir toujours à portée. On a cependant fait quelques essais, pour les fusils on peut citer deux systèmes déjà anciens dus l'un à M. Baron, l'autre à M. Martin de Brettes; le premier se servait d'une bobine d'induction et envoyait une étincelle dans la cartouche, le second employait une petite pile de quantité renfermant un fil de platine. Tous deux renfermaient les organes nécessaires dans la crosse de l'arme. Ces essais n'ont pas eu de suite.

On emploie fréquemment l'électricité au tir des mines;

A NEW RELAY.

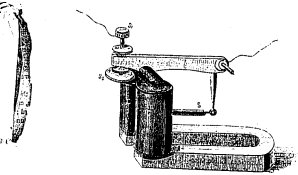
THE relay, a drawing of which is given below, is the invention of Mr. C. C. Vyle of the Postal Telegraph Department, London, and is really an adaptation of the principle used by Professor Hughes in the electro-magnet of his type-printer, though we believe the inventor was not aware of this fact for some time after his idea had taken practical shape.

In its appearance and build it is certainly not suggestive of the great delicacy which it undoubtedly possesses, as proved by exhaustive comparative trials with Post-office Standard Relays, and in actual working upon some of the longest and lightest circuits in the United Kingdom.

With slight alterations in the adjustments it is also claimed to work well as a direct double current sounder, and satisfactorily so in all weathers.

The general construction is as follows :—

An ordinary horse-shoe magnet, N, is laid horizontally beneath the base of the instrument, each leg of



the magnet being fitted with a cylindrical soft iron core-section which rises perpendicularly through the base and goes to form the cores of the electro-magnet, c, c. The coils of the electro-magnet are wound differentially to 200 ohms each, and may therefore be worked singly or duplex. At one end of the lever, f (which works in jewelled bearings), and immediately over the cores, is fixed a soft iron armature, a, which is attracted by the induced magnetism of the cores.

Towards the opposite end of the lever is attached a spiral spring, s, and adjusting screw, by means of which the force of the magnetised cores over the soft iron armature may be varied or counteracted as circumstances require. Still nearer this end of the lever are the limiting stops, s_1, s_2, inserted in the usual way.

The most delicate adjustment of the relay is said to be arrived at when the tension spring just balances the attraction of the cores and the lever lies indifferently in either position, and when the limiting stops are just sufficiently apart to break contact and prevent ill effects from the spark from the local battery.

For sounding purposes, the stops of course require opening out considerably.

From the foregoing it will readily be understood that if a current be sent through the coils tending to strengthen the polarity already induced in the cores by the permanent magnet, the soft iron armature will be drawn to or retained upon the cores against the tension of the spring ; if, however, the current should be in such a direction as to tend to neutralise the existing polarity, then the attractive power will be lessened and the spring will do its work by drawing up the lever to the top stop.

The relay, when well made and well adjusted, will give good signals with one Daniell cell working through a resistance of 10,000 ohms, and if the latter be all removed the relay will still respond properly without requiring to be re-adjusted ; this is a great point.

Although Mr. Vyle may not have discovered any new principle in his relay, yet he has certainly shown that there are still some old ones to be worked out.

until the commutator brushes are moved, so as to reduce the exciting current, and consequently diminish the current in the lamp circuit. Should the current diminish beyond the normal strength the armature is released, the spring moves the scale upper ratchet wheel, when the result will be opposite to that just described.

The incandescent lamps, in connection with which this regulator is more especially intended to be used, are connected in multiple arc ; that is, they are connected across two parallel wires, so that the current is divided up between all of the lamps in the same circuit. Now, it is obvious that, when a number of the lamps are removed, the current would, under ordinary circumstances, be much stronger in the lamps that are allowed to remain in the circuit, but when the regulator is applied there is no perceptible difference in the light given out by the lamps, whatever may be the number in circuit.

As many as 64 lamps have been brought up to over 30 candle-power each in a single circuit by one large machine, and the lamps have been removed from the circuit until only one remained and then all replaced, the regulator meanwhile adapting the current perfectly to the widely varying conditions.—*Scientific American.*

TELEGRAPHIC APPARATUS IN USE IN THE BRITISH POSTAL TELEGRAPH DEPARTMENT.

XXI.

THE UNIVERSAL BATTERY SYSTEM.

WITHIN the last two years the system of working several circuits from one set of batteries has been revived with great success. This system, which was tried many years ago, appears to have failed on account of the unsubtleness of the batteries employed for the purpose, and also, no doubt, on account of the imperfect state of the insulation of the lines at that period, which rendered heavy battery power necessary for working a single line when the weather was bad and leakage considerable. At the present time, when the lines are kept in a high state of efficiency, the Universal system is entirely successful and economical.

The possibility of the Universal system is dependent upon the fact that when a battery has a low resistance the connection to it of several lines of equal resistance reduces the *total* resistance in the circuit of the battery nearly in direct proportion to the number of lines connected up, and as this reduction of resistance increases the amount of current flowing out of the battery proportionately, the total amount of current when split up amongst each of the lines gives to each a current of nearly the same strength as that which would be obtained on a single line connected to the same battery. If we suppose the current from the battery with one line connected to it to be 1, then 1 will be the current working the line. If now we connect two lines to the battery the resistance in the circuit of the latter becomes halved, consequently the current

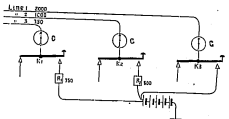


FIG. 70.

flowing out will be 2, and half of this will flow through each line—that is to say, there will be a current equal to 1 flowing through each. Similarly, if we have three lines, the current out of the battery will be trebled, and a third of this, or a current equal to 1, will flow through each line, as at first.

If the resistance of the battery were equal to 0, then no matter how many lines of equal resistance we added on, the current through each would still remain the same. But it is, of course, impossible to get a battery of a resistance equal to 0 ; as long, however, as the joint resistance of all the lines is not *less* than the resistance of the battery, the current flowing through each line will not be very much less than that which would flow through a single line, supposing the latter were the only one connected to the battery. In fact, so long as the joint resistance of all the lines worked from the battery is not less than the resistance of the battery, then no matter how many lines we connect to the

particular with, and are in form similar to, the vibrations of ordinary matter when transmitting the same sounds. Indeed, the mathematical expression of the electric current at any point of the telephone wire is the same as the mathematical expression of the movement of the air at any point outside the telephone. Without studying the use of the words, we may say that the currents in the telephone wire transmit sound in the same sense that the movements in the air around us transmit sound. In the case of writing telegraphs and printing telegraphs the case is very different; the electrical effect on the wire have no similarity to or other than a wholly conventional and artificial correspondence with the form or printed character."

At the conclusion of the reading of the evidence it was agreed between the counsel counsel on both sides that there should be an cross-examination of the witnesses, who were thereupon released from further attendance.

(To be continued.)

TELEGRAPHIC APPARATUS IN USE IN THE BRITISH POSTAL TELEGRAPH DEPARTMENT.

XXIII.

THE WHEATSTONE AUTOMATIC SYSTEM.

THIS important instrument is now very largely used in the United Kingdom for the transmission of ordinary and press message work over the main trunk wires, and also at rare nuncliups where a large amount of work is required to be done in a short time; indeed, without the help of the Wheatstone instrument it would be impossible to transmit, without heavy delays, the large amount of work which has daily to be carried on. At the present time over 170 automatic instruments are in daily use, working up to a speed, in some cases, of 250 words a minute. At present this rate of working is found sufficient for all purposes, but there is but little doubt that a much higher speed can be obtained if necessary; indeed, a speed of 250 words has actually been attained between London and Glasgow with the existing form of apparatus.

The Wheatstone apparatus consists of three parts, *viz.*, the *punches*, the *transmitter*, and the *receiver*. The former is employed for preparing a slip of paper for transmission through the transmitter, and it is worked either by direct blows or by pneumatic action controlled by finger keys.

To understand thoroughly the action of the apparatus it will be convenient to consider first its general principle.

Fig. 86, represents a facsimile of the punched paper strip for the transmitter, and the corresponding slip with the recorded signals as it passes out of the receiver.

On the punched paper strip there are three rows of holes; the holes in the centre row are equidistant, and are for the purpose of enabling the paper slip to be drawn forward at a uniform rate through the transmitter. For this purpose the latter is provided with a small star wheel turned by perforations in the slip, and drive the latter forward by a rack and pinion movement.

The upper and lower sets of perforations, which are rather larger than the middle row, are for the purpose of controlling the currents sent out by the transmitter.

Figs. 87, 88, 89, represent the controlling mechanism in the transmitter.

c_1, c_2 are two bell-crank levers, pivoted at the angles and connected to the zinc and copper poles respectively of the battery. The spiral springs, s_1, s_2, make of stiff brass wire, tend normally to pull the two longer ends of the levers together; the inside part of these ends are faced with platinum and between them are two platinum pins, p_1, p_2, fixed to the disc, b.

Referring to fig. 88, it will be seen that if the two platinum faced ends of the levers could both rest at the same time against one or other of the pins, p_1, p_2, that the battery would be short circuited; this is prevented by means of a small screw, a, which is screwed through the end of the lever, c_1, and whose end touches against a small piece of ebonite, e, fixed in the end of the lower lever, c_2. The screw, a, is so adjusted that the distance between the two platinum faces is rather greater than the diameter of either of the pins, p_1, p_2; thus the circuit of the battery cannot be closed through either of the pins.

The disc, b, is divided into two halves insulated from each other, so that the pin, p_1, is insulated from the pin, p_2. The disc is axed behind at its centre so that it can rotate through a small angle to the left or right as required. A steel tail piece projects from the top and bottom of the disc, and against the top one a locker wheel, r, set at the end of a spring, presses; the object of this wheel is to keep the disc firmly in either of the two extreme positions it may assume—that is to say, with the top tail piece against either the left or right-hand stops between which it plays.

It will be noticed that when the disc is in the position shown in fig. 87 that the copper pole of the battery is connected to the pin, p_2, and the zinc pole to the pin, p_1. When the disc is rotated until the top tail piece comes over against the left-hand stop pin, as shown in fig. 89, then the zinc pole is connected to pin, p_2, and the copper pole to pin, p_1; thus the right and left-hand movement of it reverses the battery relative to the pins, p_1 and p_2, that is, relative to the two insulated halves of it. The "Up" line being connected to the right-hand half of the disc, the rocking of the latter connects the zinc and copper poles alternately to it.

Y is an ebonite beam which is caused to rock at its centre by means of the train of clockwork which drives the star wheel before referred to. The beam is provided with two platinum studs or pins, p_3, p_4, the left-hand one of which is connected permanently to the "Down" line. These two pins normally press against two bell-crank levers, a, b; the horizontal arms of these levers are pulled upwards by means of the springs, s_3, s_4.

The levers being hinged directly on to the frame of the apparatus are in electrical contact with one another.

To the crank, a, a rod, n, is hinged, whose end passes through a hole in the tail piece, r. A small collet, n', is screwed on to it, which, when it is moved to the right by the action of the crank, a, presses against the tail piece, r, and rotates the

A NEW RELAY.

THE relay, a drawing of which is given below, is the invention of Mr. C. C. Vyle, of the Postal Telegraph Department, London, and is really an adaptation of the principle used by Professor Hughes in the electro-magnet of his type-printer, though we believe the inventor was not aware of this fact for some time after his idea had taken practical shape.

In its appearance and action it is certainly not suggestive of the great delicacy which, in reality, it possesses, as proved by exhaustive comparative trials with post office standard relays, and in actual working upon some of the longest and heaviest circuits in the United Kingdom.

With slight alterations of the ordinary form it is also claimed to work well as a sounder double current sounder, and satisfactorily as in all other matters.

The general construction is as follows:—

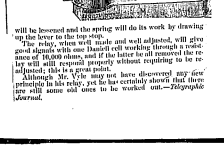
An ordinary horseshoe magnet, M, is laid horizontally beneath the base of the instrument, each leg of the magnet being fitted with a cylindrical soft-iron electromagnet which rises perpendicularly above it, the two cores being so fixed to form the cores of the electro-magnet, C, C. The coils of the electro-magnet are wound differently to 200 ohms each, and supply, therefore, he needed double or duplex. At one end of the lever, I (which works on a knife-edge bearing), and immediately over the cores, is fixed a soft iron armature, a, which is attracted by the induced magnetism of the cores.

Toward the opposite end of the lever is attached a spiral spring, S, and adjusting screws, by means of which the force of the magnetism across over the soft iron armature may be varied at pleasure. These screws, s_1, s_2, work against stops, S_1, S_2, insulated from the lever are the limiting stops. S_1, S_2.

The most difficult adjustment of the relay is said to be arrived at when the armature, a, is adjusted sufficiently close to the cores and the lever long enough to give sufficient position, and when the limiting stops are set sufficiently apart to break contact and prevent the spring from the stuck from the local battery.

For sounding purposes, the stops need course, require opening out considerably.

From the foregoing it will readily be understood that if a current be sent through the coils tending to strengthen the polarity already induced in the cores by the permanent magnet, the soft iron armature will be drawn to or attached upon the cores against the tension of the spring; if, however, the current should be in such a direction as to tend to neutralize the existing polarity, then the attractive power



will be lessened and the spring will do its work by drawing up the lever to the top stop.

The relay, when well made and well adjusted, will give good signals with one Daniell cell working through a resistance of 10,000 ohms, and if the latter be all removed the relay will still respond properly without requiring to be readjusted; this is a great point.

Although Mr. Vyle says he has certainly shown that there principle in his relay, yet he has certainly shown that there are still some end ones to be worked out.—*Telegraphic Journal.*

Scientific American.
NEW YORK, SATURDAY, MARCH 19, 1881.
Scientific Progress in England, &c.

Lecturing recently on "Electricity and the Electric Telegraph," at Kensington, Mr. Robert W. Johnson, Postmaster of the Eastern Central or "City" district, quoted some of the statistics of the Postal Telegraph system, which are interesting and instructive at the present moment. He showed that whereas the earliest telegraph of which we have any account required a separate wire for each letter of the alphabet, and that in the first really practical telegraph two wires were necessary for the transmission of a single message, as many as four messages can now be sent on a single wire at the same time—that the 6,000,000 telegrams forwarded by all the companies in their palmiest days had increased to more than 31,000,000 forwarded by the Post Office last year, and that whereas it might be transmitted when the charge for a message from Edinburgh to London was something like 12s. 6d., it was now possible to telegraph from Selby to Shetland, or from Jersey to John o'Groat's for 1s. Fifty thousand miles of wire in 1870 had increased to considerably more than 100,000 in 1880; 2,200 instruments worked by all the companies had increased to nearly 9,000 worked by the Post Office; and 2,500 telegraph offices under the old régime had increased to more than 5,500 under the new. Four thousand persons of all classes employed by the companies had increased to nearly 12,000 employed by the Post Office, and of these about 1,000 were women, of whom 600 are employed in the Central Telegraph Office alone. As to the transmission of news for the press, the Post Office had converted into an attractive monopoly what used to be a rather repulsive combination on the part of the old telegraph companies, and on one occasion quite recently as many as 7,000 words, equal to 28 average columns, had been transmitted from the Central Office alone. The former, which was of a thoroughly popular character, was illustrated by specimens of most of the instruments in use by the Post Office, as well as by a working model of the pneumatic tube system, telephones in circuit, and some minor experiments with the electric light.

Dynamo-Electric Machines in Telegraphy.—About a year since, the officers of the Western Union Telegraph Company introduced the use for telegraphing of currents generated by machines instead of batteries, and now, as Vienna, comes forward in the *Elektrotechnische Zeitschrift* with a claim that he successfully employed the currents obtained from a Pacinian dynamo-electric machine for telegraphy as early as 1876.

"515. "Improvements in telegraph posts, and in the method of fixing the same."—J. M. Newman, dated, Feb. 7, 1877. 6d. This consists in forming light and strong telegraph posts by driving two uprights of angle or trough iron into the ground, a short distance apart, and tying them together at the top by cross bars, provided with holes for the reception of insulators. In soft ground, the base of the poles in the hole is filled round with concrete, cement, or asphalt.

522. "An improvement or improvements in fixing the insulators of electric telegraphs."—J. H. Coxeaxe, Feb. 7, 1877. 6d. By this plan the bolt supporting the insulator is formed with a screw thread at its end, and screws into the insulator, a washer of india-rubber or other yielding material being placed on the screwed end of the bolt so as to be compressed between the insulator and the shoulder on the bolt, when the insulator is screwed home. This serves to keep the insulator tightly on. The insulator may be readily removed by unscrewing.

DANGER FROM OVERHEAD TELEGRAPH WIRES.

On the afternoon of the 12th instant a singular accident happened in Farringdon-street. Charles Holmes, a coalman, was driving a hansom cab, and, when near the Viaduct, one of the Post-office telegraph wires passing over the road snapped, and fell about the horse's head and body. The animal took fright, and bolted for some distance down the road, until it got entangled in the wire in such a manner that it was thrown completely over. It was with great difficulty that it could be extricated, and it was then found to be so severely injured that it will probably have to be killed. The driver had a narrow escape.

A similar accident occurred about the same time in St. Bride-street. A telegraph wire broke, and a hansom cab driver was caught round the neck by the broken wire, but fortunately he was not injured.

Another accident of the same kind in Islington was unhappily fatal. A Brompton omnibus, after finishing its journey at about five minutes past two o'clock, pulled up as usual at the York Hotel, and one of the horsekeepers, named William Stevens, was driving it to the stables when a telegraph wire was blown away, and it felt round the poor fellow's neck, and nearly cut his head from his body. Mr. Incle, and nearly cut his head from his body. Mr. George Born, of Colebrooke-row, promptly attended, but death took place before his arrival. The body was conveyed to the stables prior to removal to the parish mortuary to await the coroner's inquest.

Sir William Fothergill Cooke, who constructed the first telegraph line in England in 1838, is dead, at the age of 72. The line in question extended from Paddington to West Drayton, and the man-

PHOSPHOR BRONZE WIRE, AND ITS APPLICATION TO TELEGRAPHIC PURPOSES.—It has long been the aim to produce a wire which possesses greater conductive capacities than the ordinarily used iron wire, and of greater strength than copper wire, which, by its soft and ductile nature, requires—except for short lengths —to be supported. A combination which unites a compound wire is largely used, as called for in the laying mode of steel wire covered with a sheathing of copper, the strength being regulated by the thickness of the steel, and its conductivity by the thickness of the copper covering. The manufacture of this wire, however, requires the utmost care in order to enclose the steel wire perfectly. A slight defect permits moisture to enter between the two metals, galvanic action sets in, and the wire corrodes. Messrs. C. J. A. Dick and G. A. Dick undertook a series of experiments with wire drawn of phosphor bronze, and the tensile strength these gentlemen obtained with this material led them to experiment also on the respective capacities of these wires (of varied compositions) for conducting electricity. Compared with iron wire, phosphor bronze wire showed more than double its tensile strength, and about three times more its conductive capacity. As to the metallurgical treatment of the metals composing the wire, they say:—"Phosphor is added to either zinc or carbon,—the former by the oxidation which takes place whilst the metal is in fusion, as the carbon which is left from the melting process,—although contained in but very small quantity in the wire, nevertheless materially affects its qualities, and is particularly detrimental to its strength and elasticity; they therefore add an oxidising agent, if necessary, to reduce the carbon, and then a sufficient amount of reducing agent, such as phosphorus. Wire drawn from such metal will be found to be tougher and more elastic than wires formed of metal containing oxides or carbon; but yet greater strength and elasticity is obtained with alloys of copper and tin which are phosphoried, or, in other words, which contain a given amount of phosphorus. Although the conducting capacity is somewhat impaired by the presence of phosphorus, the following proportions of the metals may be made when used within the following specifications:—(1). When not more than 2 per cent of tin is used, the component quantity of phosphorus may amount to not more than 0·5 per cent. (2). When not more than 4 per cent of tin is used, the component quantity of phosphorus may amount to not more than 0·3 per cent. (3). When 5½ per cent of tin is used, the component quantity of phosphorus must not exceed 0·235 per cent.

Tel Journ Aug 1. '8

TELEGRAPH POSTS IN JAVA.

THE supports used for carrying the system of telegraph wires through the Island of Java merit a short description.

These are formed of the trunk of a tree known as the "Kayee" tree, which derives its name from a species of short fibred cotton which it produces. This tree possesses the two following advantages, which fit it admirably for the purpose. In the first place, when a tree is cut down, and the upper or branched part cut away, it possesses such an amount of vitality, that when placed in the ground it will at once form new roots and branches, thus effectually protecting it from the ravages of the white ants who would soon make very short work of an ordinary telegraph post. Secondly, the branches always speculating out horizontally never come in contact with the wires or insulators.

Another advantage lies in their elegant appearance as contrasted with a similar number of bare poles.

When once planted, probably no further attention would be necessary, and unless blown down by a gale (which their form would render unlikely) or damaged by lightning, they would last for very many years.

The traffic receipts of the West-coast of America Telegraph Company for the four weeks ending April 8 were at 408 per dollar, £1,499.

The report of the Eastern Telegraph Company for the half-year ended 31st March last shows a balance of £99,136, which with £22,580 brought forward, leaves available for distribution £121,122. The preferential and debenture interest absorbed £7,639, the interim dividend already paid £46,112, and it is now proposed to pay a further dividend of 2s. 6d. per share (making 5 per cent. for the year), and carry £22,179 to the reserve fund, which is thus raised to £185,565.

The traffic receipts of the Western and Brazilian Telegraph Company Limited for the month of June were £9,623 against £9,088 for the corresponding month of last year. It is stated (July 3) that the interruption between Bahia and Pernambuco does not interfere with the traffic to the Brazils and South America generally, as messages are sent over land lines between those places without extra charge and without delay. The repairing ship has left to restore communication. The cable was interrupted in shallow water.

The first annual report of the magnetic observations at the new observatory of Zi-ka-wei, in China, has lately reached Europe. An account of the result obtained—which are of considerable interest to those engaged in the study of terrestrial magnetism—is furnished by Father Perry to *Nature* (June 29).

The number of messages passing over the lines of the Cuba Submarine Telegraph Company Limited during the month of June was 2,539, estimated to produce £2,600, against 2,491 messages, producing £2,490, in the corresponding month of last year. The traffic receipts for the month of April, estimated at £2,500, realised £2,991. The half-yearly report of the same Company recommends a dividend at the rate of 7 per cent. The sum of £5,623 is placed the reserve fund, increasing it to £12,000, and £1,439 remains to be carried forward to the next account. The Report adds, that the Company's lines have continued in good working order, and that no interruption of importance has occurred on the lines of contiguous Companies.

The Directors of the Anglo-American Telegraph Company have resolved, after receiving £30,000 for the renewal fund, to declare an interim dividend, for the quarter ending June 30th, of 1½ per cent. on the Consolidated Stock, and of 3½ per cent. on the Preferred Stock, both free of income-tax, payable on the 1st August, leaving a balance of £12,000 to be carried forward to next quarter's account.

The traffic receipts of the Great Northern Telegraph Company for the month of June amounted to 365,428 francs, as against 390,076 francs in the same month last year. The total traffic receipts from 1st January to 30th June were, this year, 2,239,397 francs; last year, 1,933,269 francs.

The traffic receipts of the Direct Spanish Telegraph Company for June were £541 10s. 11d., against £1,464 3s. 2d. in the corresponding period of last year.

THE TELEGRAPHIC JOURNAL.

Vol. I.—No. 15.

WOODEN TELEGRAPH POLES.

By E. T. BOLLS, Assoc. S.c. Tel. Engineers.

THE importance of a proper selection of this article for the construction of telegraph lines cannot but be admitted, and yet the subject in practice does not appear to receive the consideration it merits.

The introduction of the "creosoting" process has no doubt been a great step in the right direction, yet even here there is certainly room for improvement. It is a plan that doubtless, under certain conditions, answers almost every purpose, but these conditions are not always fulfilled. A "creosoted" pole is by many accepted as representing *no fell wrought*, in respect of nearly everlasting preservation. This is not necessarily so. The repetition of "creosote" included to the cubic contents of the timber, the description of wood selected, and the quality of the creosote itself, are all points of chief importance to the life of a pole, but are frequently disregarded. Experience has shown that those woods which of themselves are the most lasting are least adapted to the creosoting process, as from the presence of their fibre it is impossible at any ordinary pressure to saturate them with the antiseptics. I have had to renew creosoted poles less than ten years old, where well grown spruce had been set, and the remains of these poles clearly showed that their early decay was due to the creosote having been unable to penetrate to a sufficient depth. At the ends the wood remained sound for some distance, for here the creosote had forced its way up through the capillary tubes of the wood, as well as from the surface; but as the longitudinal distance increased, the "creosote" was found only in the less dense sapwood, having failed to enter transversely the older and more solid heartwood; consequently except at the ends, and for a distance of about three inches from the pole, the wood showed no trace of creosote, and was more or less decayed. Evidently, then, where poles are to be creosoted, it is better and generally cheaper to select soft woods; one easily obtained in this country is Scotch pine (*Pinus sylvestris*), which is admirably adapted to any creosoting process. It is of very coarse grain; its annual rings are wide apart, and the intervening soft wood soon exhibits great absorption. It does these soft and spongy spars as cheap as larch, but it is not generally cheaper to select soft woods; one easily obtained in this country is Scotch pine (*Pinus sylvestris*), which is admirably adapted to any creosoting process. It is of very coarse grain; its annual rings are wide apart, and the intervening soft wood soon exhibits great absorption. It does not produce as strong a spar as spruce or larch, but it is strong enough for ordinary purposes; and where extra strength is necessary to place extra strength, by doubling, staying, or stratting.

The quality, or rather description, of the "creosote" I find to bear most materially on the subsequent condition of a pole. Mostly in the manufacture the distillation appears to have been carried on too gently, resulting certainly in a liquid containing a greater proportionate amount of creosote than if would had the pressure been urged. But this slowly distilled liquid can contain only the most volatile products of the coal tar. The pole impregnated with this soon under the influence of sun heat presents a bleached appearance, the heat volatilises a great proportion of the oil of coal tar, and the wood, though showing no sign of ordinary organic decay, is severely affected by the resi and corrosive action of the preparation it has imbibed. The vegetable tissue is partly destroyed; the wood fibre desiccated; moisture and air, two of the active agents of decay, find easy access; and although a coat of coal tar will offer a slight remedy, the result is by no means satisfactory.

Now were the distillation of the "creosote" urged, a small portion of tarry or less undecomposed coal tar would pass over from retort to receiver, and the "creosote" would then contain some pitchy matter. A pole will require greater pressure to saturate it with this product, but afterwards well repays the trouble. The weathering, as before, drives off a portion of the more volatile parts, but the pitch remains in the interstices of the wood; the pole keeps black, is perfectly waterproof—the aqueous only to make it the harder, and apparently it will last for an indefinite period.

With plain poles the conditions are of course quite changed; the wood which could be best creosoted would probably be least lasting if unprepared. There are many descriptions of foreign grown pines and firs which make excellent spars, but as a rule their price precludes their use. Norway spruce (*Abies excelsa*) is generally straight and well grown, and makes a nice looking pole, but in point of durability has little to recommend it. Scotch pine is hardly much more grown at home; the looseness of its fibre renders it peculiarly liable to the absorption of moisture and air, and to subsequent decay. Larch (*Abies larix*) is—in my opinion of, and no doubt, if properly selected, is both well; but, unfortunately, this species is seriously affected by the disease fungi and in which it is grown. Reared in the southern counties of this island, where warmth and moisture are more prevalent than in districts further north, and where the soil is less too stimulating, the larch fir produces timber more or less worthless for telegraph purposes, and poles cut from it will not stand long. I have had in renew Devon larch after seven years. But the tree grown in Scotland or Wales, on poky or stony districts, at an altitude of about 1500 feet above the sea level, yields poles of most excellent quality, which, if cut in the fall, and of about thirty years' growth, will often last fifteen years or more. It is a wood very subject to warping, and shakes under exposure to the sun, and must be preserved by coal tarring or painting—preferably the former—which will to a great extent prevent shakes in which wet would lie to the destruction of the pole. Before tarring, however, the pole should be "charred" at the butt. This process, if well performed, is of a great service, but, unhappily, the prevalent idea appears merely to burn the outside wood; this causes a lot of little cracks. The pole should at first be roasted slowly at a considerably distance from the fire, not permitting the wood to burn; the effect will be to evaporate the greater part of the aqueous portion of the sap and at the base of a tree the sap is always more watery, not having commenced solidification by inhalation and exhalation in the leaves to solidify and render insoluble its albuminous constituent, and possibly to destroy the fibrilla of fungi, *Polyporus destructor*, and variets species of *Sporotrichum*, also to mount the capillitia of the ligneous cells to admit fresh

JOHNSON AND PHILLIPS' PATENT INSULATORS.

ALTHOUGH the production of an efficient form of insulator for aerial wires is a most interesting and important problem, the advance made in this branch of practical telegraphy has by no means been as great as could be wished.

The employment of a liquid repellent of moisture placed in a recess formed around the ordinary cup form of insulator was, we believe, attempted some years ago; but either through the imperfect way in which the experiment was made or in consequence of the utility of a very high state of insulation, not being so apparent as it is at the present day, when economy of battery power and the employment of the duplex and quadruplex systems of working are points of great importance, the idea was not carried into practice. Messrs. Johnson and Phillips, who have paid considerable attention to the production of an efficient form of insulator on the above principle, have so far succeeded as to obtain patterns which have proved efficient under conditions which would be fatal to those of the ordinary form.

Although these insulators require the test of continued use under conditions that exist in ordinary aerial telegraph lines, yet the success that has been obtained is so remarkable as to deserve notice.

Figs. 1, 2, and 3, show forms of these insulators.

Fig. 1. This insulator is fixed above its arm or support in the usual manner. The lower edge of the porcelain A is turned up inwards so as to form a chamber, shown at B, in which oil or some other insulating fluid is placed.

Fig. 2. In this insulator the porcelain consists of two parts. A, the head, is firmly cemented to the bolt F, which passes freely through the second part B, containing the insulating fluid S. B is held in position by the nut N; when this nut is unscrewed B may be lowered so as to expose the oil chamber S to view for the purpose of examination or for the introduction of the oil.

In both cases the insulators are easily filled with the oil or other insulating fluid by means of a long-necked syringe.

Fig. 3 shows how an ordinary porcelain insulator may have the insulating fluid principle applied to it. The cup-shaped space S is partly filled with the fluid. C is a dished metal cover resting upon the porcelain tube T. This cover is not fixed, but is free to rotate round the bolt P; a fan F, attached to this cover causes it to rotate from time to time by the action of the wind, the object being to break any spiders' webs or filaments which might cause a leakage from the surface of the insulator to the cover. An india-rubber ring W prevents the rain from entering the oil chamber by means of the hole in the cover through which the bolt passes; it also, when properly placed, prevents the cover C from being lifted up by the wind and touching the porcelain. This form of insulator is especially adapted to districts infested with spiders or other web-spinning insects.

The following tests taken on twenty of the patent insulators and on four ordinary white porcelain insulators with a porcelain tube round each bolt speak for themselves.

The loss obtained on the four ordinary insulators is multiplied by five, to make it comparable with the twenty patent insulators, which are assumed to represent a mile of line.

The tests were taken with eighty cells, and an astatic mirror galvanometer.

The absolutely uniform insulation shewn for the patent insulators, is not strictly correct, but the deflection obtained on them never being more than two divisions, it was impossible to detect small alterations in the insulation.

FIG. 1.

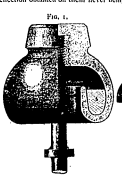

FIG. 2.

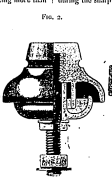

FIG. 3.

Date.	Resistance in Megohms per mile. (20 insulators)		Remarks.
	Patent.	Ordinary.	
January 15	—	—	Insulators fixed.
" 21	about 12000	250	Thaw morning;	clear evening nearly all night.
February 1	"	1·6	Bright morning.
" 3	"	0·08	Thaw; damp.
" 5	"	0·82	Thaw; fog overnight;	fog raised in night.
" 7	"	0·72	Dull; overcast.
" 10	"	1·25	Fine; overcast;	rain dew.
" 12	"	0·61	Thawing; windy.
" 13	"	2·58	Dull; overcast.
" 14	"	1·60	Shower of rain.
" 23	"	0·62	Dull; overcast.
" 24	"	0·61	Dull; overcast; damp.
" 26	"	3·12	Uncertain.
" 27	"	4·63	Fine.
" 28	"	3·72	Raining yesterday, and during night; snow first.
" 29	"	3·72	Dull; overcast;	has been unsettled.
" 26	"	7·1	Hail and hail	strong wind	doubtful measure by fog when shortly after rain ceased.
" 28	"	1·33	Fine;	bright; sharp frost.

The above figures show the great effect which surface leakage has upon the insulation of an ordinary line; the test taken on February the 12th was very marked, when the insulation of the ordinary insulators fell from 23 megohms to 1·1 megohm in a few minutes after the rain commenced. On the 26th it was equally instructive to notice how the insulation rose, when, the rain and hail ceased, and the strong wind blowing at the time, dried the surface of the insulators; the change in this case also took place in a few minutes.

The rain on the 26th had cleaned the surface of the insulators, hence the high insulation obtained during the sharp frost on the 28th.

The tests were taken at about 7 a.m.

Whilst all these changes were taking place in the ordinary insulators, it will be noticed that the high insulation given by the patent insulators, remained perfectly constant (as far as could be detected).

It should be noted that under the influence of frost the insulation still remained good, although it might have been expected that the congelation of the oil would have prevented such a favourable result being obtained.

During the late storms the Great Western line appears to have suffered the most from the destruction of the telegraph. About 150 poles were thrown down between Paddington and Reading. The block system was suspended and the old time system adopted. At one time messages could only be sent from London to Southall, they then had to be conveyed to Slough, whence they were transmitted to Bristol. Mr. Spagnoletti has been actively employed on the re-erection of the line, In addition to the ordinary staff some sappers were employed. Gov 76

Le Jour Oct 15-87

ON TELEGRAPH CONSTRUCTION.

BY JOHN GAVEY.

IRON wire, as it well known, has hitherto been almost wholly used for the conductor of an open line of telegraph. Although offering a much higher resistance to the passage of a current of electricity than a copper wire of equal section would do, its superior tensile strength, and its cheapness as compared with the latter, have caused it to be universally employed.

It is very important for many reasons that iron of a good quality alone should be used, hence wire specifications generally contain very definite stipulations as to the tests which it should withstand with success. Hitherto none but its mechanical qualities have been regarded, it being doubtless considered that the difficulty and expense involved in the electrical testing of long lengths of iron wire, in the electrical testing of long lengths of iron wire, would be greater than the advantage to be derived from the introduction of a standard of electrical conductivity for each gauge. Iron differs from other metals, unless much in its electrical resistance, according to the state of purity in which it may be obtained. Inasmuch, however, as uniform mechanical qualities are insisted upon in purchasing wire for telegraph purposes, and these qualities depend, to a great extent, on the state of purity of the metal, the per centage of variation in the conductivity of various lines, is not so great as it might be, were the conditions of the contracts less stringent than they usually are. That the resistances do vary, however, is shown by the different results given by wires erected at different periods with varying clean-as of metal.

The manufacture of iron wire is a very simple, but very interesting process. In the first operation—that of rolling—a bar of malleable iron, about 2 feet 6 inches to 3 feet long, mixed to a welding heat, is passed rapidly backwards and forwards through a series of rolls which contain grooves, varying by regular increments from three inches to one-fourth of an inch in diameter. At each passage the iron bar becomes less in diameter and increases correspondingly in length, until in the course of a few seconds it issues from the last groove, when it is wound on a drum, and appears in the form of coil of wire of somewhat large gauge. The whole operation is performed at one heating of the original bars.

The wire in this state is hard and brittle, and the next process is that of annealing. To effect this the coils of wire are enclosed in a kind of air-tight furnace, in which they are exposed to a considerable temperature, then cooled gradually. They are thus rendered soft and pliable and are in a fit state for drawing.

The drawing is a very simple operation. A number of plates of steel perforated with conical holes are fixed vertically on convenient benches, opposite to which are revolving drums of iron. A coil of the rolled annealed wire is taken, one extremity by a few dexterous blows with a hammer is reduced sufficiently in size to admit of its passing through the first hole in the draw-plate; it is then seized by a pair of tongs attached to the drum, which latter being put in rapid motion, the wire is drawn through the plate, and reduced to a uniform diameter, equal to that of the hole through which it has passed. This operation is repeated as often as is necessary, using smaller gauge draw-plates successively until the requisite size of wire has been obtained. For telegraph purposes the wire is annealed after the drawing is complete.

The final operation is that of galvanizing. To effect this the iron is first thoroughly cleansed in a caustic lye, to remove the grease which adheres to its surface in drawing. It is then immersed in a bath of *acide*, composed of hydrochloric and sulphuric acids, to remove all traces of oxide, and to leave a chemically clean surface. After being washed in pure water to remove any adhering acid, it is finally passed through a bath of melted zinc, the surface of which is covered with ammonia chloride. The zinc unites with the clean surface of the iron, and on emerging from the bath, the wire is run through a bank of sand, which cleans off the superfluous zinc, and leaves that smooth bright surface which new galvanized iron presents.

Galvanized iron is invariably used for telegraph purposes in England, although in some countries plain iron wire is employed. The preservative action of the zinc covering arises from the formation of a coating of zinc oxide on its surface. Being insoluble in water, this coating protects the remainder of the zinc, and consequently the iron from further oxidation. In smoky places, however, the sulphuric and other acids, which are developed by combustion, attack the oxide and form sulphate or other like salts of zinc These salts being soluble, are washed off by the first shower of rain, and a fresh surface of zinc is exposed to like influences, the result being that the whole of the coating is rapidly destroyed, and the oxidation of the iron of course follows. Per contra localities the wire is frequently protected by being coated with lamp or tape saturated with bituminous compounds. A simple application of coal tar, followed by dusting over the wet surface with clean sharp sand has been found effective; the difficulty with this is, however, to keep the protecting covering unbroken, for at all places where the metal is exposed rust sets in, which ultimately causes a break in the wire.

A compound conductor, consisting of a steel wire, covered with copper, has within a few years been used in America. A high conductivity with small bulk, and consequently, diminished strain on all supports is thereby attained. But little experience of its value in this country has yet been obtained.

The size or gauge of wire is denoted by numbers which correspond with various diameters. These numbers are entirely arbitrary, and several gauges are in use. That most commonly employed in this country is known as the Birmingham wire gauge. The following table, extracted from Mr. Culley's well known "Handbook of Practical Telegraphy," gives valuable information as to the section, weight, and breaking strain, of various sizes:—

IRON WIRE.

Gauge. Birmingham Wire Gauge.	Diameter.	Area of Section.	Weight per Statute Mile.	Weight of 1 Mile.	Breaking Strain.	
					Hard wire.	Soft wire.
	Inches.	sq. inches.	lbs.	lbs.	lbs.	lbs.
00	0.365	0.105	102.90	1,791	8,040	6,800
0	0.331	0.086	84.51	1,470	6,700	5,750
1	0.300	0.071	69.75	1,214	5,700	4,800
2	0.276	0.059	58.00	1,010	4,830	4,000
3	0.252	0.052	50.63	882	4,000	3,360
4	0.219	0.045	44.00	775	3,400	2,960
5	0.220	0.038	37.00	651	2,950	2,792
6	0.200	0.031	30.50	538	2,580	1,888

21	0.033	0.0009	0.91	17	85	50
22	0.028	0.0007	0.62	12	65	40

On account of the indefinite and varying sizes, which frequently correspond with certain gauge numbers, the diameters of wires are often given in decimals of an inch whose accuracy is desirable.

In preparing specifications for telegraph wire, the following rough general rules may be based upon it—It should be free from scales, flaws, splice, inequalities, cinder, and other defects, should be cylindrical throughout, and should conform within certain specified limits to the diameter ordered. Specimens from certain coils, either to be gauged with a decimal scale, or by feet lengths to be weighed, and the limits of variation to be defined. It should be highly annealed, soft, and pliable, and should stretch 18 per cent. without breaking. The wire should be manufactured in certain definite lengths, varying according to the gauge, which lengths should be marked on each coil or parcel of any description. Tensile strength and ductility to be specified. The former to be measured by the direct application of weights, the latter by gripping a certain length, say six inches of wire in a pair of vice, and counting the number of twists it takes to break the wire. In this country it is customary to *kill* or slightly stretch wire before use. This is sometimes done in the factory by running the wire from one drum to another slightly larger in diameter, both being geared to revolve at the same axial speed. This removes all bends and kinks in the wire, giving it a smooth regular appearance, which not only improves the look of the line when erected, but causes a lesser liability to interruption from wind contacts. Flaws and bad places are likewise detected by the operation, which might otherwise pass unnoticed until they caused a fault through breakage when in actual

TELEGRAPHY AND SLEDGING.

To the Editor of the Herald:—

Wide circulation has recently been given in the newspapers to a suggestion made by Mr. James Gamble, superintendent of the Western Union Telegraph lines on the Pacific coast, that the electric telegraph be used to maintain communication between Jenny sledge parties and their base of supplies. Mr. Gamble proposes that each party be equipped with a quantity of light steel wire, weighing twenty pounds to the mile, to be unreeled on the snow from a moving sledge just as a cable is laid from an ocean steamer. By means of this wire, and a portable Morse instrument at the sledge, he proposes to keep a sledge party in constant communication with the camp or its base of supplies. Even in a telegrapher's point of view this scheme would appear to be of doubtful practicability. A line of wire, even laid as suggested, over ice or snow, cools undoubtedly in a manner somewhat analogous to a cable's core, I think, take into consideration the peculiar difficulties which would arise in an Arctic region from the nature of the climate and the inadequacy of all existing means of transportation. An Arctic sledge party starts out into the winter or early in the spring, when the thermometer ranges from zero to fifty degrees below (Fahrenheit). It is, to say the least, very doubtful whether a steel wire of No. 20 gauge could be unreeled from a sledge in a temperature of fifty degrees without snapping at every turn of the reel. Admitting, however, for the sake of argument, that wire could be laid and spliced even in temperatures which render metal almost as brittle as glass, there still remains the persistent inquiry, "How would you carry wire enough to be of any use without crippling your party by enfeebling its supply of food?" It is and should be the aim of every sledge party to travel to the front of the explorations as far as possible with the least possible weight of dogs and provisions. It must carry the largest possible quantity of food and the smallest possible quantity of camp equipage. Every ounce of weight is counted. Every daily ration is allowed a thorough sparing. It is the custom to carry the smallest allowance which will keep the men in health and strength. Now, I have travelled for days in sledging parties, according to the condition of the snow, from 10 to 20 miles, and I have never yet found a sledge load of wire enough to make up over seven feet per mile. Add to this the weight of insulators, and you will find that the distance you can cover. One mile of wire, with insulators, will weigh 25 pounds. Ten pounds constitutes a weight not to be sniffed at for a team of ten dogs. If you leave the wire and insulators behind you, you will find that the moment you intend to find the wire the wire will not be there to find. In other words, for every mile of wire you lay you must carry a mile of wire, which might increase the team-load to fifty pounds, and twenty-five or thirty miles of distance which might be covered in a season by the best organized sledging party would be the maximum limit of its operations. Add to this the fact that every mile of wire carried is a high price to pay for telegraphic communication, and I think you will find that the expedition of the arctic regions, whether Jenny sledges and two or three hundred days of courage-testing travel are considered, will be found to be an unpracticable accident in the way of Morse. I say this is not practicable. I understand that Lieutenant Greely, of the Signal Service, has charge of the telegraphic outfit of the party at the ship's rendezvous. Twenty-five days under him drew over sufficiently rough for the sledge of Mr. Gamble's wire without any line, camp equipage or food. I am not prepared to say that the Signal Service has not the telegraphic outfit of the party at the ship's rendezvous. Twenty-five days under him drew over sufficiently rough for the sledge of Mr. Gamble's wire without any line, camp equipage or food. I am not prepared to say that the Signal Service has not the telegraphic outfit of the party at the ship a satisfactory arrangement for table board, sums they will not be found in the sledging parties. Of course if it could be devised without sacrificing anything else, would be of very little use. A sledge party must travel light. Every pound of weight taken from its base of supplies must be either very intact or very unessential. Lieutenant Melville, who has been the most successful sledge traveller in the Arctic regions, and who, with Lieutenant Nicholson, drew the same ship, succeeded a thousand miles, and Weyprecht, in 1872-73, were repeatedly in distances of three hundred miles from their base of supplies. Lieutenant Greely, or Master Brainard, may have had enough to undertake communication with sledge parties at the distance mentioned, but I doubt it. I have no doubt a thousand pounds of wire would have drawn up or fifteen sledges to the exclusion of everything else. Of course, I am not familiar with the extent to which the service have put through to accurately to enter to the resistance which metals and probably would have to a wire laid over ice and snow, such as Mr. Gamble proposes to use in the Arctic regions. But I am quite convinced by the opening of lines of water. The objections founded upon the insufficiency of existing transportation facilities to meet local needs in the matter of wire, and the weight of wire as an impediment to the "storm sledge" recently brought to the attention of the Navy Department in connection with the search for Lieutenant Greely, are, I think, fatal.

GEORGE KENNAN.

WASHINGTON, May 22, 1881.

axis of the former will then take the direction of the magnetic meridian. As soon, however, as the needle is fixed up, the former varies from its position, and the pole withdrawn from the needle. In order to bring back the magnet to its original position, another magnet, which we may call the compensator, is approached on the side opposite to the needle. Suppose that the needle was at the point *b*: if it is moved from its place, the suspended magnet deviates again from the direction of the meridian. But if the needle is moved further, a new position *a* can be found for it, in which the magnet returns to the meridian. If the compensator remains barely unmoved, the action of the needle upon the pole of the magnet is the same at *a* and at *b*.

(To be continued.)

EARTH-BORING FOR TELEGRAPH POLES.

By JOHN HAYES.

The usual method of digging a post-hole with the pick and spade requires but a brief description. A rectangular opening, averaging 4 feet by 2 feet, is made in the ground, and the earth moved uniformly throughout to a depth of 2 feet 6 inches, where, by a step-like arrangement, the length of the hole is gradually shortened, until at the bottom it does not exceed 1 foot.

The depth at which it is customary to plant telegraph poles may roughly be considered to vary from 4 feet 6 inches for a pole 24 feet long, to 5 feet 6 inches for one 28 or 30 feet; 6 feet serving up to, say, 40 feet, and 7 feet for any height.

It may be taken, as the result of experience, that the average number of holes which a workman will dig in ten hours is represented in the following table:—

Soil.	No. of Holes per Day.	
	4 ft. 6 in. to 5 ft. 6 in.	5 ft. 6 in. to 7 ft.
Clay	6	5
Digging soil ...	5	4
Hard gravel ...	4	3 to 3½

The digging of a pole-hole 4 feet 6 inches deep may be said to involve the removal of 30 cubic feet of soil, which will represent a weight varying from 2850 lbs. to 3600 lbs., according to the nature of the soil; whilst one 5 feet 6 inches deep will contain 44 cubic feet, with a weight of 4180 lbs. to 5280 lbs. This allows for the sloping manner in which such a hole is generally dug.

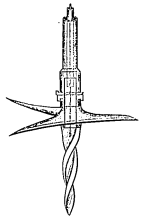
To reduce the great amount of unnecessary labour here involved, the most obvious step is first of all to effect a reduction in the size of the hole. The first instrument invented for carrying out the object was the "Spanish spoon." It consists of a circular metal disc, the chord of the arc forming a cutting edge. The periphery of the disc was provided with a ledge about 2 inches high, to retain whatever might accumulate on its surface, and the whole was fixed at right angles to a long handle.

Various modifications in the form of the spoon have been introduced with more or less success; but the principle of all forms of this apparatus is the same, namely, loosening the soil with a suitable bar, and collecting and raising to the surface the *débris* thus broken away.

* Abstract of a Paper read before the Society of Telegraph Engineers.

The most marked improvement in the method of opening holes for telegraph poles appears to have been the introduction of earth-borers, amongst which may be mentioned those invented by Spiller by Marshall, and by Baldhan.

Spiller's is but a modification, on a large scale, of the ordinary ship's auger: Marshall's and Baldhen's are both constructed on the same principle, but are essentially different from Spiller's. A general idea of their construction can be obtained from the accompanying diagram of Marshall's apparatus.



Spiller's borer the author found to be very effective in sand, clay, and ordinary soil, but ill adapted for gravelly or stony ground. Marshall's borer was very effective in ordinary soil, clay, and gravel.

These borers have obviously one defect; they cannot be worked close to a wall or a hedge, position where—in most telegraphic especially—it is frequently necessary to erect poles. This difficulty has been overcome by fitting one of the borers with an ordinary ratchet handle, lightening each of the parts as admit of it, and replacing the long tapering point by a shorter one. This modified instrument will bore in clay and ordinary soil, but in gravel it only acts as a spoon, the soil having to be broken up with a bar.

The advantages of these apparatus may be summarised as follows:—

1. Speed: a number of pole-holes can be opened out to a given depth, with the same force of men, in less time than by ordinary methods.
2. Diminution of labour in filling in.
3. Greater solidity of the pole thus erected.
4. Less disturbance and mixing up of the soil,—a point of some consequence in erecting lines of telegraph through private property.
5. The advantage of being able to work in wet soils without baleing or pumping.

to a force in the direction shown by the arrow-head.

In reply to Mr. *Culley*,

The PRESIDENT further said—If the force was always in one direction, then there would be nothing to loosen the pole *n a*. The pole *n a* would give the full resistance. I think that if there were forces acting always in the one direction and sometimes in the other, it is even possible that there would be less resistance with the two poles than from the one alone, from the fact that if the pole *a* would get loosened by forces acting in the direction of the arrow-head. It seems to me that although both poles become loosened, the resistance might be less than with a single pole. If the force is always in one direction (as that shown by the arrow-head), then, when the pole is loosely joined at the top, the resistance would be greater undoubtedly than with a single pole; but probably not quite so much greater as double. Although this is not a good arrangement, it would be better than the arrangement shown in the diagram. I think that if the poles were close side by side, there would be less than double the resistance of one pole, because the whole amount of the resistance of the earth that one pole would experience would be diminished by the presence of the other. If the two were placed at a considerable distance from one another, and if they were not coupled so as to give the leverage action upon which I have commented, then the force would still be not quite equal to the half of the two because the whole force could be calculated exactly on the two poles in proportion to their maximum resistance. The leverage action of the ordinary hammer fork for drawing nails is almost precisely the same in principle as that which I have indicated in this case. I have listened with very great interest both to Mr. Gavey's paper and to the communications, and also to the general information with which other speakers have followed it up. Although it is not clear that in distant countries, and in a variety of soils and in circumstances in which division of labour, and consequent subdivision of appliances are not available, the method of making holes by the pick and spade is that upon which most reliance should be placed. Still I think that Mr. Gavey has made out an exceedingly good case for the borer in a very large class of applications. What Mr. Culley has said with reference to the trials that have been made shows that there is a large province still left for the borer. It must be remembered that the borer is a comparatively new thing; it is now only a few years; and when so much can be said in favour of the borer as Mr. Culley has said, and as has been brought forward in the paper, I think we must agree that it is a most important appliance. In a large district of country, covered with a great many lines of telegraph may have to work, and where the soil is generally of a suitable character, the borer will be of considerable value. There can be no doubt whatever of the figures which Mr. Gavey has put before us, and they show a very great increase in the quantity of work done by the labour of a certain number of men through the use of the borer in favourable circumstances. The advantage of bringing forward and describing new appliances before this society is well illustrated by the interesting information and new ideas which we have received from Mr. Gavey himself, and the light which has been thrown on the subject by the different speakers. I propose a cordial vote of thanks to Mr. Gavey for his paper.

bination with various substances, and known under the general name of iron ores, it is widely distributed. The ordinary method of obtaining the metal from these ores, consists in exposing the latter to a very high temperature, in contact with compounds calculated to enter into chemical combination with the earthy or gaseous substances united with the iron. Sometimes the ore is first calcined, or roasted in great heaps, to expel the more volatile compounds; sometimes it is filled direct into the furnace, which is a large structure, varying from fifty to sixty feet in height, and of a corresponding width. This furnace, when once started, is kept in uninterrupted action until the necessary repairs, or the reduction for the demand for iron renders it necessary to blow it out. The charges of material, consisting of fuel, ore, limestone, &c., are fed in regularly at the top, the liquid iron and other compounds being withdrawn from convenient openings near the base. The necessary draught is obtained by powerful blowing engines, which force strong currents of air, generally heated to a temperature of about 600 degrees, into the furnace. A very high temperature is attained within the furnace; the metallic iron melts and drops on the hearth, whence it is periodically drawn off and run into moulds, whilst the slag, resulting from the combination of the earthy portions of the iron ore with the fluxing material which has been added, floats on the surface of the iron, and is drawn off through a convenient opening, and passes to the "waste tip."

The pig or cast iron thus obtained, is an indefinite compound of iron, with quantities of carbon, varying from two to five per cent. The properties of cast iron are well known. It has a brittle appearance, possessing great hardness, and offering considerable resistance to a crushing force, but with a comparatively small tensile strength, or power of resisting lateral or transverse strains.

Iron deprived of its carbon and some other impurities, is known as malleable or wrought iron, and the operation by which this change is produced is called puddling. The cast iron is placed in a reverberatory furnace, which is so arranged as to cause the heat and flame from the combustion of the fuel to impinge on the surface of the metal. The latter speedily melts, and when in this state it is kept stirred, so as to bring fresh surfaces of iron constantly under the influence of the flame and hot gases. The effect of this is to consume the carbon in the iron, which latter gradually loses its fluidity, and becomes viscous and pasty. In this state portions of the iron are worked up into rough sponge balls, and placed under powerful hammers, which squeeze the sponge into rough plates. These plates are cut into smaller pieces, which being tied together, are again heated, and either rolled or hammered, the operation being repeated in some cases several times. The quality of the iron is much improved by this, and it thereby acquires that fibrous appearance, which is a characteristic of good wrought iron.

Wrought iron has very different qualities to cast iron. The power of resisting crushing strains is diminished, but its tensile strength is enormously increased; in fact, when of good quality, none of the brittleness of cast iron, it is easily bent, it becomes malleable, is readily rolled into sheets or bars, is susceptible of being drawn into wire, and possesses the quality of welding at a white heat, although it has less that of fusing or melting at the comparatively low temperature which the combination with carbon gave to it.

Steel is a certain definite mixture of pure iron and carbon, the proportion of the latter being much less than in cast iron, but varying very considerably according to the purposes to which the finished metal has to be applied. The higher class of steel is made from the best malleable iron, by exposing the latter to heat in contact with carbon, the process being known under the name of cementation; but within the last few years, systems of manufacturing steel direct from cast iron have been largely introduced. One process, due to Mr. Bessemer, consists in consuming the carbon, by forcing a quantity of atmospheric air through the melted metal, then by the addition of a definite proportion of highly carburetted iron, the exact quantity of carbon needed for the formation of steel is restored to the liquid mass.

Steel possesses many and various qualities, dependent to a great extent on the purposes for which it is manufactured. Its tensile strength and resistance to crushing forces are much greater than those of wrought or cast iron. It also is susceptible of receiving any given degree of hardness, by the process known as tempering, from that which is sufficient to scratch glass to very little above soft iron. The strength of iron, whether cast or wrought, and of steel, varies between very wide limits, according to the purity of the metal, the method of manufacture, &c.

Cast iron has been produced with an ultimate tensile strength of 11 to 13 tons to the square inch, but this is rare. The average may be taken at seven tons, though it is occasionally as low as four to five tons. The force necessary to crush short cylinders, varies from 35 to 50 tons per square inch, and the average may be taken at 42 tons.

Wrought iron may be said to have, in extreme cases, a maximum tensile strength of 30 tons, and in ordinary or average strength of 22 tons to the square inch, although this sometimes falls as low as 18 tons. These figures do not apply to the strength of wire which, within certain limits, is greater in proportion as the sectional area is less.

Steel may be said to have a tensile strength varying from 30 to 55 tons per square inch of section.

A form of cast iron, known by the name of malleable cast iron, is frequently used in minor fittings for telegraph work. It is prepared by exposing castings, immersed in a bed of iron, or other substances rich in oxygen, to a high temperature, and allowing them to cool gradually. The oxygen combines with a portion of the carbon, and the withdrawal of the latter imparts a remarkable degree of toughness to the material so treated.

Iron pole. These have not to any great extent been used in England. The principal objection to their extended introduction, is the heavy cost of that material as compared with wood. At first sight it might appear that their increased durability would counterbalance this, but except in localities where ornament is an object, it is not so. Creosoted timber is so durable, that it is quite possible that it may equal the duration of wrought iron, and even though it do not, the difference in cost is so striking, that the balance of advantages remains in

favour of the former for use in this country. Abroad, and especially in tropical countries, iron poles are very extensively used, as they present many advantages over timber. The use of iron admits of the material being so disposed, as to obtain the maximum strength, with the minimum material; the poles are likewise generally constructed in sections, so that by those means great facility of transport is attainable, a point of much consideration in countries which have not well developed systems of roads, and means of transport. Moreover, iron is of course proof against that great enemy of timber, the white ant, which is so common within the tropics.

In the application of iron to Telegraph poles, the advisability of the destructive effects of oxidation, and the distribution of the materials in such a form as will combine strength, lightness, and elasticity.

These two objects are generally attained by constructing poles of a combination of wrought and cast iron, the latter being used for that portion which is fixed in the ground, and which rises some height above it, and the former being employed for the upper portion of the pole. The advantage of cast iron for the lower piece, consists in its durability, it not being subject to oxidation under the influences which generally affect Telegraph poles, and also, location an ornamental character is, where necessary, readily and cheaply imparted to it. Wrought iron is used for the upper portions on account of its greater strength, and its superior elasticity, whereby it is better able to resist the sudden strain and jerks to which it is subjected during rough gales. The various sections of which an iron pole is constructed, may either be held together by friction, tapered joints being provided, or they may be fitted with sockets and secured by lead or other suitable cement.

Iron has, however, been applied in many ways wrought into various forms, rolled tapered tubes, bars, ribbons, angle iron, and cast iron cylinders, being variously combined. As an example of each class, we will notice briefly a few of the best known.

Hamilton Standards are examples of poles constructed principally of sheet iron. They are formed of plates varying from 1 to 2 of an inch in thickness, bent into a circular form and riveted, so as to furnish tapered cylinders about eight feet long. The sections for each post vary slightly in mean diameter, so that when fitted one over the other, poles of a uniform taper, varying from 16 to 40 feet long may be constructed.

The base consists of a cast iron taper cylinder, over which the lower section fits, and it is provided at the bottom, either with two cross pieces of angle iron, or with a base plate, which adds to the groundhold of the pole. The poles are, for convenience of handling and transport, shipped in sections, and fitted together *in situ*.

These poles are now generally galvanized, as if right it might appear that their increased durability would counterbalance this, but except in localities where ornament is an object, it is not so. Creosoted timber is so durable, that it is quite possible that it may equal the duration of wrought iron, and even though it do not, the difference in cost is so striking, that the balance of advantages remains in

base piece, at the bottom of which is bolted one of Mallett's hooked plates. These plates consist of strips of rolled iron, about three feet in diameter, to which great stiffness is imparted by their being dished, or bent into a dish-like curve. The upper portion of the pole consists of a continuous rolled taper tube, which fits into a socket in the upper portion of the cast iron base piece, into which it is cemented by means of a mixture of sulphur and oxide of iron.

Cast iron cylindrical tubes, strengthened by collars or bands of wrought iron, and lifting tabs, occasionally, have been employed as well as wrought iron, either in a taper form or varying by graduations, and attached to a cast iron cylinder fitted into the ground.

Some poles have been constructed of a species of lattice work, somewhat similar to those frequently used for signalling purposes on railways. These, however, are too costly for general use. A modification of this, formed of round rods, has been manufactured. It is of an identical form, constructed with thin bars or rhombs of iron, crossing one another at regular angles, riveted together, and strengthened with angle irons. The facility with which these poles could be climbed would perhaps be found objectionable on high roads, even though the advantages they might possess rendered their use advisable. Little or no practical experience has been obtained of their value.

For light work, we have manufactured iron poles from a few lengths of different size cast and wrought iron gas pipes, fitted telescopically. These, with the aid of ornamental cast collars, have occasionally met the required purposes in emergencies.

Iron is largely used for overhead work, and with advantage. For this purpose, rolled taper tubes, either whole or fitting telescopically, are the most advantageous. They fit at the base into a semi-cylindrical iron casting, which can be adapted, either for use in a roof gutter, or fixed on a ridge. The wrought iron height, is dished, and requires less attention than wooden supports.

The proportions which should be given to iron poles, either of cast or wrought iron, will be considered when we deal with the pole as part of a complete structure.

As has been previously remarked, iron poles in this country are used primarily in localities where the ordinary wooden structure being objected to, something of an ornamental character is needed. This involves certain difficulties, for in traversing a town the ordinary facilities for adding to the assembly exist, and if an iron pole be made sufficiently large and strong, to withstand of itself the strain of the wires it will have to carry on curves and at angles, it becomes so unwieldy as to render one. This difficulty is met by reducing the size and consequent strain of the wires, and then by using two or more sizes of poles, one, as light and airy a structure as is suitable for straight lengths, the other heavier, for curves and angles. As a rule, two dimensions of poles should serve for any given work, and uniformity of design, should for such work be preserved, the strength only being varied. The stiffness of light poles may be increased by trussing.

Iron Sockets to screw into the ground, and adapted for holding wooden poles, have been ex-

IRON TELEGRAPH POLES.

WHEN the progress of telegraphic extension rendered it necessary to construct long ranges of lines through the semi-civilised regions of India, Central and South Australia, and South America, where it is often difficult, and even impossible to procure suitable timber for poles, or where the peculiarities of climate insured the speedy decay of wooden poles, even if it were possible to make use of them, the economy of using iron poles became so apparent as to scarcely require discussion. When we consider the difficulties of transportation, labour, and maintenance, in these partially civilised countries, inhabited by a rude and scattered population, and compare the relative first cost and duration of wooden and iron poles under such conditions, the saving which must result from the employment of the latter is readily seen. But in the more thickly settled countries of the world, where transportation is abundant and cheap, and the cost of inspection and maintenance is comparatively low, the question of relative economy becomes a much more complicated one. It is not proposed to enter into an extended discussion of the relative cost and advantages of iron and wooden poles, for the reason that so many different considerations enter into the question that perhaps nothing short of a somewhat lengthened experience with the two systems of construction under corresponding conditions would enable results, even approximately correct, to be arrived at.

One of the earliest inventors who turned his attention to the subject of iron poles was that eminent telegraphic engineer, C. W. Siemens. Considering that the object in view would be most completely met by a design which should combine lightness and convenience of construction, with the maximum degree of stability and resistance to sudden strains, as well as to oxidation, he was led to abandon the ordinary method of securing poles by setting a considerable length of them in the ground, and to make use of a horizontal wrought-iron foot-plate buckled or corrugated into the form of a shallow or inverted dish, which combines a great degree of rigidity with a peculiar elasticity, which enables it to yield without injury to sudden and considerable strains. The portion of the post which is partly buried in the ground, and is therefore exposed to the action of moisture both from the earth and the atmosphere, is made of cast-iron, and of a tubular form. This tube is fastened to the foot-plate by three bolts, and is provided at its upper end with a socket for the reception of the upper tube. The latter, which forms the principal part of the pole, above ground, is made of wrought-iron. The upper tube is cylindrical for a distance of about a foot above the socket, and from thence tapers gradually to the top. This form ensures a distribution of metal, which, with a minimum expenditure of material, gives a maximum degree of rigidity or resistance to a horizontal strain. The upper and lower tubes are cemented together by means of a fused mixture of sulphur and oxide of iron.

The height and dimensions of these poles vary according to circumstances. If only one or two wires are required, and economy is an object, poles having a total length of 19 feet 8 inches are used, standing 17 feet above the ground in their position, it being usual to place the pole 2 feet 8 inches in the ground. The total weight of such a pole is 183 lbs., as it may be conveniently in three separate parts, the weight of the heaviest piece not to be less than 100 lbs. At all points where the line is exposed to an extraordinary strain, a heavier pole, weighing 258 lbs., is made use of. For a heavier class of lines a larger-sized pole is made, weighing 334 lbs., with extra poles weighing 500 lbs. The ordinary number of poles to a mile is about twenty-one.

Iron poles of this description were first erected by the firm of Siemens Brothers, in Spain and South Africa, as long ago as 1865. Since that time more than 180,000 of these poles, representing over 9000 miles of line, have been erected in New Zealand, Ceylon, India, Persia, Russia, Mexico, Brazil, the Argentine Republic, Chili, and Peru, and are said, in all cases, to have remained in perfect working order ever since their erection.

As a rule the Siemens poles are estimated to cost from two to three times as much as good wooden poles of corresponding strength,—say from 6·50 to 17·50 dollars each, according to size and strength.

In many countries, however, where both wooden and iron poles would have to be transported over great distances, the latter means are usually available in half-civilised countries, as poles become as cheap as wooden ones at the point of destination, owing to their weight being so much less, and their transportation so much easier, on account of being carried on a comparatively insignificant weight and bulk. It will, therefore, be seen under what in tropical countries where wood is subject to rapid decay, and where wooden poles have to be renewed every few years, that the relative advantages of iron poles of this description are very great indeed. In civilised countries, however, the advantages to be gained by the use of these poles instead of wooden ones is not so obvious, and we do not find that they have as yet been introduced to any considerable extent.

The rapidity with which wooden poles were found to decay, and the expense and interruptions occasioned by the continual renewal of the poles and the transfer of the line from the old poles to the new, led the telegraphic administration of Switzerland to construct an experimental line upon iron poles, as early as 1858.

The experiment was continued up to 1868, but the T iron which was employed for building the line proved was replaced by two or more cylindrical poles screwed together by means of a threaded coupling. After an experience of three years, which served to demonstrate the fact that this manner of joining the poles did not insure a sufficient degree of rigidity, this form was in turn abandoned. After successive trials made with specimens of various designs, it was at length decided upon to use conical tubular poles formed of a single piece, as this seemed likely to fulfill all the necessary conditions.

The length of these poles varies, according to circumstances, from about 6 feet 4 inches to 24 feet 7 inches, but practically they have always remained within the limits of 21 feet 4 inches and 18 feet 8 inches. The minimum diameter measured just below the top of the pole is invariably 4 inches; it increases regularly towards the base in all cases, so that a pole 10 feet long has a diameter of 7·56 inches, and one of 18 feet 8 inch pole a diameter of 9·25 inches, at the base. The thickness of the iron is uniformly 0·2 inch.

The poles are firmly secured in the ground by means of sockets of stone whose dimensions depend upon the length of the poles. For the small sizes these sockets are about 2 feet square. The insulator brackets are placed in round holes drilled transversely through both sides of the pole, and are fastened by iron wedges or keys.

The durability of these poles is of course almost unlimited, provided they are properly covered, from time to time, as may be required, with a coat of varnish for the protection of the iron. The results obtained in regard to the insulation are said to be not unfavourable, and the Swiss administration has had reason to be very well satisfied with this system of construction. It protects, however, one inconvenience, which could hardly have been foreseen, which will nevertheless be somewhat difficult to remedy. This inconvenience results from the comparatively small number of wires that these poles are capable

3476. S. C. Denis, of Surrey. *Improved means o preserving telegraph signal posts and other wood post from dry-rot and decay.* Dated October 22, 1873.—This invention has reference to improved means o preserving telegraph, signal, posts, and other wood posts, the lower ends of which are inserted in the ground, from dry rot or decay. According to this invention the lower parts of such wood posts are sur rounded with a collar or casting of zinc or othe suitable metal, the upper and lower edges of suc collar being bevelled off and either forced into the wood, or caused to enter a saw cut or channel formed at an angle in the surface of the post around which it is placed. When the plate or collar of zinc is fixed around the post, the edges are soldered together to form a perfectly water-tight joint.

3437. E. T. Hughes, of the firm of Hughes and Son, London. A communication from *L. B. Blythe*, of Bordeaux, France. *Treating wood and vegetable fibre in general by "carbureted steam" and compression, to strengthen and preserve such matters from decay.* Dated October 22, 1873.—I construct an apparatus consisting of a strong iron chamber forming an oven, and a long boiler extending the whole length of the oven is set in the brickwork below it. Flues are arranged around the oven to heat it externally, and are connected with a furnace or furnaces. Pipes with stop-cocks connect the top of the boiler with the upper part of the oven, and a return pipa also provided with a stop-cock connects the bottom part of the oven with the bottom part of the boiler. Safety valves are provided to the boiler, the chamber or oven and the boiler is charged with water, to which is added from one-third to one-fifth by weight of heavy hydrocarbon oil. The water and oil is heated together, making "carbonetted steam," which passes into the oven by the upper pipes, while the liquids condensed in the oven return to the boiler by the lower pipes which connect them together. After the temperature in the oven has attained 212° F., the heating is continued till all the albumen and sap in the wood is decomposed into resin, acetic acid, and oleaginous matter, which are distilled for after treatment.

3083. A. Wilkinson, of Middlesex, engineer. *Improvements in Coating and Preserving Telegraph Wires, Ropes, and Cables.* Dated September 19, 1873. This consists, first, in coating the fabric-covered wire with a solution of white lead, pitch, boiled or raw linseed oil, tallow, and asphalte, and afterwards coating the threads or strips of fabric over the wire by passing the wire through a bath containing white lead, pitch, and boiled and raw linseed oil; thirdly, in first coating threads in a solution of white lead, pitch, or its equivalents, until they become dry, these threads being then wrapped on to the bare wires, which are afterwards further coated by lead or other metal.

ART.

In science is systematised knowledge, art is applied knowledge, or the application of universal laws to particular facts. It is derived from *ars*, strength, the primary sense of power, and therefore of skill. It is the modification of things by human skill to serve some intended useful purpose. There are many branches of art as there are of science. Thus we have the art of shipbuilding, of gardening, of painting, of engraving, of printing, of telegraphy. And not only have we the art of producing, but that of criticism, or of testing the genuineness, truth, or correctness of things done by others. A judge of pictures tests the truth of a production before him, by comparing it with certain laws that he has learnt from observation, or has been taught by experience; and an electrician tests the value of an instrument submitted to his inspection, by comparing it with certain principles or conditions that he has acquired by his scientific training. A scientific training increases many times the pleasure produced by an inspection of the beautiful productions of ancient and modern skill. The telegraph engineer invents a certain instrument by applying those particular facts that observation and study have brought to his notice, and the telegraphist applies his art in making use of the instrument so invented. Universal laws and particular facts are the extremes both of science and art, but science ascends from phenomena to conditions, and art descends from conditions to phenomena. Telegraphy may be

There are the useful arts and the fine arts—the former, besides the various trades, include telegraphy, and the latter comprehend those productions of human genius and skill which are addressed to the sentiment of taste or to the imagination. In fact a science teaches us *to know* and an art *to do*, and all the more perfect sciences lead to the creation of corresponding useful arts. Psychology is the basis of the art of education, physiology is the foundation of the art of medicine, astronomy leads to the art of navigation, and heat to that of railway locomotion. Chemistry is the root of many useful arts, and electricity is the foundation of the art of telegraphy. Although the primary position has been given to science, it must not be forgotten that art is usually the precursor of science, and that it is from the art itself that the science has often been evolved. The fact that science is systematized knowledge implies the existence of isolated facts upon which the mind is able to generalize, and these facts are usually the consequence of the pursuance of the arts. Hence an expert in the art by no means implies an expert in the science, and unfortunately the two are rarely combined, especially in the telegraphic world. It is a very regrettable fact, for none have such opportunities of acquiring a knowledge of the science of electricity as those who are engaged in pursuing the art of telegraphy.

ON TELEGRAPH CONSTRUCTION.

By JOHN CLAYTON.

(Continued from vol. iii. page 291.)

4.—DISTRIBUTION AND LAYING OUT OF STORES.

The survey being complete, the consents obtained, and the stores selected, the next operation in the construction of a line is the distribution and laying out of the materials.

In a line to be erected along the highway, it becomes necessary to select, at convenient distances, say fifteen or twenty miles apart, temporary store depôts, for accumulating the smaller stores which it would be unsafe to leave exposed to possible depredations or damage. These depôts should be selected with regard to the facility with which the stores can be collected, either from an adjacent railway station or canal, and with which they can be distributed as required over the work as it proceeds. Poles, wire, and such like heavy materials, the cartage of which is costly, should be sent to the nearest railway or canal stations along the route, independantly of the sub-depôts previously referred to: the length of the poles and

The Eastern Telegraph Company have just opened a new route to Egypt across France, *viâ* Marseilles and Malta. They have leased a special wire for this purpose from the French Government.

PNEUMATIC TELEGRAPHS FOR LONG DISTANCES.

Paper read at the meeting of the Society of Civil Engineers of Paris, on the 4th June, 1875.

By M. L. CHIDDEN.

(Concluded from page 208.

I now proceed to the considerations of the speed with which the boxes will travel in a pneumatic line of unlimited length, in which, by the methods described above, the vacuum will be kept at 0·5 metres of mercury, and the pressure, admitted by the relays at intervals of 7,000 metres, equal to 0·76 metres of mercury; the tube to be one-tenth of a metre in diameter.

My point of comparison will be the speed in the tubes of the Paris system, where a pressure of 0·4 metres of mercury gives a speed of 20 metres per second, in a line 1,000 metres long, and 0·008 metres in diameter.

The increase of diameter will increase the speed in the proportion

$$\frac{100}{65} = \sqrt{\frac{10}{8}}$$

say 25 metres per second.

The fact that the line if kept exhausted of air will reduce the friction in each length of 1,000 metres to an average equal to that of 600 metres at most, for at the beginning of each section, that is to say, at the moment when the train passes the pressure relay, there is no column of air travelling with it; at the termination of the section only, will the column of air which drives the train have a length of 1,000 metres. If the vacuum were perfect, the average friction length of the column of air would be but 500 metres. The diminution in the frictional length of the column of air gives an increase of speed in the proportion

$$\frac{1000}{600} = \frac{33}{24}$$

The speed, raised to 25 by the increase of diameter, now becomes

$$25 \times \frac{33}{24} = 36 \text{ metres.}$$

We have then the increase of the difference of pressure, which is also in the ratio of the roots

$$\frac{26 + 50}{40} = \frac{115}{65}$$

The application of this last ratio indicates a speed of nearly 70 metres per second.

This is an enormous speed, and would in all probability be attended with some inconveniences, but it is evident that we should work with the highest speed possible.

Now, observations made with trains running under similar circumstances at speeds of 50 to 55 metres, have shown that these practical speeds are quite admissible in regular working. It is only necessary to employ a very strong material, arranged in such a way that it shows shall wear without wearing the line; this end is attained by fitting the rubbing parts of the boxes with a cutter useful than that composing the line.

The New Western Union Office of Cincinnati, Ohio.

The well known building at the northwest corner of Fourth and Vine streets, formerly occupied by Rogers & Eckstein in the drug business, has lately undergone, in a recasting of its stone facings, and in the manipulations by carpenters and joiners, frescoers, paper hangers, etc., so complete a change that, with its well restored raw materials, the rejuvenation renders it better than new. The last credit was given on account of its proposed occupation principally by the Cincinnati office of the Western Union Telegraph Company; and, in a minor way, by railroad companies and other business houses. Not as yet has the building received its finishing touches for habitation purposes, though the railroad companies have already established quarters on the first floor.

The Fourth street front of the ground floor is taken up by the passenger ticket and freight contracting agencies of the Indianapolis, Lafayette and Chicinnati and Cincinnati, Hamilton and Dayton Railroads. These railroads have recently entered into a pooling arrangement as regards the profits on Western freight and passenger fares, and having done this, their agents are able to occupy a joint office in harmony together. Mr. E. L. Stark is passenger agent for the Indianapolis, Cincinnati and Lafayette Road, and Mr. A. F. Lindsey for the Cincinnati, Hamilton and Dayton Road. Mr. J. H. Lynch is freight agent for the Indianapolis, Cincinnati and Lafayette, and Mr. W. H. Allen for the Cincinnati, Hamilton and Dayton. The corner they now occupy is more convenient and convenient than the time honored one on Third street.

The rest of the first floor of the building will be taken up by the Western Union Telegraph Company, which will not be ready to take possession for a month or more. The batteries will be located in the basement, and will consist of fifteen hundred cups. The number of wires running into the office from points outside of the city will be fifty-one, and including the city "loops" will be seventy-five or eighty. In the way of battery capacity, the new office will be much enlarged, as in the old place there are only one hundred and eighty Grove cups and two hundred of the Callend description.

The front of the counter, on the street floor, will be the office of the manager and the receiving and delivery clerks, and the wall fronting on Vine street, will be situated the offices of the superintendent and his clerks.

The second and third floors will be for rent for offices. On the fourth floor will be the office of the Gold and Stock Company, and the telegraphic operators' reception room for those who call to see the operators, and a cloak and lunch room for lady operators. The book-keeper's room, on this floor, fronts on Vine and Fourth streets, and its dimensions are fifty-six feet by twenty-eight feet. The entire fifth story, of dimensions of one hundred and four feet by twenty-eight feet, will be taken up by the tables of the operators.

The employes of the company are U. T. Williams, Superintendent; Frank Armstrong, manager; R. H. Johnson, chief operator, and three assistants; A. F. Lindsey, night operator, and two assistants; and W. A. Fowler, chief book-keeper. There are sixty-one operators, night clerks and office boys, who perform clerical duty, and fifty-two night and day messengers. The business of the company is very extensive. For the month of August the number of messages passing through it was 112,256. The collective of press reports. For the press the number of words handled during the month was 2,917,008. The average is small, as during winter, when Congress and Legislatures are in session, and there is more general news, the number of words passing through the office is more than doubled. In summer the average of city messages is about 1,000 a day, and in winter, when business is brisk, from 1,200 to 1,500 city messages are handled.

The company will retain an office at the old headquarters, and will extend it in order to accommodate the bankers and other down town business men, who frequently require the transmission and reception of messages with a rush.—*Cincinnati Commercial.*

Excellent and Successful Telegraphic Management and the Result.

In the last number of THE TELEGRAPHER, in commenting upon the Annual Report of President Orton, we incidentally alluded to the management of the Montreal Telegraph Company and its satisfactory results to the stockholders and the public. It has occurred to us that the subject could be profitably treated more at length, and the contrast to the management and results of telegraphic enterprises in the United States generally is so striking, that it may serve a useful purpose to present the matter for the consideration of those who may be engaged in initiating or managing similar enterprises.

The Montreal Telegraph Company was organized in January, 1847, commencing business in July of that year, with a line between Toronto and Quebec, a distance of 340 miles. The amount of the original capital was $50,000, which it will be conceded was by no means excessive for the length of the line. The company appears to have been carefully and economically managed from the start, Sir HUGH ALLAN, its President now, and Mr. JAMES DARKER, its present Secretary, having been originally connected with its management. A definite policy, and, as it has proved, a very wise one, was adopted, which was to pay to the stockholders a reasonable dividend on their investment from the proceeds of the business, and devote the surplus, whatever it might be, to extending and strengthening the lines and furnishing additional facilities, as they were required. This policy has been steadfastly adhered to up to the present time, and under it the line has been exceedingly profitable to the fortunate holders of its stock; the public has been provided with adequate telegraphic facilities as they were needed, and the company has become one of the leading telegraph organizations of the Continent. A dividend of ten per cent. has been paid to the stockholders every year since 1851, with the exception of two years, in which the dividends were eight and nine per cent., respectively. The surplus expended in extending the lines has been returned to the stockholders as a stock bonus, from time to time. In this manner the capital of the company has been increased from $50,000 to $1,750,000, and its lines have been extended throughout the present Canadian Dominion—the great- est length of line ever worked by the company being 1,750 miles. The company now owns and operates 12,000 miles of wire, 10,000 miles of wire, and has 1,300 offices. It will be seen that the present capital of the company is by no means excessive, being only $140 per mile of poles owned by the company. The lines and equipment are kept in excellent condition, and ready for any demand which may be made upon them. The tariff was reduced, from time to time, until January 1, 1870, when the low rate at present existing was adopted, and the company has now a uniform tariff to all Canadian points of twenty-five cents (gold) for a ten word message—date, address and signature free, as on United States lines—and one cent for each additional word. To this there is but one exception. When the distance is less than 32 miles the rate is 25 and 1 (gold). The American currency rate of the company is 20 and 2. At the time this reduction was made it was regarded by telegraph managers and others on this side of the line as a hazardous one, but the result has proved that the management of the company entered intelligently, and the reduced rate has proved not only satisfactory, but profitable—the revenues having steadily increased.

In the management of this model company there is no expensive red tape; everything being simplified as much as possible, as we understand; and while the agents of the company are held to a rigid accountability, it is not considered necessary to expend a dollar to discover a possible discrepancy of ten cents.

The Montreal Telegraph Company has no debt, either bonded or floating, and it is hardly necessary for us to state that its stock is held in high estimation by investors. The shares, whose par value is $100, are held at $125, and are seldom to be obtained even at the latter figure.

It should be remembered in this connection that the territory covered by the company is much inferior, telegraphically, to that of the principal United States companies, being more sparsely settled, and embracing but few large cities or places, and none equalling many in our own country. It cannot be said either that the company has not had active competition to contend against. During its existence several rival telegraph companies have been organized, and the Dominion Telegraph Company, now in successful operation, is by no means a competitor to be despised, and is pursuing, under its present management, a policy similar to that of the Montreal Company, and with satisfactory results. The Dominion Company is yearly extending its lines, and the season now closing will have added 700 miles of line to that which it previously had. This company is also paying dividends regularly to its stockholders—that for last year, and we believe for the year previous, having been at the rate of 5 per cent. In fact, telegraphic enterprises that do not pay dividends are not much in favor with our Canadian friends.

We do not know of any existing telegraph enterprise in this country, with the exception of the Northwestern Telegraph Company, which can compare favorably with those of which we have been stating the simple facts. We do not desire or intend to make any invidious comparisons, but these facts and figures are certainly significant, and worthy of the earnest consideration of our telegraphic managers, and especially of those who are now in view the immediate future may now telegraphic enterprises. We have frequently pointed out what have appeared to us to be errors in telegraphic management, without the use of the less satisfactory pecuniary results. One of these is much too common, and cannot but be considered a very damaging one—that is starting companies with its inflated nominal capital, selling shares at a quarter to half their nominal price, and distributing large amounts of bonus stock to promoters and contractors for which it can receive no adequate return. If the nominal capital of a telegraph company represented the real actual investment at the start, and was increased only as the property of the company would warrant the expenditure of revenue or by additional investments, it will be seen that a heavy load which most of our telegraph companies have to carry would not encumber, and prevent its pecuniary success, and the money would be more carefully husbanded and economically expended. It is time that American investors should get over the fallacy which has received to pressure so much attraction, and been believed in quite generally, that dividing a dollar into two or more parts will make it go the further two or more dollars, as the case may be, while in fact the result is merely to impair or destroy its intrinsic value. Inflating the capital of a telegraph or any other corporation only decreases the ability to pay dividends on the nominal amount.

With a reasonable capital representing the actual value of the property, and economical management, there is no reason why telegraph companies in this country should not show results as handsome as that of the Montreal Telegraph Company. There must in each case be no "dogs" to absorb the profits, either in extravagant salaries or profitable pickings by the officials or contractors, in which the shareholders do not generally participate. The lines must be managed for and in the interest of the investors and of the public, for whose service they are supposed to be constructed and operated. While remunerative prices should be exacted for the service rendered, these should be as reasonable as is compatible with the proper and adequate compensation of the employés, the maintenance and extension of the facilities, as required, and a reasonable return for the investment will permit.

We should very much like to see a national telegraphic enterprise thus established and conducted in this country, and have no doubt but that its success would be assured, even with all the odds that might exist against it at the start. If the lines and companies now competing with the great telegraphic corporation of the country could be brought under one control and management, and consolidated on a fair and reasonable basis as regards capital, we have no doubt but that the additional capital required to extend and complete the system could be obtained without very little difficulty. The obstacles to such a consolidation, so far as the majority of their stockholders are concerned, are by no means so formidable or difficult to be overcome as is generally supposed, and we once more renew our oft repeated and urgent recommendation that they shall, in their own interest and for the general welfare, take such action as may be necessary to bring about the result which all concerned admit to be desirable and necessary, but which, up to the present time, very little effort has apparently been made to secure.

Correspondence.

No notice will be taken of anonymous communications

Congress and the Telegraph.

WASHINGTON, D. C., *June 3*.

TO THE EDITOR OF THE TELEGRAPHER.

Less than three weeks of the present session of Congress remains, and the Committees are working industriously to get through with the business which is absolutely necessary to be done before the adjournment.

As there is scarcely a probability that any action will be taken upon the matters during the brief time remaining, any information under the familiar head of "Telegraphic Intelligence" can scarcely be expected to prove of engrossing interest. Still it is necessary that the record should be as complete as possible for future reference, and that we may know hereafter where to pick up the threads of events.

The House Committee on Foreign Affairs have agreed to report a bill relating to telegraphic communications between the United States and foreign countries, general in its character, and under its provisions the Secretary of State is authorized to grant permission to lay cables to any citizen or association upon the conditions prescribed. Similar bills have been presented and reported heretofore, and one or two have passed either the House or Senate, but have ultimately failed to become laws. It is not likely that any definite action can be had on this new bill at this session. It will be reported and go over with the unfinished business.

There was no Wednesday of last week another session of the "War, Orton and Western Union Telegraphing Society," —this time before the House Committee on Appropriations. The Western Union Company was represented by their counsel, Messrs. Lawrence and Porter, of New York, and Mr. Geo. B. Prescott, of Boston. Objection was raised with the usual amount of statistical information. Mr. Hubbard was also present, but he had had his say previously, and therefore did not attempt to enlighten or bolge the Committee.

Mr. Lawrence addressed the Committee at some length, arguing in the first place that the evidence of Mr. Hubbard is inconsistent. This was rather a new point to the latter, and did not seem to strike him favorably. Mr. Lawrey proceeded to introduce statistics, prepared by Mr. Prescott, which may be of sufficient interest to be given in full. The first table was GRAPHIC, showing that the Western Union Company operates more miles of telegraph line than all Europe. Sweden, Norway, Switzerland, Spain, Hungary, Bohemia, Denmark, Norway, Austria, Prussia, Italy, Wurtemburg, and Egypt, previously examined, it operates more miles of telegraph, and annually transmits more messages than all Germany, Spain, Hungary and Australia, notwithstanding the fact that these countries contain nearly the same area of territory, and nearly four times the population of the United States. Europe has a population of 300,000,000, and sends annually 50,000,000 messages, being one message to six persons. The United States have 40,000,000 inhabitants, and the Western Union Company alone sends 15,000,000 messages, being one message to two and a half persons. In 1868 England had 80,656 miles of telegraph wire, and in 1873 had 103,492 miles, being an increase of 22,836, or 28 per cent. In 1866 the Western Union Company had 75,000 miles of telegraph wire, and in 1873 175,357, being an increase of 99,357, or 120 per cent. In 1866 England had 9,161 telegraph offices, and in 1873 5,471 do., being an increase of 3,325, or 154 per cent. In 1866 the Western Union Company had 2,250 offices, and in 1873 5,000, being an increase of 2,750, or 161 per cent. In 1867 England transmitted 7,500,000 messages, and in 1872 14,250,000, being an increase of 7,250,000, or 97 per cent. In 1866 the Western Union Company sent 5,891,284 messages, and in 1873 13,362,651, being an increase of 7,471,433 messages, or 123 per cent.

In 1866 the average toll upon the English lines was 38 cents per message. In 1874 the average toll is 23 cents, being a reduction of 15 cents per message, or 39 per cent. In 1866 the average toll upon the Western Union lines was $1.10 per message, and in 1874, 55 cents, being a reduction of 55 cents per message, or 50 per cent.

Another hearing was to have taken place on Friday, but the committee came to the conclusion that the pressure of business upon them was too great to admit of their devoting any more time to the subject at this session, and so notified the parties, but adding, that any letter that might be submitted would be carefully considered.

Judge Porter was to have addressed the committee on Friday on behalf of the Western Union Company; and three reasons to believe that it was fortunate for Mr. Hubbard that the matter went over, as he would have been likely to have some of his statements answered, and the Judge an opportunity to take him in hand.

This ends the farce for the present session, and it is to be regretted that it is to the poorer of any person to recuse and revive it another session. It is to be hoped all hands that neither Mr. Hubbard's assigned subject nor a Government Telegraph project, stands any chance; and it is under the circumstances unprofitable that the telegraph interests of the country should be put to contribute public and expensive time themselves against the actual attacks of any man or set of men.

In order that the public may have the evidence in Washington published, Mr. Hubbard is engaged in various lobby schemes, and the publishers of the several Bank Note Engraving Companies in their contract with the Treasury Department for the printing of the currency, which, under existing laws, has been transferred to the Department.

CAPITOL.

TELEGRAPH PROFITS.—The gross receipts of the Great Northern Telegraph Company last year were 158,031, and the net profits, after paying all expenses, were 64,586; as the latter result called for the payment for the year of 94,3551. *Eng June 26*

Long Words in Conference.—One of the results of a recent telegraphic conference at St. Petersburg, is that in messages sent from India to England, or any other country in Europe, and vice versa, any word containing more than ten letters is counted as two words, and charged for accordingly. *Eng May 1/76*

Australian Telegraphy.—The steamship Edinburgh, with the contract for the Telegraph Construction and Maintenance Company (Limited), recently brought out to Australia a new cable, which is to be laid from Port Darwin to Adelaide—about 1,200 miles. The Duke of Sutherland, we learn, is to connect a telegraph line between South America and Western Australia.

TELEGRAPHY IN SCOTLAND.—The sixth anniversary of the transfer of the telegraphs to Government was last week celebrated by the telegraph staff of the Glasgow General Post Office. Mr. HUNTER, superintendent of the Central Telegraph Office, who presided, said that there were now about 800 telegraph stations in Scotland, having the uniform charge of 1s. per message, and the whole staff employed numbered 1,200. Referring to the work of the Glasgow Central Office alone, he observed that they were in direct communication with 197 offices and various other offices by means of 2,000 miles of wire, annually passing through their hands (in addition to an enormous amount of express business) 2,000,000 public messages, and this vast number was steadily increasing. The work passing through the Glasgow Postal Telegraph Office gave employment to nearly 200 persons. This society held a meeting in Edinburgh last *Eng May 1/76*

Resumption of Dividends by the Western Union Telegraph Company.

A MEETING of the directors of the Western Union Telegraph Company was held at the Executive office of the company at noon on Wednesday, June 3, at which President Orton presided, and presented the following report, which was accepted and adopted, together with the annexed resolutions:

To the Directors.

The net profits of the company for the eight years commencing July 1st, 1866, and ending June 30th, 1874—three for the present month of June not yet audited—are $24,077,503.23.

Of this sum there has been distributed in dividends to stockholders, as follows:

Paid for the construction of lines, and the erection and the enlargement of additional wires	$4,537,722 76
Dividends paid in cash	14,028,953 23
Do. do. subject to an annual rental	200,000 00
Western Union stock (72,071 shares)	4,804,133 33
Quarterly Stock Telegraph Company stock (67,716 shares)	1,171,680 00
International Ocean Telegraph Company stock (20,000 shares)	1,000,000 00
Pacific & Atlantic Telegraph Company stock (26,666 shares)	266,660 00
Anglo-American Telegraph Company stock (21,000 shares)	10,000 00
Do. do. do. do. (500 shares)	20,000 00
Western Union bonds redeemed and cancelled	1,060,000 00
Premium on bonds purchased and not yet cancelled, including interest accrued	60,000 00
Real estate, exclusive of telegraph property	218,753 84
Cash in the Pneumatic Tube Telegraph	45,336 00
Cash in the Merchants' Union Telegraph	12,852 12
Western Union bonds not cancelled ($7,000)	6,750 00
Premium of stock, and loans, redeemed and cancelled	42 50
Total	$19,595,907 78
Leaving a balance of net profits	$4,481,595 45

Represented as follows:

Cash on hand and from agents	475,000 00
Advanced on account of the new building, fitting-up and lay-out, and for the purchase of mortgages loans	1,000,000 00
Real estate, materials, and other supplies on hand	3,006,595 45
	4,481,595 45

Of this sum, $1,000,000 is the net profit for the six months ending June 30th, being about $2,000,000 being the net profit of April, May and June. This is an increase of more than $250,000 over the net profits of the same three months last year (1873). In view of this favorable increase in rates throughout the South and West, which took effect on the 1st of July, 1873, and of the universal improvement in most kinds of business which followed the financial panic of September last, such a result is most encouraging, and seems to furnish grounds for the belief that, with the general business of the country improved, the receipts and profits of the company will continue to increase. The Executive Committee have had under consideration for some time past, the subject of a resumption of the suspended dividends upon the preferred stock. They were at first disposed to recommend a dividend equal to the net earnings of the current six months, which would be about 4 per cent on the capital outstanding. To do this, however, would necessitate either the funding of the amounts expended in the construction and on the new building, to take care of the loan made for that purpose, or the sale of a portion of the common stock now in the treasury. On mature deliberation it is deemed advisable to do neither, but to limit the dividend to the profits of the current quarter. This course they have unanimously advised in

the recommend to the Board, and, in pursuance, of which the following resolutions:

Whereas, The business and financial condition of the company justify the resumption of regular dividends by the stockholders, which, in the judgment of this Board, should be made quarterly; therefore,

Resolved, That a dividend of two per cent. from the net earnings of the three months ending June 30 be, and the same is hereby declared payable on the 15th day of July next.

Resolved, That for the purpose of such dividend the stock books be closed at the close of business on the 30th instant, and be opened on the morning of the 16th of July.

W. H. GARNER,

Unreasonable Rivalry in Australia.

THE Melbourne, Victoria, correspondent of the *Saturday Review*, in a communication to that newspaper, calls attention to the necessity which exists for a more rational system of management of the Telegraph Department of that colony. It seems that Mr. Longmore, who has been Postmaster-General for the last two years, in order to diminish the difference between the receipts and expenditures of the telegraph branch of the postal service, has cut down the maximum competition rates to a point which is unremunerative. The reduction in the rate between Melbourne and Sydney, from £250 to £100 per annum, and the consequences it has had in necessitating the department to engage in similar service in other colonies, Sydney, where there are now three liberally organized, much to the detriment of the service. He says:

Very recently three first class men have left the department to accept better positions in some of the other colonies. One of these received a salary of £180 per annum, the maximum pay for a first class man, in almost any other part of the world would be better rewarded. The Sydney Government give him £280 per annum as a minimum salary. Two other Victorian operators, one receiving £195, the other £168, go to the same country, each receiving there £60 per annum. In fact, the salary adopted towards the service here is killing it. There is no reward for any of the skill, one of the most skilled branches of the public service, and I apprehend that in a short time the Victorian telegraphic service will rank in every respect as the lowest in all the Australian colonies. The Telegraph Department, like railways, wants at the head of it a man of some standing in life, whose efforts will be directed to maintaining the revenue by increasing the efficiency of the service, rather than by cheese-paring the salaries of able men, and making it appear impolitic to increase the staff, and thereby to avoid having to fix proper rates for the value of securing its benefits, undertake the cost of its construction and maintenance. This is the smarter lesson taught by the history of southern the towns at Quarantipeque, Castlepeque, Cornwallis, Antigonish, Tatamagouche and Maccan.

"Guatemala stretches out her hand towards us, and we, in the exuberance of our feelings, cry, 'Come, enter, I am the *ensalig* season, to connect with ours. Next morning we find ourselves in a friendship and under the chain of fraternity between the two neighboring states, I helped some merchants to get a railway, and such are leads onward to ultimate perfection."

The people of Guatemala appreciate the need of the cost of maintenance and operation, though they are increased considerably. Associated with it, if therefore, is the necessity of increasing the revenue to meet the Government necessarily demanded—that is, if Guatemala is to pay a fair interest upon the capital invested.

On the 20th of December, 1873, the Supreme Government made a contract with Mr. Charles H. Billings, as an inducement for the commencement of the line of telegraph between the capital and the port of La Libertad. Having procured the necessary material Mr. Billings began the work on the first of March following, and completed the line, office in La Libertad on the 27th of April, 1870, and that of Santa Tecla on the 20th of May following. On the 24th of May the contract for the Western line was signed, on which the first instalment that proved to be due was received from Don Nejapa in this city on the 20th of October, and the second instalment was received at Quezaltenango on the 20th of February, and Santa Ana on the 20th of following December, and the last that of Jacapitio the 6th of February, 1871; the work having lasted nearly a year, in which interval a sufficient number of men were employed to construct the telegraphic system as to carry on the business of the rising stations.

Mr. Billings, the Territorial Government of Manuel Gonzales, penetrated with the importance and utility of the telegraphic system, appointed Mr. Stanley McMillor the eastern lines, with offices at Sonsonate, Chalchuenago, Tihlanco, Sensuntepeque, Cojutepeque, San Vincente, Zacatecoluca, Cuscluan, Chinameca, and San Miguel, the central office was opened on June 18th, 1872.

It being found very difficult to maintain this line, which followed the cart road from Zacate-Coluco, Guatemala, to Santa Ana, on account of the frequent encroachments of the bush, and the wires being interfered with the wires, the route being almost unpassable—a new contract was made, June 8, with Mr. McNider, for the building of a direct line between Chalchuapa and Santa Ana, which was completed on the first of July following, under the direction of Mr. Money. To avoid the dense forests and uninhabited districts it was proposed to construct this line through the open plains and valleys to the north of the volcano of Sigunteyepec, but on arriving at the margin of the Lempa, with the view on the 19th of that month, he was obliged to suspend operations on account of the opposition of the Governor of San Vincente. Finally, the Government not appreciating the advantages of the telegraphic system, refused to pay the rents, which were now in arrear, and, decided, against the opinion of the contractor, upon another route, which occasioned three months' delay in the construction of the line, and increased the cost and subjected it to the same difficulties and disadvantages before-mentioned.

The inhabitants of several towns and cities, eager to possess the advantages of telegraphic communication, offered to take upon themselves the expenses of construction and operation, which resulted in an extension of the lines of seventy-nine leagues, which brings all these places in instantaneous communication with the capital and the rest of the Republic. At the present time there are in operation 1,000 miles of wire in the three districts mentioned. Besides the principal lines of the system, there are upwards of 300 miles of wire constructed, the lines unstrung awaiting for the completion of the wires, which are much larger than (No. 4 Morse) ordinance is at four times) the private lines used.

The remainder of the report is occupied with details of accounts, orders of organization, and the necessary for more executive authority being vested in the Director or Superintendent of the system.

The Survey for the Pacific Cable.

THE U. S. steamer Tuscarora, engaged in soundings for the Pacific Cable, arrived at Yokohama, Japan, April 22d, after a passage of fifty-four days from Honolulu, Sandwich Islands, via Port Lloyd, Bonin Islands. The survey of the Southern route, from San Diego, California, to Yokohama, via the Sandwich Islands, is now complete. The result of the last portion of the survey, from San Diego to Honolulu, has already been published in THE TELEGRAPHER, together from the report of Commander Belknap to the Navy Department, dated May 25th, and bearing that date. Soundings were generally very close for the work, and over seventy-three casts were made, the deepest being 2,287 fathoms, at which depth the working of the patent reel of Mr. William Thomson and the plans were was so admirable and satisfactory as ever. At that great depth a person standing on the topgallant forecastle, and watching the running out of the wire from the reel in the paying-out, could tell the moment bottom was reached.

A glance at the profile charts shows that after the seven bad prayer is reached, near San Diego, the land descends in comparatively gentle curves and undulations to the vicinity of the Sandwich Islands, with depth of 2,554 fathoms is found; thence, westward, the depth increases until the two hundred and fifty-seventh fathoming is reached, after one of those extensive plateaus so common in the Bonin group.

The bottom of the Bonin group is volcanic, and the character of its soil nearly uniform between San Diego and Honolulu, a range of submarine mountains is found to exist between the Hawaiian and Bonin groups, with peaks of varying character, the valleys swelling by light yellow-brown ooze or mud in the specimen cups, and the sides and tops of the mountains coral, limestone and sand, with fragments of lava. In three or four instances, too, solid rock was struck, the cup coming up empty and the points freshly battered. In others the lead from the plateaus was found to be covered with specimens and fragments of lava; and, in one specimen brought up, sixty miles from the land, was found material submarine peaks, quite a heap of the same material having been found on the top. It is also found all the way from the Bonin group to the coast of Japan, and, indeed, the entire region west of the Hawaiian Islands would seem to have been subjected, at some remote period, to volcanic disturbances.

Six of these submarine mountains were discovered, ranging from 7,000 feet to 12,000 feet in height, and thence inland, which rises scarcely more than from thirty to sixty feet above the surface, lies directly in this range. A cone shaped mountain, the land appears a depth of 1,400 fathoms, coral and sand being found on the sides, with other occasionally broken with large, black, volcanic looking rocks. Between the mountains the deep appearance characterized the bottom of the shores of the Bonin archipelago of the Japanese are all composed of broken coral and sand, and are not impracticable to explore that Marcus Island forms the apex of a volcanic cone or island, perhaps, in ages past, much higher than now. A thick growth of trees covers the island, and myriads of birds were flying over and around it.

The ocean bed between the Bonin and the coast of Jeddo Bay is irregular, as might have been sup-

grown it, I remained where I was in the pelting rain all night, and it was now my turn. Things then becoming serious I fully determined to try it at all risks, so plunged in and got on my knee but had a good spell, and was desirous of regaining his mate, he swam splendidly and regained the other shore." I remained there that day just to recruit myself, and then tackled it again with both knees and equipment, crossed successfully, and remained at the creek for the night. Next morning commenced the last two days, where with the saddle and as few loads as possible, quite made the attempt to cross [illegible] level. I had, however, been too sanguine, for I had hardly got fifty yards into the water when I found myself in deep water, when here and myself were rolled over and over in the water, the saddle-pad for the time being the only thing to float me up and prevent my drowning. However, by great exertion I got myself clear of my horse, and shortly after went bump against the other side, and succeeded in landing myself safely up to the surface, and straddled across a branch. On reaching my eyes on stream I saw my horse caught against another tree, but with his legs uppermost, so I swam him out for last, and just managed to get him away when he gave a struggle, freed himself, and floated in my direction.

As he came past, I made a grab and caught him in the fore-top of the bridle, and succeeded in pulling him up, and held him till I was quite exhausted, and then let him go, when he struck out and reached the bank a quarter of a mile below where he went in. The blood was now running freely from my nose, and I felt a dizziness coming over me, so moved higher up the tree, and having got myself a rest, I was determined to have a stop holding a knife, pipe, pouch and tobacco with me. I stopped myself for about an hour, and then started for when I found myself quite the worse for the fatigue of the day, and must have been there several hours, having started at daylight. I felt very weak, and my back and legs were literally skinned with the rasp on the saddle-pad. However, I got on my horse again struggled myself on with my head and shoulders first, above the saddle. I was getting on slowly, but soon made me shift out of that, and I got up as high among the branches as possible, and made a cushion of my head with twigs and leaves. Feeling desirous of a smoke, I lighted my pipe, and after a few puffs, I was sound asleep in my whiskers to dry, which they soon did, and so managed to breathe in a comfortable way. Next evening I began to feel hungry, and to add to my unpleasantness, the creek, instead of falling, kept rising slowly. I determined to vacate my seat; so, getting on to a limb about ten feet from the water, I made a dive head first in. When I came to the surface I struck out for my life, and down, down I went, and seeming to get a lot nearer the bank, and I came to a turn in the creek, where I made a great effort and managed to reach the edge and made land-ways with my feet. In the meantime the native police had been sent out after me, and the *Gympie Gold Mining* had a report in its columns that I had been drowned. I returned to my station, started again next day, and reached at the creek. A man was sent with provisions for me and orders to return; this I declined to do, and before the men left me had another try, but my horse knew too much for me, so I tried the same here. He, however, only got into swimming water when he plunged on it, turning short round, and I was compelled to swim myself and me, I being in the stream a middle one station. I then sent back a message for the two black boys, who came down two days after; and, at the earnest request of the men, I made another attempt, finding some broken bridges and thirty-five inches very calmly swimming behind. This magnificent record of history and intrepidness is reserved for those who have reached the topmost branch of the tree in their own particular line."

The Telegraph in Central America.

NOTWITHSTANDING the many difficulties which have had to be overcome, the telegraph line made considerable progress, and on the 15th of September the first semi-circle of a belt of the States of Central America, the State of San Salvador has been the most prominent in this work, and the telegraph has already connect many of its principal places, and are being constantly further extended. The lines are also being continued to connect that State with the adjoining States, and when the line to Guatemala is finished mail will be completed; and the construction of a line connecting San Salvador with Conzagua, the capital of Honduras, will soon be commenced.

From a communication, or report, by Mr. A. Money, the Superintendent of the Salvadorian telegraphs, to the Government, made at the commencement of the present year, which has been translated for THE TELEGRAPHER, an interesting account of the telegraphs in that State, and the difficulties which have been encountered in their construction, and the progress which was effected. The Central and South American telegraphs are owned and operated by the governments of the several States and countries, and are more extensively used for Government purposes than for private correspondence, though they are all open to private use, and the earnings for commercial and social correspondence increasing as the country is settled and developed, and the public become accustomed to the use of telegraphic facilities.

The interesting report of Mr. Money alludes, in opening, to the completion of the line of the Republic of San Salvador took the lead of her sister States in the introduction of telegraph, and to the obstacles with which she had to struggle, arising from the elements, financial embarrassment, and the hostile opposition of the her rustic population, and says: "From the City of Santa Ana to the frontier of Honduras, a distance of seventy-one miles and spanning the wide-spread plains, the line was built in the most substantial manner, and the poles are of iron. Such is the admirable work that, almost from the commencement of the undertaking, public opinion, manifested in its organization as it exists to-day, I have had the honor, in conformity in all the difficulties of its construction as in all its intricate counter material obstacles, to see that over the malicious inducements of its credulous enemies, until I behold it almost perfect itself, and come to an indispensable power in the life of the people; and I feel a glow of satisfaction and pride in having, each day increasing enthusiasm and its general utility among all classes of our population."

After referring to the good faith of the employés, to whom are reasonably entrusted the most important secrets and confidences in regard to private and government affairs, he alludes to the favorable appreciation of the service on the part of the municipal authorities and the people of the towns, and of the readiness with which for the sake of securing its benefits, undertake the cost of its construction and maintenance. This is the smarter lesson taught by the history of southern the towns at Quarantipeque, Castlepeque, Cornwallis, Antigonish, Tatamagouche and Maccan.

"Guatemala stretches out her hand towards us, and we, in the exuberance of our feelings, cry, 'Come, enter, I am the *ensalig* season, to connect with ours. Next morning we find ourselves in a friendship and under the chain of fraternity between the two neighboring states, I helped some merchants to get a railway, and such are leads onward to ultimate perfection."

The people of Guatemala appreciate the need of the cost of maintenance and operation, though they are increased considerably. Associated with it, if therefore, is the necessity of increasing the revenue to meet the Government necessarily demanded—that is, if Guatemala is to pay a fair interest upon the capital invested.

On the 20th of December, 1873, the Supreme Government made a contract with Mr. Charles H. Billings, as an inducement for the commencement of the line of telegraph between the capital and the port of La Libertad. Having procured the necessary material Mr. Billings began the work on the first of March following, and completed the line, office in La Libertad on the 27th of April, 1870, and that of Santa Tecla on the 20th of May following. On the 24th of May the contract for the Western line was signed, on which the first instalment that proved to be due was received from Don Nejapa in this city on the 20th of October, and the second instalment was received at Quezaltenango on the 20th of February, and Santa Ana on the 20th of following December, and the last that of Jacapitio the 6th of February, 1871; the work having lasted nearly a year, in which interval a sufficient number of men were employed to construct the telegraphic system as to carry on the business of the rising stations.

Mr. Billings, the Territorial Government of Manuel Gonzales, penetrated with the importance and utility of the telegraphic system, appointed Mr. Stanley McMillor the eastern lines, with offices at Sonsonate, Chalchuenago, Tihlanco, Sensuntepeque, Cojutepeque, San Vincente, Zacatecoluca, Cuscluan, Chinameca, and San Miguel, the central office was opened on June 18th, 1872.

It being found very difficult to maintain this line, which followed the cart road from Zacate-Coluco, Guatemala, to Santa Ana, on account of the frequent encroachments of the bush, and the wires being interfered with the wires, the route being almost unpassable—a new contract was made, June 8, with Mr. McNider, for the building of a direct line between Chalchuapa and Santa Ana, which was completed on the first of July following, under the direction of Mr. Money. To avoid the dense forests and uninhabited districts it was proposed to construct this line through the open plains and valleys to the north of the volcano of Sigunteyepec, but on arriving at the margin of the Lempa, with the view on the 19th of that month, he was obliged to suspend operations on account of the opposition of the Governor of San Vincente. Finally, the Government not appreciating the advantages of the telegraphic system, refused to pay the rents, which were now in arrear, and, decided, against the opinion of the contractor, upon another route, which occasioned three months' delay in the construction of the

The Builder of the First Telegraph.

A few days ago a telegraphic despatch from Maine announced the decease in that State of Mr. O. E. Smith, who constructed for Professor Morse the forty miles of magnetic telegraph from Washington city to Baltimore, which constituted the original of the vast system of telegraphs now extended throughout the world. That line was completed for use in the last week in May, 1844, the first news despatch having been sent over the wire on the 25th of May. The quite recent death of the constructor of that line naturally carries the mind backward over the thirty years of its exist-

ence of the magnetic telegraph, and brings into bold view the feeble beginning of the marvelous progress of this peculiarly American work. After the patient but persistent efforts of Professor Morse for several years, Congress in 1843 made an appropriation of $30,000 for an experiment with the Morse telegraph between Washington and Baltimore, and it was this line that was completed in the spring of the following year. The money, grudgingly granted in the midst of scoffs and jeers and references to "animal magnetism," etc., has been frequently referred to as a munificent gift in the interest of Science and the diffusion of intelligence. Perhaps it was, but it may serve at once to illustrate the magnitude of the growth of the telegraph, and how greatly the government profited by its generosity, to say that quite recently, within a period of five years, the Western Union Telegraph Company alone paid to the Treasury in taxes $850,000, and in gold duties, on imports of telegraphic wire, $28,000 more. Thus the investment of that $30,000 repaid itself in taxes two times since, in these five years alone, and now one company alone, more than thirty-fold.

Going back to the forty miles of wire between Washington and Baltimore, which measured the whole dimensions of the magnetic telegraph this day thirty years ago, we are able to appreciate the two hundred thousand miles of wire which form the network of the telegraph over the United States to day. Of these two hundred thousand miles of American wires, which would encircle the globe more than eight times, about one hundred and seventy thousand belong to one company. In June, 1851, there were two operators at work; in June, 1874, there were nine thousand nine hundred and thirty persons employed by one American company, and about twelve thousand by all the American companies. In this exhibit of the growth of thirty years, we built the figures to the statistics of our own country, leaving the Old World out of view altogether.

In some other respects, the change wrought by the telegraph is less than the period of one generation is still more striking. It requires no strain upon the memories of even the junior partners of some of our old business houses and offices to recall the anxious times when they were more or less at the mercy of shrewd and active men who used carrier pigeons, relays of fast horses with their hardy express riders, semaphore signals from hill top to hill top and along the coast, and other similar expedients for getting advance views of important events, with all the resulting advantages. In those days fluctuations in the prices of commodities in the great markets of the world were frequently secretly known only to a few, who sold their knowledge to another few, and then a small knot of men in every commercial center were enabled to buy the property of their unfortunate neighbors for far less than its value, or sell their own for far more than its value. Now all business men get their information simultaneously, and, if they wish it, they can get it from all the markets and money centres of the world. The merchant at our Commercial Exchange is in immediate communication with corn, cattle, cotton, produce, shipping, and commercial exchanges everywhere in our own country and abroad. The banker on Third street has his wire extending from his office to New York, Chicago, San Francisco, New Orleans, London, Paris, Frankfort, Berlin, Amsterdam, Constantinople, Bombay, Calcutta, Rio Janeiro and Shanghai, and all cities and countries between. He sits there with instant knowledge of the financial, commercial, political, and other important current events of Europe, Asia, Africa, Australia, the East and West Indies, and South America, as well as of his own country. The telegraph, the Associated Press, and the newspapers within that organization concentrate this universal intelligence, and lay it before the whole public simultaneously at least twice every day; and all this

marvelous change and the vast and wonderful system that has brought it about is, as the dreams of the builder of the pioneer line sharply remind us, the growth of but thirty years.—*Public Ledger.*

MITCHELL, IOWA, *Sept* 23.

TO THE EDITOR OF THE TELEGRAPHER.

In response to the questions of the editor of the *Journal of the Telegraph*, in his home of August 15th, regarding my duplex, would say, like Mr. Farmer (I quote from the above Journal), "by adjusting the antagonistic forces of the spring so as to equal the attractive force of the magnet when acted upon by one battery," to the extent of my adjustment. I said in above issue, "outgoing current does not operate relay at that station," and not "does not affect it." I did not say "without adjustment," but did say "without any changing of adjustment above that required in the single working circuit."

I still claim a permanent adjustment or equation in batteries, *i.e.*, that sum which allows them both to relay and is never disconnected from main line, so that the battery connected with sending key at "A," is there is never opposed by battery, therefore both currents are subject to the same variations. The last assertion is totally incorrect, because none of the current from working battery flows through relay there, the principle of which he admits when he says "were the keys open or closed, how can it affect the polarity of the opposing currents or batteries?"

Truly, my "supposition is that when both batteries are connected to line no current will pass through the relays" from "M M," the *receiving* battery, "*for the reason* that any tendency in the battery connected to relay to set up a current "with" "M M," *is in short circuit*, the opposing current from the battery connected with the sending key "A A" *is closed*," is balanced by the resistance coil."

S. J. M. DEAN.

for the use and benefit of the Institution." On the communication of this generous response, preparations were at once made for the laborious undertaking, and the inauguration of the enterprise was fixed for the year 1868.

In January of that year, however, occurred the disastrous fire which so seriously embarrassed the labours of the Smithsonian Institution for several following years; it became necessary to indefinitely postpone this meteorological work, which, indeed had, through its whole history, been envied on with much limited financial means, and was quite dependent on the liberal co-operation of the different telegraph companies.

It will thus be seen," writes Prof. Abbe, "that without material aid from the Government, but through the enlightened policy of the telegraph companies, and with the assistance of the unsolicited bequest of James Smithson, "for the increase and diffusion of knowledge," the Smithsonian Institution, first in the world, organized a comprehensive system of telegraphic meteorology; and has thus given, first to Europe and Asia, and now to the United States, that most beneficent national application of modern science, the Storm Warning."

ON THE DISCHARGE OF ELECTRIFIED CONDUCTORS.

BY M. BICHEVA.

THE electrical equilibrium at the surface of a system of conducting bodies results, as has been shown by Poisson, from the following condition:—The resultant of the actions exercised by the several electric strata upon any point taken at the interior of the conductors should be nil. If we designate by σ an of those electric masses, affected by a sign according to its nature, by r its distance from a point situated at the interior of a conductor, the function—

$$V = \Sigma \frac{\sigma}{r}$$

should then have a constant value for all points situated at the interior of the same conductor. The function V, introduced by Laplace in his *analyse*, has been designated by Green under the name of the *potential function*.

If we designate by m and m' two electric masses of the same nature, situated at a distance r, each of the masses is repulsed by a force equal to $\frac{m\,m'}{r^2}$; if the distance of the electric masses becomes $r+dr$, the sum of the elementary works of the repulsive forces is—

$$\frac{m\,m'}{r^2}\,dr = -d\left(\frac{m\,m'}{r}\right).$$

The sum of the elementary works of all the repulsive forces is then equal to the increment of the function—

$$W = -\Sigma \frac{m\,m'}{r},$$

where the sum is extended to all electric masses, supposing each of them effected by a sign. The function W, is designated, according to Gauss's notation, under the term of *potential of electricity*.

The fathers of XIII. Heindhelm and Clausius have particularly called attention to this function, which plays an important part in the phenomena of electric discharge; the increment of potential represents, in effect, the work effected in the electric discharge. M. Clausius has shown that the potential can be easily expressed by means of the charges and of the potential functions relative to each conductor; if we call V the potential upon a conductor, Q its charge,

$$\Sigma\, V\, Q$$

If we call V_1, Q_1 the initial values, V_n, Q_n the final values relative to a conductor—

$$W_1 - W_n = \tfrac{1}{2}\,\Sigma\, V_1 Q_1 - \tfrac{1}{2}\,\Sigma\, V_n Q_n$$

measures the work effected in the partial discharge of the system of conductors, and, when the conductors are reduced to a neutral condition, the work of the complete discharge is—

$$\tfrac{1}{2}\,\Sigma\, V_n Q_n.$$

The mechanical equivalent of the discharge is independent of the manner in which the discharge is effected; it depends only upon the initial and final values of the potential, so that the first and the effects of the electric discharges remain the same, whatever the nature of the discharge.

M. Heindhelm has already evaluated the momentum gained by electricity in passing from the surface of a conductor to an infinite distance; but he has considered the potential of the electricity of a conductor as a constant quantity, whilst in reality the potential diminishes upon the conductor proportionally to the charge; this diminution has for its effect the re-diminution of the expression for the work which is produced in the discharge by air.

Let us consider an electric conducting body having a charge q, and suppose a quantity of electricity dq to escape from the electrified body and disappear in the air. When this electricity dq passes from a plane surface where the potential has a value V to a plane surface infinitely near where the value of the potential function is $V + dV$, designating by d the infinitely small normal portion comprised between the two surfaces at the point considered, the repulsive force exercised upon dq is $-\frac{dV}{d}\,dq$. The elementary work of repulsion,

in passing from a plane surface to a surface infinitely near, is $-d\,V\,dq$. Consequently, when the quantity of electricity dq is extended to infinity, the corresponding work has for its value Vdq, if we term V the potential function at the surface of the conductor, or, which is the same thing, at the interior of the conductor: this expression has already been given by M. Helmholtz.

The potential function V is proportional to the charge q of the conductor; we can put $V = \alpha q$, α being a constant particular to the conductor. The work necessary for the infinite repulsion of the quantity of electricity dq is $\alpha q\,dq$. Consequently, if we term q_1 the initial charge of the conductor, the work necessary for the infinite repulsion of all the electricity of the body has for its expression—

$$T = \alpha \int_{q_1}^{0} q\,dq = \tfrac{1}{2}\,\alpha q_1^2 = \tfrac{1}{2}\,V_0 q_1.$$

V_0 being the initial value of the potential function upon the conductor.

Also the work consumed in the infinite repulsion of all the electricity of the body is equal to the potential of the electricity, or, in other terms, the mechanical equivalent of the exterior discharges is equal to the potential of the electricity. The result is evidently the same for a system of electrified conductors.

32

C. H. C. suggests that telegraph companies plant trees on which to hang their wires. "In most sections of the country, the tree first planted would cost but little more than a pole, and after two or three years in growth would be a permanent pole which can rot at the bottom or need resetting, and would be seldom struck by lightning. Having many times seen from three to a dozen poles, in a row, shivered by a charge of electricity running along the wires, the above question arises in my mind."

Scientific American 3rd '75

New Style of Telegraph Poles.

There has lately been erected at the junction of Broadway and 23d street, in this city, an example of a new form of telegraph pole, of iron. It is said to be lighter than a wooden pole of the same hight, stronger, and capable of supporting a greater weight.

It is constructed of a number of wrought iron bars, rolled out the entire length of the pole, which bars are placed around light cast iron cores, arranged at proper intervals from each other. The cores have seats or notches to hold the bars in their places to prevent their moving sideways, and the bars also have notches, into which the cores fit to keep them from moving up or down. Around the outside, where each core is placed, a ring or band of wrought iron is tightly fitted, which holds the bars firmly in their places, and thus forms the whole into a light, open, and graceful column. Any number or any size of bars may be used, but it is found that six very light bars of angle iron arranged in this way afford a strength that fully meets that required for a telegraph pole of fifty feet in hight. The cores are large at the base and are made smaller as they approach the top, which gives the column a graceful taper, and the whole is surmounted by a suitable crosshead to hold the arms for the wires. Such a column is very simply constructed, and is without a rivet throughout its entire length. No machinery or shop labor is required to put it together, other than the making of the suitable rings or bands by an ordinary blacksmith, so that the pole may be ordered in pieces and put together at the point where it is to stand. The column is suitable not only for telegraph poles but for masts for iron ships, derrick masts and booms, stringers for bridges, lamp posts, and a variety of other purposes.

The Western Union Telegraph Company have begun the work of laying the telegraph wires in New York underground. Iron pipes are being placed in position under the Union Exchange, the Herald, pneumatic tubes for the transmission of telegraphic messages by the Ad Sheet are also being hooked on the line of the telegraph pipes. The pneumatic tubes are made of brass.

Jan 76

Anglo-French Telegraph Cables.

A memorial has been presented to the Postmaster-General by the Association of Chambers of Commerce with regard to a reduction in the present tariff on messages between England and France. The memorial states "that the existing tariff for telegraphic communication between France and England is incompetent with the principle of uniformity established by both countries in inland messages, inasmuch as the present charge of 1 fr. 25 c. (1s. 0½d.) for twenty words, including the telegram of twenty words to or from any point in the kingdom, rather than the metropolis, the memorialists have ascertained that a reduction in the Anglo-French tariff is favorably entertained by the French Government, and that it is prepared to bear its share of the reduction and to enter into negotiations with the English Government and the Submarine Company to that effect. The memorialists conclude by expressing a desire that the Postmaster-General would consent to a reduction of the Anglo-French telegraphic tariff to a uniform price of 1 fr. 00 c. (1s. 2d.), per message of twenty words, to apply equally to France and to England, to the provinces and to the metropolis; and that the Postmaster-General should enter into negotiations with the Submarine Cable Company and the French Government with a view to such reduction of the present tariff."

RAILWAY ACCIDENTS.—An annual number of railway accidents, chiefly collisions and derailments, must mark the most serious

The Annual Report of the President of the Western Union Telegraph Company is published in the *Telegrapher* of Oct. 14. Since the present Company was established, by the consolidation of the leading telegraph companies in the United States, the mileage of line has been increased 96 per cent., the mileage of wire 142 per cent., the number of offices 214 per cent., the number of messages annually transmitted 219 per cent., and the tolls reduced 52 per cent. The capital stock outstanding has been re-duced from 41 to 33 million dols., the difference (in the treasury), with other property acquired, re-presenting an aggregate value of nearly 12 milli n dollars. The average cost of transmitting te grams in Europe is 5-8ths of a cent more than the average cost of transmission by this Company.

Many of the officers of the late Electric and International Telegraph Company will be glad to learn that their old friend and colleague, Mr. H. Shütz Wilson, is continuing to gain laurels in the pleasant fields of literature for which, at the time for, he gave up the rougher paths of Telegraphy. His "Studies and Romances," published by King and Co., and "Philip Mannington," a novel published by Tinsley, are rapidly running through their first edition, and are much sought after at Mudie's, Smith's, and other libraries. Many will remember Mr. Wilson's early productions, published twenty years ago, in that pleasant and creditable but very scarce publication *Our Magazine*, produced entirely by officers of the Electric and International Telegraph Company. 7/6

Cavicornia, in being independent ossifications, situated on the suture between the frontal and parietal bones instead of simple outgrowths from the frontal only. A median excrescence on the forehead, in front of the above-mentioned processes, is the result of a protrusion upwards of the bones in the part.

The Pronghorn (*Antilocapra*) has well-developed horns. They are attached to ordinary bony cores, exactly similar to those of the Antelopes. They are, however, unique of their kind in that they are branched or bifurcate at their tips, a second smaller point springing from the anterior margin of the principal stem, and running forward with a gentle curve, convex upwards. In another respect these horns are even more peculiar. Mr. Bartlett, the Superintendent of the Society's Gardens, was the first to show, from a specimen living in the Gardens, that the Pronghorn is in the habit of annually shedding its horns from off their cores. This surprising discovery has since been fully confirmed; at the end of each season the cores being found covered with a skin from which the fresh horn is developed.

Respecting the geographical distribution of the Cavicornia, none are to be found in Australasia or South America. Very few inhabit North America; the Bighorn Sheep, one of the Bisons, the Musk Ox, the Mountain Goat, and the Pronghorn embracing them all. Africa is the head-quarters of the sub-order, and specially of the Antilopine family. In Europe the Ibex is a native of Poland, the Chamois and the Ibex of the Alps; while the peculiar Saïga reaches our side of the Caspian Sea. Among the best known Indian Antelopes are the Sasin or Antelope *par excellence*, and the Nilghau.

The Cheviotdale, or Tragulina, form a group of small, deer-like animals, without horns, which were formerly associated with the Musk Deer. The investigations of Prof. Flower have, more than any others, proved the independent nature of the group, which approach in their internal anatomy to the Pigs. The third stomach of other Ruminants—the Psalterium—is wanting. In the axis vertebræ, the odontoid process, instead of being scooped into a spout, as in the Deer and Antelopes, is pegs-like, as in the Swine. The second and third metacarpal bones are completely developed from end to end, and the lateral marginal intervals of the upper jaw between the canine and molar teeth are not cut away, as they are in other Ruminants. These and other peculiarities in the teeth, &c., are quite sufficient to divide off the sub-order as an independent one, ranking with the others previously described. The number of genera and species are very inconsiderable, there being two of the former (*Hyomoschus* and *Tragulus*), and not half a dozen of the latter. *Hyomoschus* aquaticus inhabits Western Africa, occupying much the same ground as does the Chinquotze. In it the metacarpal bones remain separate during the life of the animal, as in the Swine, and not in the other Ruminants. The fur is spotted like that of most young deer, throughout life. *Tragulus* is found, two species—*T. meminna* and *T. stanleyanus*—in India, the Napu (*T. javanicus*) and one or two others making Java and Sumatra their abode.

(To be continued.)

RARE ANIMAL AT THE MANCHESTER AQUARIUM

AMONG the numerous new accessions brought together to swell the list of special attractions for the thousands of Whit-week visitors at the Manchester Aquarium, one of the latest arrivals is especially deserving of notice in these columns. This is an example of the so-called "Congo Snake" (*Muræna phalo fridentici*), from the neighbourhood of New Orleans, a singular eel or snake-like animal, belonging, nevertheless, to neither of the classes represented by those two types, but rather to the true Amphibia. Judged from its shape, proportions, and colour, the uninitiated would certainly pass it as an ordinary eel, from which, on closer examination, it will be found to differ in possessing no fins, small beads-like eyes a mere puncture in the place of the ordinary gill-operculum, though more especially in having scattered at each extremity of the attenuated body a pair of feeble little legs, and each leg furnished with four slender toes. These legs may be described as almost rudimentary, but they are at the same time used by the animal, and with more marked effect than might be presupposed, when crawling over the ground at the bottom of its tank. Rising into the midst of the water, it can further swim with great rapidity, progressing then by rapid undulations of its body from side to side, after the manner of a true snake. The length of this specimen is about two feet six inches; greatest diameter, in the centre of the body, one inch and a half, tapering off from the posterior pair of legs into an attenuate and slightly compressed tail. The colour closely resembles that of an ordinary eel, being slate-grey on the dorsal surface and sides down to the lateral line, and below this, soft colour. Along the lateral line is a double row of minute punctures, the orifices, no doubt, of mucous glands similar to those existing in true fishes. The animal has to repair to the surface of the water to breathe, but this is at distant intervals, a large quantity of air being drawn through the nostrils into the lung-pouch by a singular inflation of the throat, repeated several times in succession. This specimen is exhibited in one of the octagon table tanks in the centre of the saloon, eighteen inches in depth, so that when taking in its supply of air it does not elongate leave the ground, but raises itself in a semi-erect position until the head touches the surface of the water. With the head just an inch or two below the surface, and standing, as it were, upon its posterior legs, with the anterior pair held out helplessly in the water, is a very favourite attitude with this creature, though at the same time an essentially gregarious one, reminding the observer of the somewhat similar attitude and general appearance, on a colossal scale, of the larva of *Salamandra atra* at the Geneva metamorphosis. In its native swamps the "Congo Snake" is reputed by the black population to be highly venomous, an injustice to the poor creature as great as when applied by our own benighted countrymen to the harmless Newt or Triton of English ponds and streams, and of which it is merely a highly interesting and most extraordinary zootic type.

We are indebted for this rare and, indeed, at present, we believe, in this country, unique example of this species to Capt. A. H. Mellor, of the Dunsinnie and Mantispe Steamship Company, to whose influential and friendly assistance we are also under further obligations for a fine young alligator some two feet long, the trophy of a preceding voyage.

W. SAVILLE-KENT

THE PROGRESS OF THE TELEGRAPH*

VI.

IT has already been observed that from the limited speed on the wire, the development of any extended system of electric communication between the centres of commerce in a country where great distances have to be reached, involves a vast outlay in the duplication of the circuits necessary to afford the requisite transmitting powers, and that by the application of the automatic process, in addition to the accuracy of its performance, the greater speed obtained upon long circuits enabled the telegraphic service to be conducted by a much smaller number of wires, thus relieving in a most important degree the outlay of capital expended on con-

* Continued from p. 50.

struction. It is not, however, only by the automatic process that the full transmitting capacity of a conducting wire can be attained. Metallic conductors under certain conditions are capable of transmitting more than one current at the same instant of time, both in the same and in opposite directions; and by a very ingenious system of adjustment of electric resistances and balance of currents, perfected by Messrs. Stearns, Edison, and Prescott, the American electricians, intelligence can be transmitted and recorded over a single wire in opposite directions at the same moment. This system of transmission is known as "Duplex" and "Quintuplex" Telegraphy, and is already extensively employed by the Western Union Telegraph Company in the United States, and over several of the more important circuits in Great Britain. The "Duplex" system is working in America between nearly all the principal cities, and has recently been introduced between Port Hastings, on the island of Cape Breton, where the land circuits are in connection with the submarine cables, and San-Francisco, a distance has been successfully introduced between New York and Boston, with a transmitting capacity upon a single wire equivalent to the transmitting power of four wires worked upon the ordinary Morse system. Thus, by employing arrangements such as the "Duplex" and "Quadruplex," a circuit may be worked either as one wire, or two, three, or four wires, according as the transmitting capacity of the circuit may require to be increased.

As is well known, several sounds may be conveyed at one and the same time by vibrations through a rod without interference, and it is difficult to realise the accuracy with which every vibration is separated by anyone who has not witnessed an illustration of the "transmission of sound" by solid conductors. So it is with "Duplex" and "Quadruplex" transmissions through the same wire in opposite directions at the same moment of time; it is equally difficult to realise how distinct signals can be received in either end without interfering with or destroying each other; and yet the principles involved are very simple and easy of explanation.

By the Duplex system, one of the most difficult problems incident to the successful development of telegraphic lines has been solved, namely, how to provide for the annual increase (averaging 10 per cent.) in the amount of business without the annual expenditure on capital account for the erection of additional wires. In the United States, over 150,000 miles of wire are in operation, the rate of increase being something like 20,000 miles per annum, and the Duplex system is capable of doubling the carrying capacity of these wires. The great value of the Duplex system consists in its capability to double the capacity of a wire at any moment, should injury by storm or configuration interrupt the circuits. By its means, the moment one wire is restored to continuity it becomes equivalent to two, and a second wire raises the carrying capacity of the circuits to four wires, and by skilful manipulation the system may be introduced and adjusted on a circuit in about a minute. From the earliest days of telegraphy it has been well known that two currents, either in the same or in opposite directions, could be passed simultaneously through a conducting wire; indeed, by this means, often has the frame of mind and temper of the operator at the distant station been clearly read at the receiving station, even though situated some hundred miles distant. When the direction of the currents from the two stations are passed into the wire in the same direction, the divecture force of the needle becomes more decided; but when the direction is contrary the motion of the needle will be comparatively neutralised and scarcely perceptible. The effect of a current transmitted along a wire from one station upon a galvanometer needle while currents are being transmitted from another station has therefore been long known. How this circumstance has been applied to the indication of distinct signals will now be explained.

Let us suppose two stations, A and B, are to be connected for signalling each other upon the Duplex system: the action of the coils in the instruments at the respective stations is so arranged that neither station's local or outgoing current shall affect its needle when passed into the line, its total being left free to indicate the effects produced by the incoming current from the distant station. For this purpose it is necessary to add to the coils of the instruments with two parallel wires after the manner of a differential galvanometer. Now, it is well understood in testing a line wire for resistance between two stations with a differential galvanometer, until the artificial resistance interposed has been made equal to that of the line to be tested, the battery current passed by the key into the galvanometer will move the needle in the one direction if the artificial resistance is too small, and in the other direction if the resistance is too great. It is only when an accurate balance is obtained—that is, when the two resistances have been made equal—that a current will not move the needle, because then the current is equally divided between the coil connected with the artificial resistance and that connected to the line, which two coils being wound in opposite directions counteract one another. Thus, so long as the artificial resistances (rheostats) at each end of the line are equal each to that of the circuit, each station will see the current sent by the other, while neither station will see upon its own instrument the current he is passing into the line; and for this reason, that the currents sent by each station divide equally between the line and the rheostat, passing through the coils in opposite directions, and have therefore no effect upon the needle of the sending instrument. When the distant station sends a current, it either increases or diminishes the effect of the home current; in the first case, it augments that portion which passes through the coil connected to the line, so that more flows into the line than exists in the rheostat, and the needle moves. In the second case, it reduces the current flowing to the line, and more will flow through the rheostat, moving the needle in an opposite direction. Thus if it be sent by the one operator "dot" it does not pass over another, but that when both stations send signals at the same time, the current sent by either of them acts upon the distant instrument by determining whether the currents sent by that station shall pass through the line or the rheostat. Thus we see that when station A signals separately, the current is equally divided in two, viz. through its instrument coil, and its effect is neutralised upon the needle, but it passes through both coils of the distant instrument in the *same* direction, and therefore produces a signal. If both A and B depress their contact keys at the same moment, the currents from the two batteries are united so far as the line wire is concerned, and this produces an effect upon the differential arrangements at each equivalent to a lessening of the resistance of the line, and therefore more current flows to the line than through the rheostat. It is thus seen that the Duplex system affords a means of increasing the transmitting capacity of a wire; and an invention which practically converts one wire into two, three, or four, as the necessities of business may require, is of great value.

A short historical summary of the introduction and progress of the electric telegraph, from its earliest application in a practical form to the establishment of its present world-wide reputation and utility, will following short sketch may convey in a succinct manner the steps by which progress that year by year has registered the index of improvement. It is not intended in any way to make the present sketch personal: some well-known names must of necessity be referred to, and the reader should also

be informed that the narrator in this instance has personally been more or less connected with the progress of the telegraph from 1841, the date at which this story commences, to 1875, the period under review. In the year first mentioned Charles Wheatstone, Professor of Natural Philosophy at King's College, London, was at the same time connected with a musical instrument and publishing house many of his important improvements and patents in connection with the electric telegraph were carried out, and many of the drawings connected with the filing of the specifications of these patents were, by permission of the directors of the firm, placed in Messrs. Cooke and Wheatstone were dispossed of for a sum of £20,000 to a Company called the Electric Telegraph Company, in which the late John Lewis Ricardo, M.P., for Stoke-upon-Trent, was at once the most prominent and vital element. Of this amount Cooke retained 90,000*l.*, and Wheatstone received 30,000*l.* This sum included the transfer to the Company, besides other matters, of the telegraph line between Paddington and Slough, on the Great Western Railway, already alluded to in the earlier pages of this summary. As already mentioned, this short line was a kind of Madame Tussaud—daily advertisements, and a profusion of visitors entertained, or, as they imagined, duped or humbugged, at one shilling a head, into the belief that standing before the little instruments in the Paddington station, it would *there and then* convey their thoughts, and in intelligible language return a response from a station some twenty miles distant. Inquiries as to the "time of day" "state of weather," or general health of the operator, served to test the accuracy of the new invention. Nevertheless, nine out of every ten persons who were attracted by the printed placards soon broadcast about the station, left the Paddington termini as little impressed with any belief that what they had seen represented the future germ of a great invention, as if they had viewed the automaton chess player. Necromancy, witchcraft, and delusion seemed to be the parting impression on their minds as they left, in return for their shilling charge. The announcement as issued in 1842, inviting the patronage of the public, is here reprinted; it affords an amusing souvenir of the early history of the telegraph :—

[*Facsimile of Announcement.*]

"Under the Special Patronage
OF ROYALTY.

INSTANTANEOUS COMMUNICATION
between Paddington and Slough, a distance of
nearly twenty miles, by means of the
ELECTRIC TELEGRAPH,

which may be seen in operation Daily, from nine in the morning till eight in the evening at the
GREAT WESTERN RAILWAY, Paddington Station,
and the TELEGRAPH COTTAGE, close to the Slough Station.
Admission—One Shilling, Children and Schools half-price.

Since this very interesting Exhibition has been opened to the Public, it has been honoured by the visits of His Royal Highness Prince Albert, the Emperor of Russia, the King, and Prince William of Prussia, the Duke de Montpensier, His Royal Highness the Duke of Cambridge, the Duke of Wellington, Sir Robert Peel, the Foreign Ambassadors, and most of the nobility, &c.

"In no way has the science of Electricity been made so subservient to the use of man, as in its application to the purposes of *Telegraphic Communication*, which is now brought to the *height of perfection*. The working of this beautiful apparatus can be seen in the best degree affected by the weather, intelligence can be sent by night equally well as by day; distance is no object; by the *Electromagnetic* agency communications can be transmitted to a *thousand miles* in the same space of time, and with the same ease and unerring certainty, as a signal can be sent from London to Slough, according to the best authorities, the electric fluid travels at the rate of 288,000 *miles in a second*.

"The Electric Telegraph has been adopted by Her Majesty's Government, and numerous have just completed a line of communication between London and Portsmouth, agreeably to directions received a short time ago from

THE RIGHT HONORABLE THE LORDS OF THE ADMIRALTY.

"In the late trial of John Tawell, at Aylesbury, for the murder at Salt Hill, near Slough, the Electric Telegraph is frequently mentioned in the evidence, and referred to by Mr. James Parke in his summing up. The *Times* newspaper very justly observes 'that it had it not been for the efficient aid of the Electric Telegraph, both at the Paddington and Slough stations, the greatest difficulties, as well as delay, would have been occasioned in the apprehension of the prisoner.' Although the train in which Tawell came to town was within a very short distance of the Paddington Station before any intelligence was given at the Slough Telegraph Office, nevertheless, before the train had actually arrived, not only had a full description of his person and dress been received, but also the particular carriage and compartment in which he rode were accurately described, and an officer was in readiness to watch his movements. His subsequent apprehension is so well known, that any further reference to the subject is unnecessary.

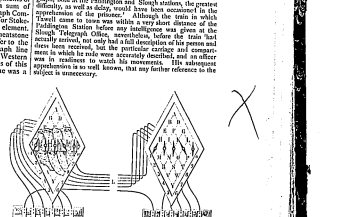

FIG. 16.—Cooke and Wheatstone's five needle telegraph.]

"The Telegraph Office at Paddington Station is at the end of the Up-train Platform, where a variety of interesting apparatus may be seen in constant operation."

The first office of the Electric Telegraph Company was at 325 Strand, a site now occupied by the Gaiety Theatre. In those days (1846) scientific men of renown crowded the instrument room to witness the progress of this great invention: George Stephenson, the Astronomer Royal, Brunel, Vignoles, G. P. Bidder, Samuda, Rennie, Fairbairn, and most of the leading engineers of the day. In

345, Strand, the magnetic disturbances and interference with transmitted signals from aurora and earth-currents were first observed and the observations tabulated, which have since proved useful, notwithstanding the then defective construction of the recording apparatus; here also the earliest lines of railway telegraph were inaugurated; the long five-inch astatic combination of the double needle and single needle instruments was employed, taking the place of less perfect apparatus. It must be remembered that, previous to the introduction of the double and single needle instruments, very cumbersome apparatus had been employed. There was the five-needle instrument, requiring five wires for the five needles, and a sixth wire for the return current (Cooke and Wheatstone's patent, 1837);

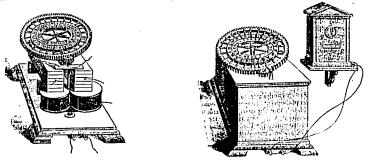

FIG. 27.—Wheatstone's letter-showing dial telegraph, 1840

the respective letter or signal being indicated by the concurrent deflection of two pointers. Obviously, this instrument became useless for extended circuits, the capital cost of outlay for the six wires restricting its use. The dial letter-showing apparatus of Cooke and Wheatstone (1840), in which the letters of the alphabet composing the word are severally presented to view at an opening in a dial-plate by means of an electro-magnet acting upon the pallets of an escapement, put in motion by independent clockwork. The communicator of the instrument is furnished with a dial-plate similar to that of the indicator, so that on the rotation of the dial of the communicator by the operator, the successive succession of make and break currents of electricity are sent through the wire and controlled so as to actuate the motion of the index-pointer of the indicator at the distant station.

THE INDIAN TRIGONOMETRICAL SURVEY*

ONE does not usually expect to find much of general interest in the Report of a Trigonometrical Survey. Col. Walker's admirably drawn-up Report, however, includes some matter of more than special value; indeed, many of the details connected with the immediate work of the Survey are calculated to interest the general reader, they are concerned to such a large extent with the peculiar difficulties to be overcome by the various parties, difficulties which make ordinary survey work look like mere child's play.

The Index Chart prefixed to the Report enables one to form a very full idea of the work which has already been done, and of how much there is yet to do. From Cape Comorin to Peshawur and all along the Himalayan frontier, and from Kurrachee on the west to Burmah on the east, the country is covered with an intricate net-work of triangulation, including, however, many gaps which will take many years to fill up. Shooting out from the northern border of the system of triangulation are numerous narrow-like lines indicating the secondary triangulation to fix the peaks of the Himalayan and Soolieman ranges. We cannot go into the details of the work of the Survey, and must content ourselves with a brief summary of the return of work during the year under review, and with a reference to a few of the more interesting side topics.

Of Principal Triangulation, with the great theodolites of the Survey, seventy triangles, embracing an area of 7,190 square miles, and disposed in chains which, if united, would extend over a direct distance of 302 miles, and in connection with which three astronomical azimuths of verification have been measured. Of Secondary Triangulation, with vernier theodolites of various sizes, an area of 5,212 square miles has been closely covered with points for the topographical operations, an area of 3,650 square miles has been operated in *part passu* with the principal triangulation last exterior thereto, and in an area of 12,000 square miles—in the ranges of mountains to the north of the Assam Valley which are inhabited by independent tribes—a large number of peaks have been fixed, many of which have already been found serviceable in the geographical operations now being carried on with the military expedition against the Duffles. Of Topographical Surveying, an area of 534 square miles has been completed in British portions of the Himalayas, on the scale of one inch to the mile, on area of 2,366 square miles in Kattywar on the two-inch scale, and areas of 690 and 63 square miles respectively, in Guzerat and in the Deccan 1/6th, on the scale of four inches to the mile. Of Geographical Exploration much valuable work has been done in Kashghuria and on the Pamir Steppes, in connection with Sir Douglas Forsyth's mission to the Court of the Atalik Ghazi, and several additions to the geography of portions of Great Thibet and of Nepaul have been obtained through the agency of native explorers.

In the course of the operations of the year under review the northern section of the Brahmaputra Meridional Series has been completed, whereby two important circuits of triangulation formed by it with the Assam and East Calcutta Longitudinal Series to the north and south, the Calcutta Meridional and the Eastern Frontier Series to

* General Report of the Operations of the Great Trigonometrical Survey of India, during the year 1873-74. By Col. J. T. Walker, R.E., F.R.S., Superintendent of the Survey. (Dehra Dun: Office of the Superintendent, G. T. Survey, &c. 3, O'Connor, 1874.)

5. A thermo-pile of 25 pairs, each of bismuth and antimony, was connected to the instrument. The heat from the hand placed at 5 c.m. distance caused a deflection of 3°.

6. Two cubes of boiling water acted differentially on the pile. At the distance of 5 c.m. the deflection was 20°; moving 1 to 10 c.m., the deflection was reduced to 5°.

Vallisneria Current.—7. A drop of water was placed on a zinc plate. While one of the connecting copper wires touched the zinc, the other was made to touch the water. The deflection was 16°.

The claim which is here made for the instrument, however, is rather for the general principle of its construction than for the advantages possessed by the individual galvanometer above described, which was constructed at short notice to meet an emergency. The comparatively small cost for which it may be fitted to the vertical line of the pile, the quickness with which it may be brought into use, the brilliantly illuminated circle of light which it gives upon the screen, the subdivided circle and needle, the great range of delicacy which may be given to the instrument by varying the coil and needle, and all experimental readjustments may be executed, and, finally, the satisfactory character of its performances as a demonstration galvanometer,—all combine to justify the record which is here made of it.

MECHANICAL AND ELECTRICAL TESTS OF IRON WIRE.

In a recent number of the Journal* the results of a series of tests of different samples of iron wire were given. Since that time a number of additional samples have been tested in the same manner, and the results are given in the subjoined table. For convenience of comparison, the results given in the former table have also been included in this table. In one or two slight typographical errors corrected. In addition to the column under the head of "Relative Breaking Strain," has been introduced, which has been calculated from the actual breaking strain as given in the fifth column, and the weight per knot as given in the second column, and shows the number of feet of its own length that each sample would be capable of sustaining. The arrangement of the table, it will be noticed, affords an opportunity of comparing in adjacent columns the relative breaking strain and relative conductivity of each sample. The tests are arranged in the order of their relative breaking strain.—*New York Journal of the Telegraph.*

NOTES.

THE iron telegraph poles in Persia are put to a novel use. A friend who has lately returned from that country informs us that between Teheran and Shiraz it is the common custom of the inhabitants to use the poles as targets for rifle shooting. Standing at one post and shooting at another, the people find the telegraph poles most convenient institutions for gun practice, and no doubt many believe that is their proper and legitimate use. The poles are made of sheet iron, and the natives test their guns by trying whether the bullet will pierce the post. Some posts are thus riddled with holes, and soon give way altogether. The reason why telegraph posts in Persia require frequent renewal is no longer a mystery.

The report of the Meteorological Committee of the Royal Society for 1872, issued on the 17th inst., contains the following information respecting weather telegraphy:—The office receives, or would receive, were the Continental telegraphic communication and that with the Shetlands perfect, fifty-one reports every morning, and nine every afternoon, except on Sundays. The observations are taken on Sundays as on other days, but are not received at the Meteorological Office until Monday morning, when the report for Sunday is made out. The stations are situate along the entire coast of the Continent, from Christiansund, in lat. 63 deg. N., to Corunna, in lat. 43 deg. N., with four stations on the coast of the Baltic

crease δ till the condition $a' d = b (L+\delta)$ is again fulfilled, when perfect signals will be again received.

23. The adjustment in the δ branch is not made by the comparatively slow method of withdrawing or inserting plugs, but by means of a contact sliding over equal increments of resistance fixed in a circular box. Moving the slide in one direction increases δ, and moving it in the contrary direction decreases it, and this adjustment is quite as simple as turning the micrometer screw of an ordinary polarised relay.

Batteries.

28. For duplex working about four times the battery power employed for single working is required, for the current—from Station I. for instance—side divides at the point x, and subsequently divides again at the point z. The key equations—

$$x+\delta = x'$$

should be controlled once or twice a week by accurately measuring the internal resistance of the battery and then unplugging in W that amount of shunting necessary to fulfil the key equation. The cells should be very carefully prepared, the same amount of amalgam by weight should be placed in each one, the rims of the jars should be paraffined, and the battery stands should be carefully insulated from the ground.

Control of the Duplex Instrument.

29. Tests of the several resistances for constancy, and of the condensers for insulation and capacity, should be made and recorded periodically.

Station of Work.

30. On commencing the day's work, and after both stations have received the line for "*permanent and transient current*," by means of the Morse instrument, Station I. for instance, signals to Station II., the word "*balance*;" Station II. then sends *intelligible*, and Station I. answers *relay*, by means of the micrometer screw for ordinary single signals, and then sends alternate signals O, U, to enable it also to adjust relay for single signalling. When this is done, adjustment by means of the micrometer screw ceases entirely, and both stations send signals simultaneously, and increase of decrease—as may be found necessary—the resistance in the δ branch, till perfect duplex signals are received. During the transmission of messages any adjustment that becomes necessary on account of variations in the line is confined solely to the δ branch. Corrections and questions are obtained as follows:—The receiving signaller, on finishing a message, makes a cross or underlines the words that he wants repeated, and places the message by the side of the sending signaller, who, after finishing what may be in course of transmission, calls for the required repetitions. In like manner the receiving signaller, who must have the sent messages near him, marks with a cross those words repetition of which is called for, and hands the message to the sending signaller, who goes on the repetitions; consequently there is no interruption to traffic—messages and calls for repetition follow one another contiguously.

Abbreviations to be used when calling for Corrections, Repetitions, &c.

THE TELEGRAPHIC CONFERENCE AT ST. PETERSBURG.

THE Paris correspondent of the *Times*, writing on the 16th inst., gives an outline of the principal discussions at the recent International Telegraphic Conference.

One of the first questions raised was that of Sunday labour. Mr. H. C. Fischer, of the English Post Office Telegraphs, claimed the right of a limited day service on Sundays for those offices which have a complete day service. This, he said, was necessary on account of the suspension of nearly all labour on Sundays.

On the proposal of M. Vincent (Belgium), who objected to exceptions in favour of particular States, it was agreed that any country may limit the hours of Sunday service, reducing this measure to the International Bureau, which will apprise the other States.

The question of responsibility for the correct transmission and delivery of messages was brought up by the French delegates, who proposed that, as in exchange for which an extra sum is paid for insurance, there should be some fixed limit of responsibility. To this it was objected that words difficult to transmit or copy might be used on purpose to set up a claim to compensation, and the Committee to which the proposal was referred reported by five to three against it.

M. Allibaud (France) urged on its behalf that registered letters had never produced lawsuits or inconvenience, but he was willing to exclude cypher messages and to limit compensation to cases where the telegram had manifestly not fulfilled its object. As to the fact that in France secret service messages is no more cumbrous, rather the number of collated despatches would not increase, and the responsibility proposed would be very slight, or it would augment, thus showing, that a public want had been satisfied. Several other private companies, he mentioned, since this law altogether was in force, the maximum compensation being ten times the cost of the message.

Herr Stephan (Germany) took the same view, thinking it unfair that the Government should be capable of miscarriage, and should be absolved from responsibility. The principle of compensation would operate as a limit to negligence and reduce greater cases. Inquiry, moreover, would always show whether the sender had been guilty of bad faith, or whether injury had been sustained.

On the other hand, Signor D'Amelio (Italy) urged that the telegraph was more liable to error than the Post Office, that faulty operators were already punished, that the best operators, owing to the nervousness consequent on their employment, oftenest committed mistakes, and that the system should first be tried in France or some other country.

Herr Stephan, in reply, said nervous operators ought to be dismissed.

M. Faber (Denmark), contended that the compensation should be divided among all the States sharing in the profits made for the telegram, but it was explained that the extra payment would be shared among all the States concerned, while the compensation would fall on the one guilty of the irregularity.

M. Nielsen (Russia) suggested that the indemnity should be limited to five times the cost of the message.

Eventually it was agreed, at a special committee of seven members should consider the question. This committee, by five to three, agreed that the cost of a registered message should be entitled to the return of his money and a fixed sum of 50 francs, the latter, however, not applying to irregularities caused by *force majeure* or

over

An iron telegraph pole has lately been erected in New York. It is said to be lighter than a wooden pole of the same height, stronger, and capable of supporting a greater weight. It is constructed of a number of wrought-iron bars, rolled out the entire length of the pole, which bars are placed around light cast-iron cores, arranged at proper intervals from each other. The cores have seats or notches to hold the bars in their places to prevent their moving sideways, and the bars also have notches, into which the cores fit to keep them from moving up or down. Around the outside, where each core is placed, a ring or band of wrought-iron is tightly fitted, which holds the bars firmly in their places. Any number or any size of bars may be used, but it is found that six very light bars of angle iron arranged in this way afford a strength that fully meets that required for a telegraph pole of 50 feet in height. The cores are large at the base and are made smaller as they approach the top, which gives the column a graceful taper, and the whole is surmounted by a suitable crosshead to hold the arms for the wires.

ELECTRICAL NEWS, August 1, 1879.

The Western Union Telegraph Co. is completing a tower of 50 feet in height on the crest of the lofty highlands of Newcastle. The operators, who are to have the most powerful glasses, will be able to distinguish steamers and other vessels 20 miles out.

At Simla a house belonging to the Government, and inhabited by one of the leading officials, was recently struck by lightning. A native subordinate of the Public Works Department was deputed to erect a conductor. In course of time, says the *Times of India*, the workmen placed four metallic rods in position on the roof, and connected them about half way down the building itself, which, material failing him, he deemed his job

CAUSES OF DESTRUCTION TO WOODEN POSTS.

By M. BOURSEUL,
Sub-Inspector of French Telegraphs.
(Concluded from page 90.)

I have often observed on rasped trees upon which the bark has been left that the *Aubier*, or inner bark, has withered; consequently the fibres of the wood tend to close up on each other, whilst the drier or harder core preserves its volume; the fibre splits, and the wood cracks. From the surface the germs of decay are installed away by rain, or carried off by wind; but in these trees they are very plentifully, and in a short time produce the fungus. The same thing naturally takes place when two pieces of wood are brought together.* In duplex poles are placed naturally on upon the other; if they remain too long in the same position, *even when they do not lie immediately upon the ground*,—if they are exposed to rain, or, being covered, if they are in the shade in a damp, badly-aired spot, the fungus asserting itself soon develops at all the points of contact existed between the poles. Should care not be taken, and the poles be plunged in that condition, it will not be long before the decay (rot) crown-burns should threaten to be mistrusted in telegraph poles, &c.

When, under exceptional circumstances, poles are obliged to be left stored in a depôt, they should be turned from time to time, so as to change their points of contact and successively expose their different parts to the light; and when the fungus has begun to develop itself, it is indispensable that the affected part be cauterised, either by fire or by sulphuric acid.

When once the *Mérulius* attacks planted poles it is very difficult to preserve them. The moment the authorities charged with the surveillance of the lines observe at the foot of a pole the existence of those filaments which denote white decay, they should lay bare its foot until they meet with no further trace of mycelium in the soil; the part of the detached earth should be thrown to a distance, and only bit of contaminated wood should be taken away by the hatchet or by cutting tool.† Then two shavings or branches, tied together around the pole earth as cramped, clipped, and free from it as possible. Afterwards leave a day mixed with water, of cement, or fat masses, will compact the whole together, and form a kind of natural concrete, often sufficient in itself to completely preserve the wood.

Because the fungus, in order to vegetate, requires access to the atmosphere, it is not developed below a certain depth, varying from 30 to 50 c.m., according to the nature of the soil. In grounds where the wood is usually attacked we must—without waiting till the "rot" has commenced—renew the earth at intervals, and well ram it down. The best instrument will evidently be the least weighty one, and one which, without burying itself in the soil, possesses the most possible surface.

By turning over and renewing the earth at intervals all

* In double poles the cross-bars are fixed with each of the poles, and therefore the same results may be expected.

† The cutting tools, straight, but rounded a little towards the end, are well adapted to this purpose.

‡ The conclusions of the experience last been observed unfavourable as far as to a depth of 3 metres. But this instance of gradual must be considered as thoroughly exceptional.

Electrician: May 28, 1881.

OVERHEAD *v.* UNDERGROUND WIRES.—The Chicago Common Council has passed the following resolution:—"No person shall hereafter erect, construct, or put up, any telegraph pole, telegraph line, or wire, electric conductor, in any street, avenue, or alley, within the corporate limits of the city of Chicago, under the penalty of 100 dollars for each and every offence. And each and every day any such telegraph pole, line or wire, or electric conductor shall be continued and maintained after the first conviction shall constitute a new and separate offence." This law rather discomforted the telephone companies.

injurious repetitions are destroyed; and for the same reason brambles must be removed, as also shrubs, since these not only produce an injurious effect by their roots, but they hide the foot of the post from the light, hinder circulation of the air, and maintain a constant dampness.

These operations will considerably retard the destruction of timbers, and will very often preserve them from "rot." It must not, however, be denied that it is very difficult to combat the fungus when once the rot, in attacker; and to make sure of guarding against it, the surface of the wood must be entirely isolated from the water and air which surrounds it. To this end a hole is made around the pole, in the form of a covered cone, to a depth of about 50 cm. This hole is filled with concrete or cement, and the black is carried from the level of the soil by an inclined surface, open and from which the rain water glides. The joints near the timber should be attended to with exceptional care.

Iron should be used for the same purpose are dear; moreover, for reasons to be hereafter detailed, their use is not recommended. Stone is the best material for the following reasons by first-rating, with sculptured ornaments, all these portions to be preserved, and afterwards covering; then with a sheet of zinc, soldered to the joint, and finely fastened above and below.

The line entrances have often assured me that the raising posts always rot in a greater proportion than ordinary supports. All but this seems impossible, but it admits of easy explanation. These posts are most often placed close to cultivate which lead to precisely on the banks of a river. The lime and sand used in their construction mix with the surrounding soil in quantities sufficient to cause wood-rotting,—an action which is also facilitated by an abundant dryness and moisture, resulting from the close neighbourhood of the trench. We should therefore be careful not to plant wooden supports too near cultivate or arched drains.

We ought equally to abstain from the fashion of planting a new pole in a hole from which a rotten one has been taken. The germs of destruction being close at hand, the second pole will perish yet more rapidly than the first.

The practice of heating all rotten poles level with the ground is very bad. They should be pulled out entire; the diseased parts should be burnt, carried away; the old hole should be filled up, and another hole made, the new pole should be placed at least a yard from the locality of the old one. If rotten sleepers or cross-beams and the ends of posts are left about, the filaments of the mycelium —in light or cracked soil—force their way through the ground in a manner and to a distance one would have deemed impossible, and will soon invade unaffected localities.

It may be remarked that when once a pole has been injured by wet-rot, if it be carefully taken up and all the rotted portions sawed away, and if it be replanted at a sufficient distance from its former position, it will not, in a usual way, be long serviceable: it will soon recommence to perish, as it is almost impossible to prevent some destructive germs remaining in the fissures of the wood. The soil is greater still if, instead of replanting the wood at once, it be left exposed for a certain time to the air. In such a case it is not worth the carriage. Once replanted, it almost always perishes with very great rapidity.

If I have succeeded in laying bare the nature of the evil so he fought against it, I understand how much easier it is to be prevented than to be cured, when once it has made its appearance. It seems to me almost certain that among the numerous coatings known as preservative compounds, one can be found capable of preserving buried woods; and supposing, which is very probable, that this

* These observations show that the position of the cavities of telegraph supports becomes more and more difficult; as we have seen, the quantity of matter in decomposition which may accumulate on the surface of ground in close proximity to railways, as much from the cinders of locomotives as from the support the rails as from the rot of the feet of poles planted.

exciting would require to be renewed at longer or shorter intervals, its use would still effects a considerable saving.

Century has not been successful. I have reason to believe that it has not generally been well applied. The tar ought to be used hot, though it should not be allowed to boil too long, lest it lose the essential oils which alone assist in to enter into the wood, and lest it become reduced to a substance in all points resembling bitumen. The wood should be well heated. By this means moisture is dispersed, the pores are opened, and the material by penetrating freely, altering and retaining layer. A single thick layer has a very bad effect; repeated and light layers should be given, though it is a difficult operation. For want of following out these precautions we simply lay on the wood a coating which is repulsed from it by resistance, and is of a brittle, cracking, and splitting character. Under these circumstances all the destructive agencies penetrate by the splits, and the wood is attacked as though it had been not at all treated. The best method consists of three distinct parts: a metallic mirror with linear facets; a blackened boiler the axis of which coincides with this focus; and an envelope of glass, allowing the sun's rays to reach the boiler, but preventing their escape after they are transformed into obscure rays. He has convinced himself (he says) that the proportion of the heat utilised to the extent of the surface of normal insolation increases with this extent, or in other words, the productive power of a large generator is better than that of a small.

He describes the large generator which has been in work at Paris for some time past. The mirror has the form of a truncated cone with parallel bases. The generating surface of this cone makes with the axis an angle of 7°; this, he (Depuis) showed best century, is the best form for that kind of mirror because the incident rays, parallel to the axis are reflected normally to the axis, and give a form of the maximum intensity for the same aperture of mirror. The reflecting surface is composed of twelve sections of silver plate, supported by a framework of iron, in which they can slide. This arrangement allows of removing each sector in order to clean it, or to substitute for the silver plate polished brass, which produces the same effect. The diameter of the aperture of the mirror is 250m.; that of the bottom is 1 metre; whence it follows that the surface of normal insolation of the apparatus is about four square metres.

The bottom of the mirror is a disc of cast iron, added to diminish the force of the wind. At the centre of this disc rises the boiler, the height of which is that of the mirror. It is of copper, blackened externally with lamp black. It consists of two envelopes of bell-form, connected at their base by an annular ring. The outer envelope is 80 centimetres in height, the smaller 70 cm.; their respective diameters are 28 and 22 cm. The water is inclosed between these two envelopes, forming an annular cylinder 3 cm. in thickness. The volume of liquid should not exceed 20 litres, so as to leave about 10 litres for the steam chamber. The boiler, when empty, is terminated by a copper tube which opens on the one hand into the steam chamber, and communicates on the other by a flexible tube with the boiler of the motor or with the fire-place of an alembic. A second flexible tube, connected with the bottom of the boiler, serves to convey the water to it.

Lastly, on the steam pipe are fixed safety valves.

As for the envelope of glass, it is a bell 85 centimetres high, 40cm. diameter, and 5mm. thickness. It allows, then, a constant interval of 5mm. between its walls and those of the boiler, and is adherent only by its foot to the bottom of the mirror. Thus arranged, the generator should turn about 50° in the hour, about an arbour parallel to the axis of the earth, and incline gradually

ARTICLES.

ON INDUSTRIAL APPLICATION OF SOLAR HEAT.

IN a recent paper to the French Academy (October 4) M. Mouchot gives an interesting account of some attempts he has made to utilise solar heat industrially. The solar generator, as he now has it made, consists of three distinct parts: a metallic mirror with linear facets; a blackened boiler the axis of which coincides with this focus; and an envelope of glass, allowing the sun's rays to reach the boiler, but preventing their escape after they are transformed into obscure rays. He has convinced himself (he says) that the proportion of the heat utilised to the extent of the surface of normal insolation increases with this extent, or in other words, the productive power of a large generator is better than that of a small.

He describes the large generator which has been in work at Paris for some time past. The mirror has the form of a truncated cone with parallel bases. The generating surface of this cone makes with the axis an angle of 7°; this, he (Depuis) showed best century, is the best form for that kind of mirror because the incident rays, parallel to the axis are reflected normally to the axis, and give a form of the maximum intensity for the same aperture of mirror. The reflecting surface is composed of twelve sections of silver plate, supported by a framework of iron, in which they can slide. This arrangement allows of removing each sector in order to clean it, or to substitute for the silver plate polished brass, which produces the same effect. The diameter of the aperture of the mirror is 250m.; that of the bottom is 1 metre; whence it follows that the surface of normal insolation of the apparatus is about four square metres.

The bottom of the mirror is a disc of cast iron, added to diminish the force of the wind. At the centre of this disc rises the boiler, the height of which is that of the mirror. It is of copper, blackened externally with lamp black. It consists of two envelopes of bell-form, connected at their base by an annular ring. The outer envelope is 80 centimetres in height, the smaller 70 cm.; their respective diameters are 28 and 22 cm. The water is inclosed between these two envelopes, forming an annular cylinder 3 cm. in thickness. The volume of liquid should not exceed 20 litres, so as to leave about 10 litres for the steam chamber. The boiler, when empty, is terminated by a copper tube which opens on the one hand into the steam chamber, and communicates on the other by a flexible tube with the boiler of the motor or with the fire-place of an alembic. A second flexible tube, connected with the bottom of the boiler, serves to convey the water to it.

Lastly, on the steam pipe are fixed safety valves.

As for the envelope of glass, it is a bell 85 centimetres high, 40cm. diameter, and 5mm. thickness. It allows, then, a constant interval of 5mm. between its walls and those of the boiler, and is adherent only by its foot to the bottom of the mirror. Thus arranged, the generator should turn about 50° in the hour, about an arbour parallel to the axis of the earth, and incline gradually to this arbour, regard being had to the declination of the sun. M. Mouchot describes how this is provided for.

The apparatus acts, of course, only in the sun. The following are some of the results obtained with it:—On 8th May, in ordinary good weather, 20 litres of water at 20°, introduced into the boiler at 8.30 a.m., took, after completion of air, 40 minutes to produce steam of 2 atmospheres—that is to say, at 121° C. This steam was then raised rapidly to the pressures of 5 atmospheres, which it reached in 5 minutes. It would have been dangerous to exceed, notwithstanding the regularity of the heating, the sides of the boiler being only 5mm. in thickness, and the total steam generated by these sides being then about 10,000 kilogrammes. Towards mid-day, with 25 litres of water in the boiler, the steam at 100° rose in less than 15 minutes to the pressure of 5 atmospheres, or, in other words, to the temperature of 152°. On the 23rd July, about 1 p.m., when there was unusual heat, the apparatus supplied 5 litres of water in the hour, corresponding to a production of 150 litres of steam per minute.

In default of a motor adapted to the apparatus, M. Mouchot used at first a large experimental engine, without expansion or condenser, the capacity of the pump being one-third of a litre. This machine made, in good weather, 80 strokes in the minute, under constant pressure of one effective atmosphere; it also work when the sun was slightly clouded. Quite recently M. Mouchot has substituted a Berlin's small steam engine; this has worked wonderfully, especially as it is directly a small centrifugal pump, which has proved too weak for the generator, and is disheated.

Lastly, M. Mouchot has brought the steam from the apparatus into contact with wine; he has thus distilled 5 litres of wine in a quarter of an hour. The steam could also be made to rapidly cook vegetables, food for cattle, &c.

From the results he concludes that the apparatus utilises, on an average, in that region, about 8 to 10 calories per minute and per square metre. This is, however, only an approximation, because the intensity of the reflected heat constantly increasing from the base to the summit of the boiler, the temperature of the latter is not uniform. The glass of the reflector being only a quarter of a millimetre in thickness, he considered to not to be therefore too small a portion of the incident heat.

DRY-ROT IN TIMBER.*

CONTINUING our notice of Mr. Britton's work we have to deal first with the important process known as seasoning. The methods employed for seasoning timber divide broadly into the natural and the artificial—the former being undoubtedly the best as far as the quality of the material is concerned, while the latter are those of great value in a commercial point of view, and are consequently the subjects of numerous patents. All wood that is used in the arts of construction, and intended to be durable both in substance and shape, should be thoroughly seasoned—that is to say, it should be thoroughly drained of sap, and have been so treated that the albuminous matter it may contain have lost their liability to ferment. When a tree is felled it contains, even if it has been barked for some time previously, a considerable quantity of sap, which consists of water holding gummy, saccharine, saline, and albuminous matters more or less in solution, and if these are not reduced to the dry and solid state, they are liable to ferment and cause the premature decay of the wood. If the drying is carried on by natural means the process is slow—two years being required for timber intended for carpentry, and double that time, and more too, for wood used in joinery. Timber in the log is liable to attack by the action of the weather, and loses by the very same process a large part of its value. It consequently soon as soon as possible, when the seasoning process is carried on with care, the actual loss is small, and with considerable increase in the value of that which does not split or warp. The most trifling great care is taken in piling the planks, and the stacks should be well-pegged and thrawed three times round; for it is found that timber which becomes bent during seasoning, or during the early stages of that process, will retain the bend when dry. With different kinds of timber different methods of treatment are adopted in the seasoning. Trees that contain little sap may remain for years in the log, and most kinds may have the splitting tendency reduced by squaring them, which will remove much of the sap wood. Where possible, timber to be seasoned should be set upright, protected from the sun and the rain, and so stacked that a free current of air may constantly circulate without the timber being exposed to strong currents of wind. But when the greatest precautions are taken there are some kinds of timber which will always warp, and others, notably white Petersburg deals, which are naturally hygrometric, swelling in a damp atmosphere, and contracting again in a dry one. It may, however, be taken as a general rule for all kinds of timber that, whatever expedient may have to be beat as regards the preliminary seasoning, some time before it is used the wood should be reduced to something near the size it is intended to remain, by the ordinary process of boat. It, however dry a piece of timber may be, it will absorb more or less when cut to a smaller seantling, in consequence of the coating being less dry than the exterior, and it should be noticed in favour of this process that a well-seasoned wood that the more rapidly the drying has been carried on the greater will be the subsequent shrinking. *ceteris paribus* in dimensions, which is largely used for curved work and the finer fittings of buildings, requires very careful seasoning, for it is easy to conceive the destruction caused by shrinking in panelling. Mr. Marshall advises that oak for this purpose should be barked as it stands—in the spring, we presume, and cut down in winter, when the sap is then partly dried out by the most natural means, and when acquires a rich brown colour. As soon as the tree is felled it is to be sawn into the required lengths and thicknesses, viz. 3in. 1in. thick, taking the first cut through the centre of the tree, so as to remove all heart-shakes. With regard to the drying, he recommends stacking in a shed with a good draught through it, laying the planks with their ends between, so as to prevent warping. If this plan is pursued it is said that the wood will not require ovens to the weather. On the other hand, Mr. Phillips, while recommending that the tree should be cut as soon as felled, would have the pieces 12in. or 6in. thick, and would stack them on end in the open, keeping them wet by artificial means if necessary, during the first three months. After being exposed for about six months it is put into a dry place for some little time, and then cut up to the sizes required by the joiner, allowing for a shrinkage of 1in. to the foot, when it is stacked in a covered shed, weighted to prevent warping, and occasionally turned and shifted. Mr. Phillips advises that oak should be cut in fortnight-old moons, or in mild moons from the centre of the tree. It is a waste of material, he says, to leave the bounty of the wood and its freedom from warping.

The two methods above given are a fair

* A Treatise on the Origin, Progress, Prevention, and Cure of Dry-Rot in Timber. By T. A. Britton, Architect. E. and F. N. Spon.

A NEW TELEGRAPH SYSTEM.—A new telegraphic system invented by Carl Cuno, vice-president of the Royal Meteorological Institute of Munich, has attracted considerable attention lately at the International Telegraphic Exhibition at Vienna. The system invented by the inventor exhibited it. The invention is thus described by the inventor:—The system does not consist in a new form of receiving and transmitting apparatus, which, by the talented combination of Hughes, Wheatstone, Siemens and others have attained such a state of perfection that great improvements seem impossible. In Cuno's system, however, opens up a new scope for telegraphy in which the electric current will some simple instrument, whereby the electric current, by being passed through different instruments obtains different qualities, which are then made perceptible by these instruments at the receiving station. Proceeding twenty parallel ing wires be led from one of the poles of a battery through twenty such instruments, then by connecting each or some of these with a single telegraphic wire the following result is obtained, viz., that at each local receiver is produced in the twenty corresponding conducting wires on the receiving station, exactly as if the twenty conducting wires on the transmitting station were connected with the twenty conducting wires on the receiving station, by means of twenty separate telegraphic wires, which, however, are replaced by a single telegraphic wire only. In Cuno's instruments consequently accomplish the same as if the number of telegraphic wires were the same as the number of instruments they are very simple, and their construction is as follows: Each of these little instruments consists of a tuning fork which is connected with an electro-magnet and two battery cells, that the electric current by traversing the instrument becomes interrupted according to the "measure" which corresponds with the note of the tuning fork, and when a then vibrating current thus traverses the telegraphic wire to the receiving station, then those tuning forks in them which have the same note as those in the transmitting instruments will be set vibrating, and then a current is caused in their local wires. It is evident that such a multiplication of a telegraph line can be very advantageously employed in many ways. Several pair of instruments supplied at the two termini of the telegraph line represent the application of a new form of telegraph by which letters can be signed to correspond with one another without disturbing the correspondence going on along the same line, and the correspondence can thus be considerably multiplied. Instruments as intermediate places can also be applied, and thus many different telegrams can be transmitted simultaneously to different stations. This system is also suitable for transmission of handwritings or drawings pantelegraphy. If, however, drawings done by the synchronous movement many times over the pencils in a single line on the transmitting and receiving station, for in the latter case the pencils or styles are kept in contact over the paper side by side, and the line of writing is produced by one passage over the paper. The vibrating currents in this system also the advantage that they do not affect other ordinary relays or receiving instruments through their insulation, so that they can pass through a line without disturbing the correspondence going on, or even in the ordinary currents from the other and affect in the same instruments. These vibrating currents thus neither disturb the ordinary telegraphing through the line nor are they disturbed by it.

Engineer Sept 75

THE Directors of the City street hill Railroad, San Francisco, two years, and subscription to new one. The road runs for some street-hill, and the cars are propelled by an endless wire rope. The engine furnishing the power is down the cities, undergrounds, made of 2 inch steel [illegible] tubes inches in circumference, and 22mh, 1875, 8,000 feet of No. 10 gauge. It is calculated that in two days when crossed, it was made to work seventeen hours and twenty while running. During the time it worked 3,200,000 passengers. A day calculated, says the *San Francisco Scientific Press*, should The Chief Engineer estimates of $6.00, wire would give 255,000,000 lb. 255,000 lb. 25,500,000 lb. 2,550,000 lb. 255,000 lb. 25,500 lb. 2,550 lb. 255 lb. 25 lb. 2 lb. 1 lb. 1 lb. 1

THE TELEGRAPH DEPARTMENT.

IN a pamphlet just issued Mr. Herring again charges the Telegraphic Department of the day since with exhibiting rare perfection in the art "how not to do it." His case, on his own showing, appears hard, but it is, unfortunately for him, an old grievance, a class of subject [illegible] it is almost impossible to interest the public. The discussion has now exceeded [illegible] years, and has recently been enlightened by Mr. Herring's reflections on the result in which the arbitrators between him and the Post Office have performed their duty. Mr. Herring not only accuses the arbitrators, Sir William Thomson and Mr. Fleeming Jenkin, of being rather the servants of the Government than impartial judges, but falls foul of Mr. Gisechen and Lord John Manners for the apathy they have exhibited concerning his real or illusory claims. So far as the pamphlet before us explains the matter at issue, Mr. Richard Herring is the inventor of a new method of printing telegraphic messages—claimed by him to be a great improvement on the Morse system of printing. The chief difference between the two methods appears to be in reversing the position of the dashes and dots of the Morse alphabet. In the latter well-known system a strip of paper moving forward by clockwork receives from a style or pointer, influenced by an electrical current, a mark broken or interrupted into long or short dashes and dots. In Mr. Herring's system the dashes and dots are made by separate styles or pointers, and they are perpendicular instead of horizontal. A great saving in space is thereby secured, and it is also claimed that greater clearness is obtained. Mr. Herring considers that he has made a distinct improvement, and continues to ask that his system may be afforded a full and impartial trial, inasmuch as if his improvement be real its commercial value is unquestionable.

So long ago as 1870 Mr. Herring brought his system under the notice of Mr. Scudamore, and a discussion ensued which, with sundry intervals, has lasted to the present time. Mr. Scudamore appears to have been at first well disposed towards the inventor, but the experts of the Post Office showed less appreciation of Mr. Herring's "method of making the dots and dashes in uniform time by using a positive current for the one and a negative current for the other." To them it appeared to offer insuperable objections, on the ground of its interference with the duplex system of telegraphy; yet he was willing that it should have a final trial, "to be carried on before one or more scientific persons acting on behalf of the Department, but not connected with it," and on behalf. It would seem, then, that the Department, although not hopeful of the success of the new system, was disposed to afford it an impartial trial, and the upshot was that Sir William Thomson and Mr. Fleeming Jenkin acted in its behalf. Mr. Herring at this juncture would have had the best of the position, supposing his improvement to be really valid, had he not taken unnecessary pains to examine the Government Telegraph officials by perpetually writing letters concerning the conditions of the trial. Some difficulties arose respecting the use of an automatic sender, which Herring declining to accept the report of the arbitrators appointed by the department as "final" and it is on the finality and completeness of this trial and report that the case now turns. Proper facilities were undoubtedly offered to Mr. Herring but, although he was treated with every imaginable courtesy, he has perhaps a right to consider that the "final trial" of his instrument, automatic sender and all, never came off. In his opinion the hostility of Mr. Culley, Engineer-in-Chief of Post Office Telegraphs, is the main cause of the rejection of his invention by the Department. To the inventor Mr. Culley appears to have been from first to last opposed to his improvement, but "willing to maintain an appearance of fairness by pretending to try an instrument which he had resolved beforehand to condemn." This is strong language, but various remarks of Mr. Culley give it a semblance of justice. He had evidently made up his mind on the subject when he wrote, in April, 1871, that "we might allow Mr. Herring to try his instrument on a line where it would no doubt die a natural death;" but, in justice to Mr. Culley, it is only fair to cite that his opinion is substantially backed by the report of Sir William Thomson and Mr. Fleeming Jenkin, who, admitting that the instrument possessed certain minor advantages, pronounced it inferior to the Morse on two points—firstly, as not being adapted to work on the double current method, by which two currents are used for each symbol; and, secondly, as being more complicated. On the other hand, the opinion of Mr. Latimer Clark and that of Messrs. Charles Hockin and Herbert Tayler, of the house of Clark, Forde and Co., is highly favourable to the instrument. Thus, the story of the Herring instrument is the old one of the disagreement of doctors, aggravated by the very natural desire of the inventor to get fair play for his invention and the equally natural determination of the Department not to have a distasteful attention forced upon them "in spite of their teeth."

Perhaps the Post Office Department has, to Mr. Herring, seemed indifferent to his invention simply because they did not quite see its commercial value as applied to an established system of telegraphy. Had the whole telegraphic lines of this country to be laid down *de novo*, probably Mr. Herring's scheme would have come in for closer attention than it was fortunate enough to receive, but it is possible that the official staff did not see sufficient merit in the alteration to justify the suppression of the Morse system. This is one of the greatest stumbling blocks of the inventor, and yet one that he must be prepared to meet with good humour. The merit of an improvement may be unquestionable, but there always remains a lingering doubt whether it is quite "worth while" to revolutionise an expensive plant to take advantage of it.

While telegraphy is before the public it may perhaps be well to call attention to the defects of aerial lines. Within the last few days communication has been interrupted between important cities—a result which could hardly have arrived had the lines been laid in pipes underground instead of being carried far above the surface on posts. There is, of course, the disadvantages of extra first outlay, but perhaps this would be covered by the reduced cost of maintenance. The improvement has also the merit of being applicable by degrees to existing lines, which, when brought down below the surface of the earth, would at least be comparatively safe, instead of at the mercy of every gale.

Proceedings of Societies.

THE SOCIETY OF TELEGRAPH ENGINEERS.

On Tuesday, the 21st ult., Mr. LATIMER CLARK, President of the Society of Telegraph Engineers, held the Annual Soirée at Willis's Rooms, St. James's Street, where he received a numerous and distinguished company.

There was a numerous assemblage, both of gentlemen interested in electrical and mechanical science, and those who confine themselves to the less ambitious sphere of practical telegraphy. Among others we noticed Sir. Gladstone, F.R.S., Professor Fleeting Jenkin, Dr. C. W. and Mr. Carl Siemens, Mr. Bramwell, C.E., Dr. Warren de la Rue, Mr. Willoughby Smith, Colonel Stotherd, and Majors Webber and Frank Bolton, R.E.; Sir James Anderson, Mr. H. Weaver, and Messrs. Wilmer Patey, Graves, Preece, Fischer, &c., of the Postal Telegraphs Departments. There was, as usual, an exceedingly interesting display of electrical and telegraphic apparatus, and of historical objects illustrating the progress and development of telegraphy. Foremost amongst these must be mentioned the

THE TELEGRA

January 1, 1876.]

Wheatstone collection, exhibited by Mr. Robert Sabine, C.E., and Mr. B. S. Culley, C.E. This collection is invested with peculiar interest at the present moment, in view of the recent death of the celebrated electrician. The Wheatstone collection begins with the five-needle telegraph, patented by Messrs. Cooke and Wheatstone in 1837, and ends with the capillary mercurial receiver for signalling on submarine cables. A five-needle telegraph was shown, which was in use at one time on the Paddington and Drayton line, and is said to have been the instrument which transmitted the message leading to the apprehension of Tawell, the murderer. Tawell, as will perhaps be remembered, was dressed in the garb of a Quaker in his attempted flight from justice; and as this ancient telegraph, despite its five needles, could not make the letter "Q," the writer is said to have resorted to the expedient of spelling the word "Quaker" The gap in the Wheatstone collection between the earliest and latest efforts of the inventor was filled up by specimens of his well-known A B C telegraph, the automatic telegraph, the Wheatstone bridge, and the instrument originally devised by him for measuring the velocity of light.

General Eckert, who visited Europe two years ago with Mr. Prescott, has suddenly resigned the General Superintendentship of the Western Union Company's lines. E. Atherly. He is about to manage, as President, the Atlantic and Pacific Telegraph Company's business, the chief competitors of the Western Union Company; and it is reported that a great and bitter telegraphic contest is about to commence in that country between these rivals.

CENTRAL AMERICAN TELEGRAPH.

THE adjourned general meeting was held on February 23, at the City Terminus Hotel; Mr. J. Hough presiding.

The report reminded the shareholders that at the last annual meeting in December, 1874, the chairman stated that probably before another year had elapsed the company would have transferred its cables to the West India and Panama Telegraph Company Limited—in accordance with the terms of the agreement with that company, which had been submitted to and approved by the shareholders of this company—and this company practically be wound up. The Trinidad-Porto Rico section of the cable had been completed and handed over to the West India and Panama Company, but the directors regretted to state that that company had refused to accept the Para-Demerara section. Legal proceedings were pending between this company and the contractors in reference to this section.

The Chairman briefly moved the adoption of the report, stating that the affairs of the company being in litigation, and the contractors with the company for the cable being shareholders of the company, he did not think it would be desirable to discuss the company's affairs any further.

Mr. A. Seymour seconded the motion.

The Chairman, in reply to Mr. S. Lawis (of Hooper's Telegraph Works Company), said the company had had no reserve, and had received nothing from traffic. The cables were in such a state that they had not been able to carry enough to pay expenses. He believed [illegible] had passed through, but the companies working the cables—the West India and Panama and the Western and Brazilian—had the receipts to cover expenses. The gross revenue would, he believed, be under £100.

The reports and accounts were then adopted.

whilst the department cannot claim to have been infallible in its management, the deficiency is mainly due to the exorbitant price paid for many of the telegraph undertakings, and to the heavy quantity of unremunerative labour, which it is compelled by statute to perform. I would, at the same time, remind your lordships that although up to the 31st of December, 1874, the deficiency of telegraph revenue to meet the interest on the stock issued under the authority of the Telegraph Acts, 1869, 1870, and 1873, amounted to the sum of £473,153 3s. 2d., yet, that if from this sum is deducted £40,136, the amount of the payments chargeable to capital, the deficiency of the telegraph revenue, after allowing interest upon the £ from deducted, to meet the interest due, is under £370,000, or less than £54,000 per annum for each of the five years since the transfer."

With reference to the number of non-paying offices, it is stated these have entirely disappeared in London, and diminished altogether in the extent of one-half since the return was taken in 1874. In the face of such facts, his lordship hesitates to recommend the withdrawal of accommodation already enjoyed by the public.

The recommendation to amalgamate the duties of the Post-office Surveyor with those of the Divisional Engineer is regarded as likely, if carried into effect, to be attended with injury to both branches of the service; whilst as regards the proposal to extend the employment of the Royal Engineers, the review continues:—

"The employment of the Royal Engineers, to which the committee next advert, is a political deal with it here in regard only to its financial bearing. The engineering staff admits of reductions; but this can only be accomplished as opportunities occur.

* * * *

The Royal Engineers can at any time return to the War Office; and, as all that would be required to replace them would be a few additional line men, nearly two-thirds of their allowances, or so, I am compelled to advocate their withdrawal. Committee, on financial grounds, to recommend a festly wrong to expose a large sum annually on an object altogether foreign to that for which the taken. In the event, however, of its being considered desirable, upon grounds of Imperial policy, that the postal telegraph service should be used as a school of instruction in telegraphy for the Royal Engineers, it will be but just that the pay of the officers and men thus instructed should fall, not on telegraphs, but on War Office funds."

His lordship does not think any attempt by legislation or otherwise to induce railway companies to undertake the maintenance of the lines of the railways would be successful, and doubts whether the Committee could be in earnest in making such a proposition. His demur to the assertion that the working expenses have increased in a greater ratio than the increase of messages; so far from this the net revenue now exhibits an increase considerably larger than the increase of messages, a fact which induces a hope that the undertaking will ere long exhibit a profitable result, provided that the capital account is charged with the expenditure which properly belongs to it, instead of being a charge against revenue.

Touching the question of tariff, his lordship remarks, that in acquiring the telegraphs, the intention of the legislature was to consult public convenience, and not to transform the transaction into a mere commercial speculation, and he adds, "it would in my opinion, be inexpedient and hardly fair, to go back entirely from what parliament granted when the Telegraph Bill was passed." The existing press rates will therefore continue except as regards the "copy" charge of 2d. which it is proposed shall apply only in cases where such copies can be delivered by hand. If this has effect, it is estimated to produce a net gain of revenue of not less than £30,000 a year. Modifications in the charges for messages handed in at railway stations, the commission on which are now paid by the department varies from 3d. to 9d. on the message, are also advocated, and valued at £12,000. A late and Sunday fee of 6d. except on press messages, to which it is not to apply, is also calculated to produce a like sum of £12,000 per annum, and it is lastly proposed to purchase up the rights possessed by certain railway companies to send free messages over the wires of the Department: the main object of which is to free the wires for other and more profitable work, and relieve the department of much correspondence.

His lordship concludes:—

"The charge is that the telegraphs in the hands of the Post Office have not turned out a paying concern. Had the increase in the number of telegraph offices from 2,488 to 5,600, and the increase in the number of messages from 8,000,000 to 20,000,000 been accompanied by a corresponding increase of net revenue, it would have been highly satisfactory; but there is nothing in the Act of 1868 to show that this was expected, nor indeed would it have been reasonable to expect it. What the legislature did intend was that the public should be better accommodated, and during all the discussions which have taken place in Parliament, or elsewhere, no complaint that this intention has not been carried out, so far as I am aware, ever has been heard. Undoubtedly, and mainly to those which are acknowledged by the committee, the financial result of the measure is not, up to the present, satisfactory. 'There are, however, signs of improvement; the service is yet but in its infancy; the business of the department is steadily increasing, and the necessity for economical management will be steadily kept in view. If the alterations which I have proposed be adopted, and due allowance be made for the charge upon revenue of expenditure fairly chargeable to capital in ordinary commercial undertakings, I shall be much disappointed if, at the expiration of the ensuing financial year, telegraph receipts, as compared with working expenses, do not show a result which would make it impossible to ask parliament to adopt the retrograde policy which the committee have felt it their duty to advocate."

The receipts of the Western and Brazilian Telegraph Company for four weeks ending 25th inst. show £2,591 increase over same period of 1875.

THE TELEGRAPHIC JOURNAL.
VOL. IV.—No. 90.

NEW ZEALAND TELEGRAPH.

THE Government of this enterprising colony has just issued its twelfth Report. It is an exceedingly interesting and well-compiled document. It not only narrates the history of the telegraphic progress of the islands for the past year, but it furnishes very complete plans of the telegraph system connecting together the three islands which are called New Zealand. It appears that the revenue for the year 1875-76, which was estimated at £62,000, has exceeded that amount by more than £1,300.

The number of telegrams transmitted during the year was 1,051,080, being an increase over the previous year of 133,958. Including the value of General Government telegrams, the gross earnings of the department for the year amounted to £79,537 7s. 11d. The expenditure exceeded the receipts by £2,803 12s.: the expenditure incurred in the repairs of the Cook Strait Cable amounting to £3,363 15s. 5d., having been debited against the vote of the department, has placed the balance on the wrong side. Owing to the increased number of stations and the additional lines, the expenditure is greater than in any previous year. Several amounts have also been charged against the vote of the department, which, it is said, might with justice have been charged upon construction, and taken out of the telegraph portion of the loan.

The number of telegrams transmitted during the year, as compared with the number of letters posted during the same period, shows that 22·21 telegrams were sent for every 100 letters posted. This proportion is rather less than last year, when the comparative number was 22·50. It must, however, be remembered that there is an increase in the number of letters of almost 700,000, so that the proportion of telegrams is very satisfactory.

Since the date of the last Report, direct communication has been established with Australia. The cable was opened for business on the 21st February last, and has been largely used. The Wakapuaka Station has, since the date mentioned, forwarded to New Zealand stations, 3,689 telegrams. Of this number, 3,395 messages were received through the cable, from Sydney and places beyond, the average of words per message being 19·3. The number forwarded from New Zealand through the cable, to Sydney and places beyond, during the same period, was 3,268, the average of words per message being, in this case also, 19·3.

The number of Money Order telegrams sent during the year was 10,712, representing a value of £40,988 17s. 3d., or an increase of 1,062 messages, and of £2,409 17s. 5d., as compared with the previous year. The commission collected by the Post Office was £1,355 19s. 4d.; and after deducting £335 12s., due to the Telegraph Department as fees on the telegrams, there remained to the credit of the Post Office, as commission on exchange, £1016 9s. 4d., almost £3 per cent. on the amount transmitted. The largest number of orders was issued in Wellington, Dunedin coming next, and Christchurch next.

During the year, 118 miles of line carrying double wire, and 90 miles carrying single wire, have been erected; and 335 miles of wire have been added to the original lines, making a total addition of 621 miles of wire.

There are now opened to the public throughout the colony 142 stations, 15 of which have been opened during the past year, 9 in the South Island, and 6 in the North Island.

The length of line maintained during the year was 2,930 miles, the average cost for maintenance being £5 18s. 10d. per mile. This is exclusive of the amount expended in the repair of the Cook Strait Cable, which is referred to above.

At the close of the year, 3,154 miles of line, carrying 7,247 miles of wire, were in circuit, showing an increased mileage upon the previous year, in line 168 and wire 620.

The nominal strength of the department, including Linemen and Inspectors, on the 30th June, 1876, was 567, against 509 of the previous year.

The duplex system of telegraphy has been further introduced on the circuits between Blenheim and Christchurch, and between Wellington and Napier. It has been in daily operation upon the circuits mentioned for some months past, and on the cable since the 18th June, 1874, and has proved the greatest success. With all these facilities, the wire accommodation is not more than the increasing work of the department requires. It must, therefore, be obvious that the perfecting and introducing of the system has proved a very great advantage and saving to the department.

The sea has been found a great enemy to overground wires. Wherever it has been practicable the wires have been carried inland to avoid the influences of the salt spray upon the insulators. When the precipitous nature of the country would not admit of such deviation, every precaution has

DIRECT SPANISH TELEGRAPH.

THE fifth ordinary general meeting of the shareholders of the Direct Spanish Telegraph Company was held at the London Tavern, Bishopsgate-street, on the 21st March, Mr. Noel Bannatyne in the chair.

The Secretary having read the notice calling the meeting, the report was taken as read. It stated that during the last six months the number of telegrams which had passed over the cables of the company was 26,625, against 37,419 in the corresponding six months of 1874. Out of the balance of £3,382 at the credit of profit and loss, £2,679 would be required for the payment of the half yearly dividend on the 10 per cent. preference shares, leaving the sum of £4,423, out of which the directors proposed paying a dividend at the rate of 5 per cent. per annum upon the ordinary shares, absorbing £4,000, and leaving £1,604 to be carried to the reserve fund.

The Chairman said, in moving the adoption of the report, the directors were in hopes up to a recent period of being able to meet the shareholders with a higher dividend on the ordinary shares, but unfortunately the Lizard-Santander cable broke on the 3rd of last month; it was, however, efficiently repaired on the 29th of the same month, and that cable was now, as well as the one from Barcelona to Marseilles, in excellent condition. The cessation of the war in Spain had rendered it of the greatest importance that they should see to the early establishment of direct communication with Bilbao, so as to get back the valuable traffic they previously had on that line, and which they had for some time been without, owing to the state of matters in the north of Spain.

Mr. Abraham Scott briefly seconded the motion, which was agreed to unanimously, and the dividend at the rate of 5 per cent. per annum on the ordinary shares declared.

La ligne de Sibérie a été de nouveau interrompue le 26 Août par de fortes inondations, au-delà d'Alabazine. Les travaux de réparation ont commencé immédiatement et on rétablit la communication jusqu'à Bingowetschensky, mais, ce-delà, la ligne est encore interrompue dans la section de Blagowetschensk à Chabarowka. Sur le parcours interrompu les télégrammes sont transportés par vapeurs; les départs n'ont pas lieu à des dates et heures fixes, mais toutes les précautions sont prises pour une aussi prompte expédition que possible.

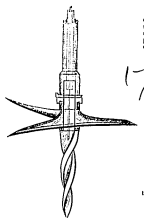
Le câble de Bahia à Rio de Janeiro interrompu depuis le 20 Juillet a été rétabli le 30 Août; mais celui de Rio Grande do Sul à Montevideo est interrompu depuis le 5 Septembre. Les télégrammes profitent de toutes les occasions que donnent les nombreux vapeurs qui circulent entre ces deux ports.

MARSHALL'S

PATENT EARTH-BORING APPARATUS.

(IN USE IN THE POSTAL TELEGRAPH DEPARTMENTS.)

The most practical and useful implement in the erection of Telegraph Lines, Signal Posts, Scaffold Poles, Flagstaffs, Mangnels, Bootls, putting up Fencing, Planting, &c., &c.



Effects an economy of Labour equal to 60 per cent. and ensures a greater firmness and stability to the fence than can possibly be obtained by any other method.

175

This apparatus has been extensively used during the last few years in England and abroad with the most satisfactory results.

Testimonials, with full particulars and price list, free.

W. A. MARSHALL, TELEGRAPH ENGINEER, BRIDGWATER.

THE FIRST OVERLAND TELEGRAPH IN CHINA.

77

The Pall Mall Gazette says: The construction of the first overland telegraph in China has been attended with considerable difficulties. It was when the Foochow affair became threatening that the Viceroy of Pekkin made arrangements with the Great Northern Telegraph Company for the construction of a line from Amoy to his Yamun at Pakchow. But no sooner was the first portion completed than the natives discovered that the erection of the poles interfered with the benign influences of the Fung-shin of the district. They therefore turned out "in their thousands" and uprooted the poles. Upon this the company appealed to the native authorities for protection, and ultimately the matter was referred to Prince Kung and the foreign Ministers at Peking. The result of this diplomatic interference has been that a new contract has been made with the Great Northern Telegraph Company, under the terms of which the Viceroy agrees to pay the company $151,500, or upwards of £30,000, for the construction of the line between Amoy and Pakchow, a distance of about 160 miles, and a further annual sum of £20,000 for its maintenance. We imagine that the natives will have nothing to complain of in these terms. The Mandarins further bind themselves to give full protection to the company's staff and material, and to be responsible for any theft that may be committed on the property of the company, or for any delay that may be occasioned by unlawful interference on the part of the natives. The company, on their part, agree to make and to keep in repair the line, and to instruct Chinese pupils appointed by the Government in the art of telegraphy.

---

un courant positif d'une force 1; dans le second, par un courant négatif de force 1; dans le troisième, aucun courant ne se produit sur la ligne, et dans le quatrième, elle est traversée par un courant positif de force 2. Donc si les quatre manipulateurs des deux stations sont au repos, il y a sur la ligne un courant continu double de force de ceux qui agissent sur les appareils quand on travaille. Cette double transmission dans le même sens peut facilement être transformée en quadruple transmission, par l'introduction des relais de chaque station dans la diagonale d'un pont de Wheatstone. M. Winter donne encore une seconde solution du même problème qui, sans différer beaucoup de la première, est un peu plus simple et plus économique en ce qui concerne l'usure des piles.

9. Quelques observations sur la combinaison de la transmission simultanée dans le même sens avec celle en sens contraire, par le Dr. K. E. Zetzsche. (Dinglers polyt. Journal, vol. 217, page 29).

Cet article traite principalement de deux systèmes, l'un de Prescott et Edison, travaillant entre New-York et Chicago et entre Chicago et Cincinnati, l'autre de Dr. H. C. Nicholson. L'auteur revendique une partie de ces inventions pour Maron.

(Nous rappelons ici notre article « de quelques nouveaux systèmes de double transmission », Journal télégraphique, vol. III, page 208).

5. Les lignes sérieuses.

1. Sur la construction des lignes télégraphiques, par Joh. Gavey. (Telegraphic Journal, vol. III, pages 139, 150, 174, 195, 219, 236, 245, 293).

Pour le choix du tracé d'une ligne télégraphique, il faut surtout prendre en considération si la route fait des courbes, si elle est bordée d'arbres et traverse souvent des villages, et s'il y a ou non des terrains non cultivés le long de la route, qui permettent une libre application de jambes d'appui et de haubans. Il faut autant que possible éviter les routes longeant les bords de la mer ou passant près d'usines avec évaporations nuisibles. Si la ligne doit suivre une voie ferrée, les tranchées, les tunnels, les grandes stations et les ponts sont toujours autant de causes de renchérissement de la construction. Les distances entre les poteaux et la longueur de la ligne en général doivent se déterminer avec une chaîne de géomètre. Le long des voies ferrées, la distance entre les poteaux doit varier entre 60 et 100 mètres. Il faut autant que possible placer les poteaux à une distance des rails telle que si les poteaux viennent à tomber du côté de la voie, ils ne puissent atteindre les rails. Il convient de poser les fils de façon qu'ils puissent facilement être inspectés d'un train en

THE TELEGRAPH IN SENEGAL.

The Senegal service comprises three lines: the first going from St. Louis to Dakar, the second from St. Louis to Dagana, and the third from St. Louis to the Bar (Mouth of the Senegal).

Dakar Line.—This line is the most important; it is 126 miles in length; its direction is from N. to S. W.; it is constructed with a single wire of 3 m.m. It connects six offices—St. Louis, Gandiole, Batele, Mbidjem, Rufisque and Dakar. The region it traverses is for the most part uncultivated, without any road, intersected by large and deep recesses, slightly undulating, with impenetrable thickets of palms and bushes of different kinds scattered over it. From Gandiole to Mbidjem the country is no longer under the dominion of the French; it was given back in 1870 to a native chief, on the sole condition that he would respect the telegraph line and the station of Batele, placed in the heart of his territory. The staff employed at each of these stations is as follows: At St. Louis, the director of the service, an employé of the 6th class on the metropolitan list, a native assistant, a superintendent, a superintending chief, and two native superintendents; at Gandiole, a military employé and two superintendents; at Batele, a military employé and two superintendents; at Mbidjem, a military employé and two superintendents; at Rufisque, a military employé and one superintendent; at Dakar, an employé of the fourth class on the metropolitan list, a head of the office, a military employé, a superintendent, and two superintendents, total, 23 employés.

Dagana Line.—This unites with St. Louis by an inscribed station in a commercial point of view, placed on the River Senegal. Its length is 77 miles, and its direction from W. to S. E. This line serves four offices: St. Louis, Lampsar, Richard-Toll, and Dagana. The office at Lampsar is closed for the time being. The country traversed by this line is under French rule, it is often inundated during the winter season by the swelling of the river. At Lampsar resides a superintendent; at Richard-Toll, a civil employé and a superintendent; at Dagana, a civil employé and two superintendents, total, 6 employés.

The Bar Line.—The length is nearly seven miles. It traverses a region intersected by morasses, and by the tributaries of the river; its direction is from N. to S. It unites to St. Louis the pilot station placed at the mouth of the Senegal. A civil employé has charge of the office.

Staff.—These nine offices are supplied with the following staff. A head clerk from the Metropolitan Administration, director of the service (M. de Clauvillebrain); two employés from the Metropolitan Administration, one of whom is at St. Louis (M. Sabbe-Marie-Pidoll, and the other at Dakar (M. Fleuiot); four employés of the 6th class, military; seven military employés; a chief superintendent and fifteen native superintendents. The native employés are recruited by means of examinations. The military employés are not, by the native infantry, at the disposal of the telegraphic service; they receive instructions at St. Louis and Dakar, and they are then sent to the inferior stations. The native superintendents form a very good staff, many of them having been in the service since its organization, twelve years ago; they are well up in their duties, thoroughly disciplined, and capable of bearing the fatigues and privations of a journey on foot in this unhealthy climate.

Interior Service.—The offices are open every day from 7 to 10 o'clock in the morning, and from 2 to 6 o'clock in the evening. The offices at Lampsar and Richard-Toll were closed in 1872.

Tariffs.—Between any two stations 2 francs for twenty words; 0,50 fr. more for each fraction of five words. Between St. Louis and La Barre, 0,50 fr. for ten words; 0,05 fr. for each additional word.

	Francs.
The amount received for private dispatches transmitted.....	9,923.85
The transmission of official dispatches corresponds to a sum of.....	18,629.00
Total.....	28,117.85

The total number of messages transmitted during 1873 was 8,231.

The stations Gandiole, Batele and Mbidjem, being distant from any centre inhabited by Europeans, have only very few messages.

Superintendence of the Line.—This service is very trying, especially during the winter season; the hot-sands of rain and the violent tempests overthrow the poles and break the insulators. Notwithstanding these difficulties, only three days' interruption have taken place during the year. The materials, including the poles, are carried on the backs of mules. Nearly all the disarrangements are caused by the fall of the poles, which the sandy soil will not retain firmly; there is no stone in the interior of the country to consolidate them, and the wooden traverses are soon rotted or exhibited by Termites; fortunately, however, they do not attack the injected poles. Many poles are also destroyed by the fire which the natives set to the bush grass to clear their fields. The thunderstorms, notwithstanding their great electrical intensity, lead to no durable perturbation over the lines and in the apparatus. As to the disarrangements caused by malevolence, these are exceedingly rare. The blacks, very superstitious, fear to break the lines; they believe generally that it serves only to indicate to Europeans the road to follow in going from Dakar to St. Louis.

THE TELEGRAPH CONSTRUCTION AND MAINTENANCE COMPANY.

At the half yearly meeting of the Telegraph Construction and Maintenance Company, held on Tuesday, July 29th at the Cannon Street Hotel, London, Sir Daniel Gooch said that the work that they had had in hand during the present year had been very small. In the course of a few days, however, he hoped that the company would conclude a contract for a cable, 1,200 miles long, from Sidney, New South Wales, to New Zealand, and he trusted that for the rest of the year they would be well employed. They knew of no other work like the one he had mentioned coming forward, but they were quite prepared to take work should it present itself. He did not think it was unfortunate, even for them, that there should be a cessation for some time in the construction of these long cables. He thought this work had gone on now for some time, and with a little rest he hoped the existing cables would remunerate their shareholders better than they had in the past.

LITERATURE.

Telegraphy—By W. H. Preece, C. E., Divisional Engineer Post Office Telegraphs, and J. Sivewright, M. A., Superintendent (Engineering Department) Post Office Telegraphs. Second Edition. London: Longmans, Green & Co., 1876.

This work is evidently intended as a manual or text book for the information and guidance of the ordinary employés, such as operators, linemen, etc., of the English telegraphs. It professes to be in some sense an introduction to Culley's well-known hand book, but if the average British telegrapher is anything like the average American telegrapher, which we presume he is, the little volume before us will be of far more practical use to him than Culley's, or indeed any other work with which we are acquainted. The authors of this treatise evidently possess a thorough knowledge, not merely of the subject they are writing about, for their names are a sufficient guarantee, but what is of at least equal importance, a knowledge of the mental peculiarities of the class of persons for whose benefit it is designed. One of these peculiarities is exemplified, for instance, in the mingled sentiments of aversion and terror which are incited in the mind of the ordinary telegrapher by the sight of even the most harmless and inoffensive algebraic symbols, and which is comparable to nothing in the world except perhaps the feelings of a party of plantation negroes suddenly confronted by a group of armed "ku-klux," arrayed in the disbelief contained of the "klan." With the exception of a very few equations, which have been skillfully concealed in the latter part of the book, where the reader will not be likely to dip at them till he has read the greater part of its contents, the authors have conscientiously abstained throughout from the employment of mathematics. In fact, the simple, clear and concise language by which the ideas an l information sought to be communicated to the reader have been conveyed, is worthy of the highest praise. Commencing with a brief explanation and definition of the electrical terms in modern use, the first subject taken up is that of batteries. The varieties in actual use in England are well described and illustrated, and the methods of setting them up and managing them which experience has shown to be preferable, are detailed at length. This is followed by a description of the various instruments in use, including the needle, Morse recorder and sounder, alphabetical dial, etc., at the close of which we note an interesting discussion of the relative practical utility of the various systems. The average number of words per message in England, including service signals, is stated to be 24 words, averaging 4.5 letters each. On this basis a table is given, which is stated to be a fair average, not of what the instrument can do, but what they do do in actual every-day work in that country.

Messages per hour.	Per day.
Sounder,	60 250
Ink-writer,	40 175
Needle,	30 125
Dial (A. B. C.)	15 60

For news and commercial purposes, where the amount of business is sufficient to justify the employment of skilled labor, the conclusion arrived at is that the sounder is unquestionably superior to the record-er, and will ultimately supersede it. In the chapter on circuits, we find also a discussion on the vexed question of the relative advantages of the open and closed-circuit system, which affords an explanation of the reasons why the former system has been so obstinately adhered to by the English in the face of what has seemed to Americans the incontestable advantages of the latter. We quote:—"There can be no doubt that where many intermediate stations are fixed on one wire worked on the Morse principle, the closed-circuit system offers considerable advantages over the open-circuit system. . . . But in England we never do use the Morse on such circuits. The needle is far preferable, and in that system no adjustment whatever is needed. It is an exceedingly rare thing to fix more than four stations on one Morse circuit, for the simple reason that it is almost impossible to group four Morse stations together without filling the wire—that is, without producing a sufficient number of messages to occupy the wire during the whole of the day. If there is not enough work to fill the wire, the needle instrument, from its simplicity, economy and certainty, is used in preference; so that the necessity for employing the closed-circuit in England has not been experienced, while its extra cost, as compared with the open-circuit, and injurious action upon gutta-percha-covered wires have proved it to be really objectionable. . . . Every country has developed its own system, and the conditions which have rendered the closed-circuit necessary in America do not exist in England."

A considerable portion of the book is occupied by matters relating to the laying out, construction and maintenance of pole lines, housetop lines, and underground lines, most of which is of much practical value, although it is to some extent specially applicable only to the English system of construction, which is in many respects radically different from ours. The various faults and interruptions to which lines, instruments and cables are subject, are classified, and the process of detecting, locating and removing them explained with great clearness and precision.

We know of no work which gives such an accurate and intelligible idea of the English telegraphic system and its every day working as this one, and we regard it as a fortunate circumstance that one of its authors, Mr. Preece, should have been selected by the Post Office authorities to examine and report upon the practical working of the American telegraphic system, a duty which, as many of our readers know, he is at the present time engaged upon. Mr. Preece has been a frequent contributor to English telegraphic literature for the last fifteen or twenty years. His productions have been characterized not only by their marked ability and originality, but by a candor in respect to the treatment of controverted subjects which is far less common, at least among writers upon telegraphy and kindred subjects, than could be desired, and we shall therefore look forward with unusual interest to his statement of the results of his observations in America.

Before dismissing the book under discussion, we wish to speak with special praise of the illustrations, which are all new and appropriate, and have been drawn and engraved with great care and skill, by some artist who we risk little in venturing to say is a telegrapher as well. Most of the figures of apparatus are to scale, and are so well done that they would in many cases serve for actual working drawings. The book is so attractive in appearance and contents, so handy in size and so cheap in price, that we are not surprised that a second edition has been called for within so short a time of its original publication.

JOURNAL OF THE TELEGRAPH.

VOL. X., NO. 24. NEW YORK, DECEMBER 16, 1877. WHOLE NO. 243

Original Articles.

EXPERIENCE WITH PLAIN AND GALVANIZED WIRES IN EUROPE.

In reply to a communication from Mr. George B. Prescott, electrician of the Western Union Telegraph Company, to telegraph administrations in Europe, asking information in regard to their experience in the use of plain and galvanized iron wires for telegraphic purposes, the following communications have been received:

IMPERIAL GERMAN GENERAL TELEGRAPH } OFFICE, BERLIN *October 29th, 1877.*

Mr. E. Prescott, Esq., Electrician Western Union Telegraph Co.:

The General Telegraph Office begs to inform you, in reply, in your favor of 6th inst., with regard to the experience gained by us in the use of galvanized and plain iron telegraph wire, as follows:

1. In 1851 the first iron wires were erected in Prussia. Plain iron wire was then used.

2. From 1852 till 1856 inclusive, a majority of the lines were constructed of plain iron wire. Some of the longer lines were constructed with galvanized wire.

3. From 1856 till 1871 inclusive, all the lines were constructed with plain iron wire, owing to the greater expense of galvanizing the wire, and the small amount of the appropriations which were granted at that time to the Administration of Telegraphs for the purpose of meeting the increased requirements.

4. From 1872 up to the present time, galvanized wire has been used exclusively.

A single line of galvanized wire of 3 millimeters thickness (No. 11, B. W. G.), has been used as far back as 1857 together with the stouter wire of 5 and 4 millimeters (No. 7 and 8, B. W. G.). The former is used mostly when it is required to remove the weight of stout wire from the poles.

It will thus be seen that we have had an experience of almost twenty-six years with galvanized and plain iron wire for telegraphic purposes. This experience has shown that the old lines constructed of 5 and 4 plain wire, after having been in use for twenty-five years, have suffered so considerably from rust as to necessitate their replacement by new wires at an early date. Up to the present time the replacement of these old plain wires has been limited only to comparatively short distances, and mostly those where the wires were exposed to the action of the vapor from chemical factories, or near railroad depots to the smoke from locomotives, which has caused a more rapid destruction.

As for, however, as the lines constructed with galvanized wire of the same size is concerned, it is a fact that even the oldest ones which have been in use from 1852 to the present time (25 years) are yet in a perfect state of preservation, and nowhere is any destruction of the zinc coating visible. It is evident that galvanized wire is by far preferable to non-galvanized or plain wire, provided that the zinc coating be properly performed.

In connection with the latter, we make here the following requirements:

(a.) The zinc coating should have a smooth surface, cover the wire everywhere continuously, and stick so fast to the wire, that

A wire of 5 millimeters thick (No. 6.) shall take 5 spiral turns;

A wire of 4 millimeters thick (No. 8.) shall take 6 spiral turns;

A wire of 3 millimeters thick (No. 11.) shall take 8 spiral turns around a wire of the same thickness for a length of six inches of the covered wire, without the zinc coating sustaining any flaw, or even exfoliating.

(b.) The zinc coating should be so thick that:

The 5 millimeters wire endures 8 immersions, each lasting one minute;

The four millimeters wire endures 7 immersions, each lasting one minute.

The 3.5 millimeters wire endures 6 immersions, each lasting one minute, in a solution of one part of sulphate of copper in five parts of water, without covering itself with a continuous copper coating.

The costs of zinc coating amount to (according to the price of iron) about fifteen to twenty per cent. of the price for non-galvanized wire, but by expending this additional amount, as is shown by the information given hereinbefore, we obtain a not yet fully ascertained longer duration of the wire, which bears such a favorable proportion to the additional expense of galvanizing, that the undersize use of galvanized wire for telegraphic purposes undoubtedly is decidedly a great saving for telegraph companies.

BUDDE.

SWISS CONFEDERATION, } BERN, *October 30th*, 1877.

We are in receipt of your honored letter of the 6th instant, and hasten to give you the following information on the use of plain and galvanized wires in Switzerland.

From 1852 to 1857 we used non-galvanized wire only, of 3 millimeters diameter (No. 11, B. W. G.).

From 1857 we have used galvanized iron, usually of 3 millimeters diameter (No. 11, B. W. G.). For some direct lines wires of 4 millimeters diameter (No. 8, B. W. G.) have been used, and for international wires 5 millimeters diameter (No. 6, B. W. G.). Non-galvanized wire lasts from eighteen to twenty years, and while the galvanized wire will certainly out-last the former, we cannot give you any exact comparative results, as the oldest of our galvanized wires have been in use only ten years.

All we can say about the latter is that they still look very well. The outside has become darker, and a few have become black, but the surface is still smooth, and does not show any rust.

The Director of the Swiss Telegraphs,
HERTLEIN.

ROYAL TELEGRAPH OF NORWAY, } CHRISTIANIA, *October 30th*, 1877.

In reply to your esteemed letter of the 6th instant, I have the honor to state, that in Norway we have used galvanized wire only, and have, had therefore, no experience as to the durability of plain iron wire.

As galvanized wire, in any case must be more durable than the unprotected iron, and as our lines, for the greater part, go over mountains where there are no roads, and transportation is consequently very costly, we are obliged to use the material that will last the longest.

NEILSON.

MINISTRY OF FINANCES, } DEPARTMENT OF TELEGRAPHS. THE HAGUE, *Nov. 2*, 1877.

In answer to your honored letter of October 6th ult., I beg to inform you, that the first government telegraphic office in the Netherlands was opened in the latter part of 1852, and that in the course of this years a wire put up in 1846 for the use of a railroad company, was transferred to my administration. This was a plain iron wire of No. 6, B. W. G., and the only plain wire which has been in use here, all the other wires being galvanized.

This plain iron wire was replaced in 1872, when its diameter had been reduced to half its original size, and its electric resistance greatly impeded telegraphic transmission.

With regard to our galvanized wires put up in 1852, lasting now been in use for twenty-five years, not a single one has been replaced up to the present time, and the results of repeated tests show that the resistance of these wires has changed very little, so that the time when they have to be replaced may be considered to be pretty far off.

It is my opinion that galvanizing well does considerably increase the time of duration of iron wire, and that it is fully worth the increased cost.

The Director General of Telegraphs in the Netherlands.

STARING.

ST. PETERSBURG, RUSSIA, Oct. 27, 1877.

Concerning the question mentioned in your letter of the 6th ultimo, the Russian Telegraph Department has the honor to inform you, that in consideration of the high prices for zinc-coated wire, there is employed iron wire from 6 to 4 millimetres diameter for the construction of Government lines in Russia and for city lines iron wire with a diameter of 3 millimeter. Such a wire ought to fulfill every demand contained in the technical conditions for delivery of the wire in question, annexed to the present communication. Zinc-coated wire (3½ millimeters) is however employed, only for fixing the wire upon the insulators.

Director General,
LITKENSKY

such as it is. Few galvanometers are seen in the offices, the faculty of a break being estimated by receiving the return shock on the finger! There is no official called a repairer, who "knows a little about our "Sosman" and our "Whitehouse," who does the rounds, and who is paid from £150 to £200 per annum.

Closed circuits have been and still are the favourite system of working, although they are gradually giving place to open circuits, especially for long distances. They have the advantage of the battery being all in one place; but the substitution of the relay being all in one place; but the substitution of the relay being all in effects a saving in battery power.

As regards instruments, the number is most generally used. Wheatstone established a few such systems, and spoke very highly in favour of the combined use of which he has advocated for some years past. All the apparatus required to rig up an American office are a key, a relay, and a small sounder. As long as circuits requiring are used, the principle of "relay" sitations have not yet been studied with several of them. The weather sense of these can be cut out, but in find a remarkable fact, that no apparent loss of speed resulted from their cessation. This is, of course, a direct variance with our experience here.

Compound or multiple telegraphy is largely adopted in the States, the duplex, quadruplex, and various other "plexes" of Stearns, Gilliss, Prescott, Gray, and others all coming in for a share of attention. In telegraphic systems as established on the London-Liverpool circuit by the country for that purpose, who recently visited Wheatstone, I may be mentioned here that the quadruplex of Messrs. Smith and Hamilton, who recently visited gives highly satisfactory results.

Type-printers are employed, to some extent, principally on the lines established by Mr. Hughes, on the basis of that invented many years since by Professor Hughes. They have, however, chiefly confined to private wires.

Edison's automatic system is used by the Atlantic and Pacific Company, and very flattering accounts of its performance are given. The maximum rate has been witnessed is 72. Proctor did not exceed 200 words per minute.

On the Chicago and Dubuque circuit there is a certain is carried on without, manifestly through erroneous working. The telephone, however, does not seem to play any great part as yet, in commercial telegraphy.

In concluding his remarks upon the telegraph companies, Mr. Preece remarks upon the telegraph companies, the workshops, and says surprised that he visited some of mechanics are employed. Much of the work done by England principally, especially for large distances. In America is done by machinery, operation, who, as before, Sosman, are very skilful.

Some curious and characteristic terms are current in America, and Mr. Preece highly amused his audience by hearing a few of them. The "sounder" is called a "click;" a step is to "break;" a "relay" is "taking it;" contact is "closing;" calling a disinterested system, and, strikes in America is the important system, and, strikes in America is the "sounding." A country where so much sound is used in business. In every town a most complete and perfect system of fire signals has been established. When a fire or an something the alarmist has only to pull a handle at the station and equally simple; this rings a bell at the office, and indicates the locality in which the fire is to be found. The effect of this system is that they can get engines for the slightest carpet in a few minutes, and incomprehensible to us. Mr. Preece states that he and Mr. Fischer, when inspecting the working of the system, timed the operation of getting an engine on and away. A gong was sounded, the engine-house in which gas the signal serving to release the horses, who, at the engine, were harnessed in two minutes and a half. The sound of three observations gave 8 minutes as the time elapsed from the sounding of the alarm to the starting of the engine. Mr. Preece also testified to a still more perfect state of things existing at Chicago. There the high-current not only sounds the gong and switches the horses, but it also draws the bolts from a series of traps-doors; and, that nothing may be left to chance, it supplies the current of the men whose beds are placed with regard to the trap-doors that they are (It was not stated whether the men turn in with their uniform on, or whether the current puts this on for them).

But even this close approach to automatism is not left unsurpassed; for many buildings are provided with automatic alarms which sound any abnormal increase of temperature above a certain point, and "sound an alarm."

Domestic comfort is studied and ministered to in a variety of ways. Compact, and not unsightly, little boxes are fixed up in a convenient place in the house. This box has a dial divided into compartments headed, respectively, messenger, butcher, salt, beef, and a pointer simply pressing a lever in the person's wants are at once made known at the nearest call-station, as also the house from which the call proceeded, and in the briefest possible time the required person or article puts in an appearance.

With regard to the general question of the organisation of the staff, the American telegraph system is characterised by far greater elasticity than ours, more being left to the discretion and energy of the officials than is the case with us. The result cannot fail to be beneficial to the service; and has shown administrative capacity displayed by their superiors. The spirit of emulation is fostered, and a wholesome consequently, far less of that half-heartedness, and frequently characterises the English employé.

Financially considered, the American telegraphs are a greater success than the English, as they "pay" better. It must be remembered, however, that they are still in the process of joint stock companies, and that, early being places which are "paying" as a fair amount of traffic being served. In England the system has been commercially developed, since its acquisition by the Post Office, upon principles of national utility rather than with an eye to large revenues.

In view of these and other considerations, Mr. Preece would not attempt any close comparison between the two systems; such is admirable in its own way, and America the natural to be in advance of the other in increased by the requirements of multiplex working, in England the same end has been sought, and to a great extent attained, by the perfecting of fast speed instruments, such as that of Wheatstone automatic, &c.

In the matter of invention there are some notable points of difference between the two countries, and the comparison is apparently unfavourable to us. Here, it has to rely principally upon his own private resources, in America, invention is subsidised—in fact, men are practically of the day, one of the most eminent Union Co., and furnished with a magnificent, well-

RUSSIAN TELEGRAPHS.

An interesting résumé of the Russian telegraphic service has recently appeared in the *Moniteur des Chemins de Fer*, giving the details up to the end of 1876, the latest that have been made up by the Department. At the commencement of that year, the length of the telegraphic lines worked by the State was 61,287 versts (1 verst equals about ⅔ furlongs), with 138,209 versts of wire, while there were 778 telegraph offices. In the course of the year 32 new lines were opened for service, of the length of 2,973 versts, with 6,697 versts of wire, and 46 offices, of which 48 were in Russia in Europe, 8 in the Caucasus, and 11 in Russia in Asia. Twenty-one of these offices were on account of the war necessities. The lines worked by the railway companies in 1876 were increased by 622 versts, with 1,304 versts of wire and 130 new offices. The line of telegraphs to private companies have only undergone extension to the amount of 93 versts, comprised in the of Ahovel, an undertaking which was carried out by the Northern Telegraph Company. On the 1st January last year, the total of Russian telegraphs were as follow:—

	Versts of line.	Wire.	Stations.
State network (recent)	68,620	124,627	864
Railways	16,009	30,000	1,198
Anglo-Indian line	3,407	7,200	53
Submarine cable (Aboard Islands)	36	72	2
Private lines	22	22	1
Military and police of the capitals	350	378	23
		350	1
Total	85,030	169,577	2,163

At the close of 1876, the Administration employed 7,253 persons, viz.:—Central Administration, 291; mechanicians, 143; superintendents, 686; telegraph operators, 4,057 (2,020 women); messengers, porters, &c., 2,126. During the year 3,858,228 paid messages, 258,842 free messages, were sent in the Inland Department; 327,451 paid and 9,169 free were sent in the Foreign Department, which also received 324,880 paid and 12,009 free messages; while in the Imperial service there were 74,412 messages in hand—making a grand total of 4,220,261 messages for the year, an increase of about 10 per cent. over the year before. The following is a table of the proportion of messages from each country to Russia:—

	1876.	1875.		1876.	1875.
Germany	816,051	660,754	Denmark	16,126	15,021
Great Britain	117,891	113,097	Roumania	9,622	6,652
France	76,481	74,677	Switzerland	9,622	6,593
Austria	74,198	72,553	Servia	3,212	2,404
Sweden	36,793	27,005	Greece	2,891	2,366
Turkey	25,702	25,707	Spain	2,197	1,217
Italy	22,832	20,849	Malta	971	1,233
Belgium	16,017	16,749	Portugal	182	1,233
Turkey	16,126	15,021	Montenegro	47	55
Norway	10,710	10,059			

As regards the Eastern nations, the particulars were :—

Persia	4,497	3,013	Cuba	438	457
Turkey in Asia	3,497	3,610	India	151	177
Armenia	1,195	1,018	Japan	111	94
Egypt	646	621	Australia	7	11
Japan	470	640	Arabia	7	1

There are only some 37 towns in Russia which do any foreign business by telegraph, and these do about 90 per cent. of the whole. For instance, St. Petersburg received 107,859 foreign messages; Moscow, 32,974; Odessa, 29,881; Riga, 24,561. Warsaw, 21,326. The gross receipts, which in 1875 were 4,802,386 roubles, rose in 1876 to 5,506,111—an increase of about 15 per cent. The expenditure in 1875 was 4,604,670 roubles, and in 1876, 4,940,000—an increase of 7 per cent. The average total of the telegrams was 1 rouble 43 copecks (1 rouble equals about 2s. 2d., 3 copecks equals nearly 5d.), and as the cost of the telegram was about 1 rouble 15 copecks, the Treasury gained 28 copecks by each message.

SCHOOL OF TELEGRAPHY.—The French Government has established a school specially devoted to the study of telegraphy.

QUEENSLAND.—In Queensland, telegraph extension is in progress between Dalrymple and Junction Creek, 170 miles; Gympie and Kilkivan, 50 miles; and Burdekin and Cape Bowling Green, 50 miles; making an addition of 270 miles to the existing telegraph system.

GREAT NORTHERN TELEGRAPH.—It is announced that the Hong Kong Amoy cable has been provisionally restored. The further repairs required have been postponed until the Singapore route has been re-established. Messages are received for all China and Japan stations.

THE TELEGRAPHIC SYSTEM OF AMERICA comprises about 300,000 miles of wire, of which the Western Union Company has about 195,000, the Atlantic and Pacific Company (now consolidated with the former), 36,000, the Montreal Company 20,000, the Dominion Company 7,000, and smaller companies and railroads 40,000.

CHRONIQUE

Voici une bonne nouvelle que nous donnons avec joie à nos lecteurs :

Le câble transatlantique français se construit en ce moment dans les ateliers de la maison Siemens, à Woolwich.

Il serait à désirer que cette ligne nationale pût servir à relever le goût des études télégraphiques en France et que des opérateurs français fussent chargés de la transmission des dépêches.

Mais un pareil résultat ne peut être obtenu sans une éducation préalable, car la manœuvre des télégraphes sous-marins demande une instruction spéciale, que tous les opérateurs ne possèdent pas.

Nous croyons donc faire plaisir à nos lecteurs en leur annonçant que nous avons visité l'école de télégraphie de Londres dans le but de nous assurer que nos jeunes camarades qui voudraient être initiés aux mystères de la télégraphie sous-marine, y trouveraient les mêmes facilités que les étudiants anglais, et que l'enseignement, s'ils se connaissent plusieurs, leur serait donné en langue française.

Le *Journal des Postes* du l'Empire d'Allemagne nous apprend que le gouvernement japonais vient de concéder une ligne allant de Yokohama à San Francisco. Espérons que ce n'est point à une compagnie allemande.

La compagnie concessionnaire, quelle que soit sa nationalité, est en instance auprès du gouvernement chinois pour obtenir le droit d'attirer à Tien-Tsin et de conduire la ligne atlantique jusqu'à Pékin. S'il en est ainsi, l'électricité pourra bientôt faire le tour de la terre.

THE ELECTRICIAN.

TO CORRESPONDENTS.

We cannot undertake to return drawings or manuscripts, and must, therefore, request Correspondents to keep copies.

All letters intended for insertion in THE ELECTRICIAN, *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

SUBSCRIPTIONS.

THE ELECTRICIAN can be had, by order, *from any newsvendor in town or country, at the various railway stations; or it can, if preferred, be supplied direct from the office, on the following terms (paid in advance):—*

Quarterly	6s. 6d.
Half-yearly	13s. 0d.
Yearly	26s. 0d.

All communications to be addressed to 250, Strand, London, W.C.

NOTICE TO EDITORS.

We shall be happy to exchange with the Editors of Scientific journals who receive the first numbers of THE ELECTRICIAN.

Nous serons heureux de faire l'échange avec Messieurs les Rédacteurs des Journaux scientifiques qui recevront les premiers numéros de L'ELECTRICIEN.

Es wird uns ein Vergnügen sein mit den löblichen Redactionen der Journalen und anderen wissenschaftlichen Zeitschrifte, deren die ersten Nos. des ELECTRICIAN *zu Händen kommen möchten auszutauschen.*

I Signori Editori di giornali scientifici che ricevranno i primi numeri dell' ELETTRICISTA *possono con profitto scambiarlo il cambio che loro offriremo.*

SOUTH AFRICAN TELEGRAPHY.

The question of telegraphic communication with our South African possessions is rapidly assuming definite shape. Of the several alternative routes that have been proposed for effecting this much desirable object, and which offer a veritable *embarras de richesses*, none present so many points in their favour as that along the East Coast from Aden, *viâ* Zanzibar and Mozambique either to Delagoa Bay or Port Natal, with a branch line from Zanzibar to Mauritius, lapping Madagascar at its northern extremity. Its marked superiority over any of the western lines *viâ* the Atlantic, either by deep sea cables from the Cape Verd Islands to Ascension, St. Helena and the Cape, or by coast lines by Senegal, Upper and Lower Guinea, Walfish Bay, we had recently occasion to dwell upon. Lately, however, it has found a rival in an overland route across the eastern side of the Dark Continent in the entire length north and south. As this scheme has been highly spoken of, and, indeed, warmly recommended, by no less an authority than Mr. J. Sivewright, at present in charge of the Telegraph Department, Cape Colony, we are likely to hear a good deal about it for some time to come; hence it may be useful to examine its merits, and once for all dispose of its pretensions to serious consideration.

It proposes to carry a line from Natal and Transvaal through Matebeleland northwards to Tete, Sena, or some other point on the Lower Zambesi, thence *viâ* Lake Nyassa or the Unyamuesi, and across Lake Victoria Nianza to Uganda, and down the Victoria Nile to Gondokoro, or rather Lado, on the White Nile, where it would form a junction with a line connecting Egypt with its recently-acquired equatorial provinces. But, notwithstanding the eloquence with which it has been advocated in some quarters, this project will scarcely bear serious discussion. The line, however judiciously chosen, would necessarily have to traverse no less than four-and-twenty parallels of latitude, or some 1,650 miles of country from the Limpopo River on the northern frontier of Transvaal to Magungo on the southern frontier of Egyptian Soudan a country either totally unknown or but partially explored with a dangerous climate, infested in many places by the tsetse fly, and inhabited mainly by fierce and unfriendly tribes.

No doubt, an apparently similar *line de force* was successfully performed in 1872 in Australia, where the wire has been laid down for a distance of 1,972 miles right across the Continent, from Adelaide on the Southern to Port Darwin on the Indian Ocean. But the circumstances are so entirely different that the astonishing success of this magnificent undertaking cannot be appealed to as a precedent. Before the attempt was made, the unknown country between South Australia and the northern territory was roughly explored by J. McDonall Stuart, and was found to present far less serious physical obstacles than had been anticipated. The country was especially free from troublesome native tribes, except near the McDonnell Range, and at one or two other points, where the judicious application of a few electric shocks was sufficient to inspire the aborigines with a permanent and wholesome respect for "the whitefellow's devil." But the warlike, powerful and intelligent Mazitu, Wamasai, Wanyaturu, Wasipan, Lenywé, and other East African Bantu nations, are not to be so easily disposed of. Nor would it be possible to subsidise them, so numerous are the independent chiefs, especially in the region east and north of Lake Nyassa, all of whom would have to be dealt with separately. These districts may be said to be in a chronic state of petty warfare, and are from time to time laid wast, especially by the fierce Mazitu and Wamasai predatory hordes under such formidable leaders as Mirambo, who generally make a clean sweep of everything, and would not be at all likely to spare the telegraph poles. These objects, if "fetish," and therefore sacred in the eyes of one tribe, would in all probability be regarded with all the greater aversion by their neighbours. In any case, if we have not yet acquired influence enough to put down the detestable slave trade still openly carried on in these regions, or to induce the natives to allow free passage to an occasional explorer or missionary without subjecting them to oppressive exactions, the time must be still more remote when we shall be in a position to keep open an overland line along the proposed route, except at an utterly ruinous expense. When it is added that such a line could under no circumstances develope any local traffic, except at Zanzibar, and at its extreme ends north and south, that its repair would be always a difficult and costly matter, and that the scheme itself is for the present at least *in nubibus*, it seems scarcely deserving of a moment's consideration when compared with that already carefully thought out and matured by the practical and experienced minds connected with the Eastern Telegraph Company. This powerful and influential corporation has applied itself to the solution of the problem, and has pronounced emphatically in favour of the route along the eastern seaboard, which thus promises soon to pass from the regions of fancy and theory to the world of realities.

Including the contemplated branch from Zanzibar to the Mauritius, not by any means the least desirable part of the project, the length of cable required by this route to connect the Cape and Natal with Aden and the rest of the world would be either 5,520 or 5,600 miles, according as it might be landed at Natal or the Portuguese station of Lourenzo Marques, Delagoa Bay. At the rate of £250 per mile, the price for which the Telegraph Construction and Maintenance Company have actually undertaken to construct and lay such a line, there would be needed a capital of about 1,380,000l., which might be raised under an Imperial guarantee at 3½ per cent. The interest on this sum (48,850l.), together with the general charges for working expenses, stations, repairing ship, &c., would involve a yearly outlay of, perhaps, 60,000l., and as the line is not calculated to yield for the present more than 40,000l. of revenue on traffic, there would be a clear deficit of something like 20,000l. It should, however, be remarked that, whereas some of the proposed alternative routes could possibly be commercially remunerative at first, if at all, the deficit in this case would be amply covered by the subsidies already either promised or anticipated from the several Colonies or States directly interested in the undertaking. In this way, 5,000l. might be reasonably expected from the Sultan of Zanzibar, 5,000l. from Réunion, 10,000l. from Mauritius, the same from the Cape, 5,000l. from Natal and Portugal, altogether about 40,000l., leaving for shareholders a net profit of 14,000l. at once, with a fair, not to say a certain prospect of a steady increase of traffic in such places as Transvaal, Mauritius, Madagascar, and Zanzibar.

But, even should some of these promises prove delusory, we understand that the Eastern Telegraph Company is still prepared to make such liberal arrangements with the British Government and the Colonies for the working of the new line as would amount practically to an annual subsidy of about 10,000l., thus securing, under the most adverse circumstances, a surplus income of at least 20,000l., from the commencement.

There can be little doubt that, should this route be adopted, a cable would eventually have to be laid down between Mauritius and Ceylon—a distance of not more than 1,700 geographical miles. The South African Colonies would by this means be brought into direct telegraphic connection with India, China, Japan, Australia, and New Zealand, whereas by the West Coast line their communication with these important regions would have to be made by a most circuitous route, *viâ* Cape Verd Islands, Lisbon, and the Mediterranean, involving a practically prohibitive tariff and the constant risk of interruption between the Cape Verd Islands and Lisbon, where there is only a single deep-sea cable. This point alone ought to outweigh all other considerations with our enlightened brethren, who, when they come to study the matter in all its bearings, will scarcely fail to recognise the overwhelming advantage presented by the East Coast route over all the alternative projects hitherto proposed.

THE *London Telegraphic Journal*, in a recent article upon the admitted pre-eminence of telegraphic improvements and advances in the United States over all other nations, expresses the opinion that this superiority of the Americans is due to the excellence of our patent laws, which encourage inventors to obtain patents, and place no restrictions upon them after they are obtained.

TELEGRAPHS.—Owing to a typhoon, the Great Northern Telegraph Company's cables between Nagasaki and Shanghai, and between Shanghai and Amoy, are interrupted. The repairing steamer is on the spot, and a speedy restoration is expected. Meanwhile messages for Hong Kong and Amoy cannot be accepted, and messages for Shanghai will be forwarded from Nagasaki by steamer. The company's lines to all Japanese stations work well.

ACCIDENT TO A TELEGRAPH STEAMER.—Lloyd's agent at Singapore, in a telegram dated September 24, 6.5 p.m., reports that the British steamer *Edinburgh* had gone ashore there, but would probably be got off without damage. The steamer referred to in this telegram belongs to the Eastern Extension, Australasian, and China Telegraph Company, Limited. She is an iron A 1 steamer, built at Glasgow in 1855, and her dimensions are:—1,317 tons net, 2,315 gross, and 229·2 under deck. The steamer is stated to have been on her way to Penang to repair the telegraph cable when she met with the mishap.

Imperial Chinese Telegraphs.

THAT such a line of telegraphs really exists and is in daily work is now an established fact, the first line of telegraphs ever erected by the Chinese Government having just been completed by Mr. J. A. Bate, M.S.T.E., Director of the Imperial Telegraph College, Tientsin, and the students of the college. Although the line is but a short one, connecting the offices of the Arsenal with the Yamen of Li Hung-Chang, some six miles distant, its erection marks a new era in the policy of the Chinese authorities. With all the pressure that was put upon the Chinese at Foochow, the Great Northern Telegraph Company failed to get the line through from that port to Amoy, and after two years of hard fighting the erection of the line was finally abandoned by the company. The line at Tientsin has been put up under very different conditions, being ultimately erected by the Government with native labour. No the slightest opposition was offered by the people; permission was readily given to erect the poles of the lowest in Tientsin, or places in their vicinity when necessary—not an angry word was heard, and the line was got through with considerably less difficulty than is frequently experienced in England. The River Pei ho is crossed by a piece of submarine cable, with two large placed in the terminal poles on each side. The instruments used are Morse inkers, worked by Leclanché batteries. *The Li Hung Chang* has since got interest in the work, and spends many hours in the office, which is one of the private rooms of his Yamen.

The success of this line at once proves the ability of the Chinese youth to learn the technicality of foreign science, and the absurdity that "Pung-Shin" has anything to do with the opposition which telegraphs and railways have hitherto experienced in China. Mr. Bate has been requested to proceed to Formosa with some of his students to construct a line along the Western Coast of the Island from Kee Lung to Ai-an-tan, and a line from Tientsin to the provincial capital, "Tsan-ling-fou," is also contemplated.—*The Telegraphic Journal.*

57

IRON TELEGRAPH POLES.

Passing from cables to aerial lines, there is at the entrance to the French annex a fine exhibit of iron telegraph poles, shown by the French Telegraph Administration, MM. Vuilleumier et Fils and M. Dargoffe. In some countries wooden poles cannot be used. Either want of wooded tracts from where to obtain poles, chemical conditions, or ravages of insects, or some or all of these combined, serve to prevent the use of wood. The iron poles shown are of varied design, from light poles to carry one wire to heavy poles to stand on the banks of rivers, nearly 50 ft. high, constructed to carry from 40 to 50 wires. The lighter poles are constructed of T and U angle iron, or of iron strips wound spirally inside three uprights. The heavier poles are of angle iron of different kinds. Some of these poles are fitted with boxes, which will hold tools, etc., necessary for the repair of the line, or instruments for testing purposes. The arrangements in use in one or two cases are so made that the leaves contain curved grooves for the junction of aerial and subterranean wires. It has been suggested that lighter and stronger poles of iron and might be made by using steel. It is true that as yet steel is not so widely used as it will be in future, and it may be found that the suggestion is of practical value. We should be glad to have statistics relating to the question of lightning upon lines constructed with iron poles. Is it found that less damage is done, or more?—*The Engineer.*

THE VOLTAIC BATTERY.

A COURSE OF SIX LECTURES,

By DR. JOHN HALL GLADSTONE, F.R.S.,

Fullerian Professor of Chemistry, Royal Institution,

DELIVERED AT THE ROYAL INSTITUTION OF GREAT BRITAIN.—CHRISTMAS, 1874-5.

(Continued from page 137.)

LECTURE VI.—THE ELECTRIC TELEGRAPH.

IT was in 1820, little more than half a century ago, that Oersted first noticed the action of the voltaic current upon a magnetic needle. I have had occasion to show you this action two or three times already, but I must show it to you again. We will take this needle, pointing at present to the north with a wire passing over it. By just making contact between the wire and a battery, we shall find that the needle will turn round. There you see the needle turning away at right angles. Now, of course, we can make and break as we please, and by sending the current the other way, the needle will turn over to the other side. So we can make it go either to the right or to the left. Now this has led to the invention of what are called galvanometers. This is the simplest form of galvanometer, but if, instead of taking a straight wire we made it coil round many times, and especially if we take what is called an astatic needle, that is, two needles which are fastened together with their poles reversed, so that the north pole of one is over the south of the other with the wire passing between, we should be able to produce movements of the needle by exceedingly feeble currents. You are aware that this has been fully carried out in Thomson's galvanometer which we have here. I explained that to you on a previous occasion, and mirror responded on the needle, and how we were able to throw a light from that moving mirror upon the screen.

Now what may be done with an ordinary galvanometer. I can move the needle which way I please, or reverse it as often as I like, by the power that comes from the battery. Now, we can attach marriage to these movements of the needle. We can read one as "A" and another as "B," and so on. We might then carry the instrument to that table. I have only to make the wire longer for that purpose, or I might take the instrument up into the gallery, and do just the same as I have been doing here. But I need not be content with that, for I could take this instrument out into Albemarle-street or Piccadilly; or I might carry it to Hounslow or Bayswater, and still, if there was a sufficiently long wire, the voltaic force would flow through and reach the instrument, and our needle would act in response to what took place here. Now, you see by giving certain meanings to these swingings of the needle; we can make communications at a distance to those places. I have spoken of, for instance, as to Birmingham or Edinburgh, or anywhere else; and hence, we have the invention of the electric telegraph.

In the same year that Oersted noticed this movement of the needle, another great electrician, Ampère, suggested it as a means of indication at a distance. Communication by means of electricity had been suggested before that, but I believe that there was no actual electric telegraph made and used till Gauss and Weber, who were making certain observations in 1833, carried a wire from their physical cabinet to their observatory and back again—a distance of a mile—and made a needle swing, and were then able to communicate from one place to the other. There were partially successful attempts by Ritchie and others, I believe, in this building, but we may go on to the year 1837, when Cooke and Wheatstone took out their patent for the use of the electric telegraph. They employed five different needles moved by five different wires, and they were able to speak at a distance. This was employed upon the Great Western Railway, and this was the commencement of that long series of electric telegraphs which now send their metallic threads all over England and over all the civilized nations of the world. Of course, it is necessary that these wires should not touch one another, and that they should be separated from other conductors of electricity, and, therefore, they are insulated, as it is called; they are covered with thread or with something else which keeps them from other bodies. Gauss and Weber hung their wires up in the air. Cooke and Wheatstone first of all employed insulated wires, and carried them underground, but you know now very well that along our lines of railway we see the electric telegraph wires hanging in their various curves as we go along, and we cannot see, but we may imagine, if we please, the messages that are passing along these lines.

But this was only the commencement—the very infancy of telegraphy. It has since had an immense amount of attention paid to it, and an immense amount of success has attended it. Mr. Steinheil, in 1838, stretched wires in the air by insulated supports, just as we see them now arranged on poles. I do not know whether he employed the porcelain which is employed now, but there are various ways in which the wires may be suspended on the poles, so as to keep them from the damp earth. But Steinheil made another important discovery, that is to say, that it was not necessary to have two wires. It is necessary merely that you should have one wire—one wire going from your battery to your instrument, right along where you want to send the message. All that you have to do is to bring your battery in connection with the earth, and your instrument at the other end of the wire, in connection with the earth there also. Large plates are sent down into the ground to some place which is permanently damp, so that the plate may continue in connection with the earth.

Perhaps it may be difficult to explain how the earth acts; but we know that the result is a very satisfactory one. We actually got less resistance than if we employed return wires.

I must say a word about this resistance. You recollect I have spoken of different substances having very different powers of stopping the galvanic current, or, in other words, of conducting the current, and I have said that silver is that which conducts it most readily. Platinum conducts it by no means so well. Now, if we take wires of the same size throughout we find that the amount

Home-Made Electric Telegraph.

At the request of several correspondents, we will explain the fundamental principles on which the electric telegraph is based, and will attempt to make it so clear that any one of ordinary intelligence and in the possession of some iron and copper wire, sheet copper, zinc, and a few small pieces of rod-iron, will be able to construct a telegraph by bringing his material into proper shape at the vise, with the help of a few files. The possession of a little is convenient in this respect for turning the iron core, winding the coils, etc., but is not absolutely necessary.

The Battery is the motive power by which the electric wave is sent over the wire; two cups of the same are seen at the left side of our figure. The battery here represented on a small scale is a so-called gravity battery, at present quite popular among the telegraphic profession, but undoubtedly soon to be superseded by a totally different apparatus. This gravity battery has a piece of sheet copper at the bottom of the cup, with crystals of sulphate of copper laying around it, a disc of zinc is suspended at the top, while the cup is filled with water as high as to entirely submerge the zinc. After awhile the sulphate of copper commences to dissolve in the water, the zinc in top is attacked and

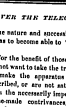
HOW A MESSAGE IS SENT OVER THE TELEGRAPH WIRE.

changed, first into oxid and then into sulphate of zinc, while metallic copper is precipitated on the copper disk at the bottom. The solution of sulphate of copper being heavy, will remain below, and only slowly rise in a very diluted condition until it reaches the zinc, where its sulphuric acid combines with the zinc, which is first oxidized at the expense of the water. The hydrogen which escapes in a fierce battery, that is, one containing free sulphuric acid and no sulphate of copper; see beginning of page 229, Vol. IV.,) combines in this battery with the oxygen of the oxid of copper, and instead of hydrogen escaping copper is precipitated. This battery is called a Daniel battery, but is modified so as to do without the objectionable porous cup, (see the end of page 228, Vol. IV.) Other forms of batteries also used for the same purpose may be found more extensively illustrated and described on page 229, Vol. IV., and page 155 of this volume.

If the place with which we wish to communicate is distant, so that the wire is necessarily long, two or more cups must be combined in the manner shown in our cut, or of the seven cups represented on page 229, Vol. IV. The wires proceeding from the first and last cups are called the electrodes, and one of them is soldered to a copper plate buried in the moist ground, so as to use the earth for the return current, while the other electrode is connected with

The Key.—This instrument, with which the messages are sent, is represented at the extreme left of our figure. It may have different forms; according to the most common form it is simply a metallic lever turning on a pivot, and by means of a spring kept at a very short distance above the end connection of one of the electrodes of the battery. The lever carries at its extreme end a flat ivory or rubber knob to receive the finger point of the telegraph operator. When he depresses it, the lower surface, which is provided with a platinum point, touches the platinum end connection of the battery electrodes, and thus "closes the current," as it is termed. This current is then at once sent over the wire which is stretched through the air, and supported from distance to distance on poles, by means of the insulators made of glass, porcelain, or rubber, as the wire must not touch the wood of the poles or the walls of houses.

At the other end of the line is the receiving instrument. This consists simply of an electro-magnet, as represented in the adjoined small figure, or better, as represented in the large cut; it consists of two round cores of iron screwed to a cross piece below, and each surrounded by a coil. When the current passes through the coil, the iron becomes magnetic and attracts the armature suspended by a spring, each attraction makes a click, and these clicks differ in their nature when the contact made with the key is of short duration, or if it is continued for some time. The first corresponds with the dot or point, the second with the line or dash; and after some practice the operator becomes able to distinguish the nature and succession of the clicks to such a degree as to become able to "read by sound," as it is called.



For the benefit of those who do not want to take the trouble to make the apparatus here described, or are not satisfied with the necessarily imperfect home-made contrivances, we give here an estimate of the minimum expense of a small private telegraph office between two stations, one mile distant:

Eight cells battery, at $5,	$40
Two keys, No. 2, at $3,	6
Two sounders, No. 2, at $2 50,	5
Two miles wire, No. 16,	25
Twenty insulators, glass and bracket, at 25c.,	5
Office wire and sundries,	9
	$100

The total expense of two offices, one mile apart, is thus $100, of which more than one half is for the line and its supporting posts. The expense of the line increases in a direct ratio to the distance, while the other expenses remain the same, except the battery, which also requires some increase for increased distance; but in any case the line is, if the distance is a mile or more, the most expensive part of the whole arrangement; any contrivance therefore able to make a single wire do a multiple duty, is of great importance in an economical point of view, and for this reason the method of transmitting two messages simultaneously over the same wire in opposite directions, as described on page 229 of our former number, is important in all cases where the business of the line is so active as to require a continual dispatch and reception of messages, which with the usual appliances would require two lines, and therefore almost double the expense.

The Eastern Telegraph Company have sent out [illegible] cable with core sheathed in [illegible] it will withstand the [illegible]

TELEGRAPHY IN BRAZIL.

According to the last published report the extent of the lines has increased to 6,000 kilometres (about 4,000 miles). The small number of stations (97) over this length is represented as adding to the many other drawbacks in the matter of maintenance. The maximum number is limited to 101 over this distance, the only use of one-half of which is to facilitate and aid the service, seeing that the revenue is actually nothing, without even a reasonably remote prospect of the point being arrived at for the adjustment of deficits. As examples:

20	stations	produce	less	than	315	monthly.
10	"	"	"	"	25	"
12	"	"	"	"	40	"
8	"	"	"	"	50	"

The annual expenditure in maintenance and facilitation of these lines is stated at $125,000. The receipts from the State telegraph lines in 1.76 were about $ 46,000; the relative expenditure was about $740,000.

Telegraphy in Japan.

Mr. E. Gilbert, who for more than four years past has had charge of the Government Telegraph department of Japan, as Superintendent-in-Chief, but whose engagement is about to terminate, was entertained by the Acting Minister of Public Works, Yamao Yoso, at a banquet at Shiba Palace. The Minister for the Home Department and about thirty other gentlemen were present. A very cordial and pleasant evening was spent, and all united in expressions of good will and good wishes for Mr. Gilbert's future happiness. We believe that Mr. Gilbert has given the government ample satisfaction, from the way in which he has conducted the important department under his charge, and leaves the lines of telegraph in as excellent a condition as the best lines in any part of the world.—*Japan Daily Herald.*

Management of Government Telegraph Lines.

An order has been recently issued from the War Department relative to the control and management of United States Telegraph Lines, which have been placed in charge of acting Signal officers. Interference with the duties of the latter is prohibited, and all commanding officers are directed to render them, upon application, such proper assistance as may be necessary for the maintenance of the lines.

Electrician May 28, 1881.

Telegraph Wires in New York.—A Bill just presented to the Senate at Albany enacts that all wires going in a northern or southern direction, on that part of the town comprised between the Battery and Forty-two-street, shall be placed underground, or be carried on most metal supports; that the companies shall begin to effect this change after the 1st July, 1881, and that it shall be completed by the 1st May, 1882; that after this latter date it shall be illegal to use wooden poles as supports for wires; and lastly, that the laying of wires shall be done under the direction of the Commissioner of Public Works.

delegates from the Physical Society, the Society of Telegraph Engineers, and the Royal Institution of British Architects, had accepted an invitation from the Council of the Meteorological Society, and would shortly assemble to settle all doubtful points.

The lecturer resumed his next month's warm applause.

On the motion of the chairman, a hearty vote of thanks was passed to

Mr. SYMONS, who, in returning thanks, cordially invited those present to attend the ordinary meetings of the Society.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY (LIMITED).

The Extraordinary General Meeting of the Members of this Company, adjourned from the 6th ult., was held on Wednesday, the 4th inst., at the City Terminus Hotel, Cannon-street, "for the purpose of approving an Agreement made with the Governments of the Australian Colonies or some of them, for the duplication of the Australian Cable, and passing Resolutions authorising the Directors to execute all contracts and to do all acts requisite for carrying such Agreement into effect, with such modifications, if any, as the Directors may determine; and further authorising the Directors to raise the capital required for this purpose and for the general purposes of the Company, by the issue of Debentures or otherwise upon such terms and in such manner as the directors may think fit."

The CHAIRMAN, in opening the proceedings, said: Gentlemen, the secretary will read the notice calling this meeting.

Mr. HAYES (the Secretary) read the notice, as above.

The CHAIRMAN then said: Gentlemen, a month ago, when the extraordinary meeting was adjourned until to-day, I stated that I thought—in fact, that I felt confident—that I should be able to-day to announce to you that the agreement with the Australian colonies had been signed. You will have had a good deal of telegraphing during the month, and I am happy to say that this morning I received the following telegram from Colonel Glover:—"Perry, in London, will have all signed the agreement, and will deliver complete. Hope this will be in time for general meeting. Documents left here to-day by Francis Dove." Now, before making my remarks upon the importance of this contract (which has been made with the Australian colonies, I think it is better that I should read out the cablegram to read the agreement, and after you have heard it I shall make a few remarks, and then I shall be glad to hear from any shareholder his views on the agreement. I may state that Mr. Berry is the Prime Minister of Victoria, and Mr. Burns is the Treasurer of New South Wales, and I may say that they both have been authorised by their respective governments to sign the agreement. The agreement is, of course, not perfected, though it is signed, and is virtually perfected. It must, however, be perfected by the Board, and is virtually perfected. It is best, I believe that the colonial representatives are still in London. Mr. Hayes has the original contract.

Mr. HAYES, the solicitor, accordingly read the Agreement as follows:—

1. That the Company shall, subject to the approval of the shareholders, contract with the Governments for the construction of a second line of cables, Singapore direct to Hanjoman, thence direct, to Port Darwin, for an annual subsidy of £6,000; and, thereupon, the Company shall sign the Contract and accept the conditions on or before 1st July, 1879.

2. That the subsidy shall be payable for a period of Twenty years, subject to the provisions hereinafter contained.

3. That the Company shall, throughout the whole of the period during which the subsidy shall be payable, maintain in full working order the whole of the present lines of cables between Singapore and Batavia and Singapore and Port Darwin.

4. That the Company shall, before such subsidy shall become payable, construct a second cable between Singapore and Penang, and thereafter in like manner, and to the same (the not of Set) as the Queen's enemies accepted, the first lines of cable between Singapore and Penang, Penang and Madras, and Penang and Malacca, in full working order.

5. That the Company shall, in consideration of the subsidy hereby agreed to be paid, and whilst the same shall be duly payable, allow a rebate for Government messages, hereinafter defined, on messages passed between England and Port Darwin, reducing their own proportion of the charge for the transit of 20 words, at the present rates, and on Press messages exchanged between Singapore and Port Darwin, as hereinafter defined, one-third of their own proportion of the charge for the transit of 75 per cent. upon their own rates, provided that such reduction shall not be extended to any cables other than such as may contribute to the payment of the subsidy.

6. That the Company shall construct and open for communication the second cable above mentioned between Singapore and Port Darwin, and thereafter in like manner, within eight months from the date of the signing of the contract, provided always that the Company shall not be held liable for any loss or damage which the Colonies may sustain in consequence of delay in completing the said cables in the event of such delay occurring by war, inevitable accident, or other contingency over which the Company can have no control.

7. That in the event of the Company completing and having the duplicate cables hereinbefore mentioned open for communication within the period herein contracted for, the subsidy payable by the Governments shall commence and accrue from the date of the completion of the contract, but the Company shall not be entitled to any payment under this clause until the cables shall have been actually completed and are open for communication, as aforesaid.

8. That the said subsidy shall be payable quarterly in London to the Company in sterling money, free of all deductions.

THE TELEGRAPHIC JOURNAL. JANUARY 15, 1879

W. M. WARDEN & Co.,

TELEGRAPH ENGINEERS AND CONTRACTORS,

27, GREAT GEORGE STREET, WESTMINSTER, S.W.

Contractors for the Erection and Complete Equipment of Lines of Telegraph, and for the Supply of Telegraph Stores.

MANUFACTURERS OF IRON POLES AND TELEGRAPH WIRE.

ALSO OF EVERY DESCRIPTION OF

TELEGRAPH INSTRUMENTS AND APPARATUS.

W. M. WARDEN, of the late Firm of Warden, Muirhead and Clark.

WALTER HALL,

MANUFACTURER OF INSULATED WIRE,

For Electric Lighting, Telephones, and every description of Telegraphic Apparatus.

Silk and Cotton Covered Copper Wires, suitable for Electrical Instruments. Gemmas Silver Wires for Resistance Coils. Cotton Covered Iron Wire. Resistance Coils and other Instruments Wound and Tested to order. India-Rubber, Gutta-Percha, Cord and other kinds of Insulated Wire supplied in Coiling up Electric Bells for domestic and other purposes. Telegraph Cables for Submarine, Subterranean and Aerial Telegraphs; Mines and Gunnery Experiments; also for Naval and Engineering purposes. Electric Tubes, Guttа-Percha, Tumblers, India-Rubber and Hard-Lac Varnishes, &c., supplied.

Works: Manufield Street, Southwark, S.E. City Office & Warehouses: 10, Love Lane, Wood Street, E.C.

INDIA-RUBBER, GUTTA-PERCHA, AND TELEGRAPH WORKS COMPANY, LIMITED.

Offices and Warehouses: 106 & 100, CANNON ST., LONDON, E.C.

Works: Silvertown, Essex; Persan Beaumont, France.

TELEGRAPH ENGINEERS AND MANUFACTURERS OF

CABLES.—Subsea, Subterranean, and Aërial.

WIRE.—India-Rubber and Gutta-Percha covered in all gauges.

INSTRUMENTS.—"Morse" Inkers, Single Needle, Wheatstone's Alphabetical, Prescott & Walker's system of Sounders "Block" Instruments, Bells, Resistance Coils, Sir W. Thomson's and other Galvanometers, Condensers, Testing Instruments, &c.

BATTERIES.—MANUFACTURERS FOR GREAT BRITAIN, IRELAND, AND THE COLONIES OF THE CELEBRATED LECLANCHÉ BATTERY, which has received the most favourable reports from Telegraph Engineers, and is in general use on English and Continental Railways. As a Battery for all Telegraphic purposes it is undoubtedly pre-eminent. All other kinds of Batteries also manufactured. Particulars of Carbon Plates, &c.

The Leclanché MEDICAL Battery is the best Medical Battery of the day.

INSULATORS.—Ebonite, Porcelain, Stoneware, &c.

MANUFACTURERS OF THE MOST IMPROVED APPARATUS FOR RAILWAY BLOCK-SIGNALLING.

SEMAPHORE REPEATERS "LIGHT" INDICATORS, AND WALKER'S "PASSENGER AND GUARD" COMMUNICATOR.

TELEGRAPH STORES AND APPARATUS OF EVERY DESCRIPTION.

TORPEDO APPARATUS.

THE INDIA-RUBBER, GUTTA-PERCHA, & TELEGRAPH WORKS COMPANY (Limited) are Patentees and Manufacturers of a Complete System of Torpedoes for Harbour and Coast Defence, and of the

TELEGRAPH EXTENSION IN AFRICA.

The electric telegraph is being rapidly extended over the dark Continent. The active energies of M. Lesseps are being directed towards the establishment of a line across the Great Desert, from Algeria to the French settlement of Senegal, and the French have already extended their Algerian lines eastward to Tripoli. The Egyptian lines reach to the Equator, and those of South Africa will probably before long be in communication with them; and, by and by, we may expect to see an overland line from Cape Town to Cairo and Alexandria. The extension of communication in the same direction will aid in protecting the wires; and it is stated as regards the northern lines that the Arabs, finding their camels travel much faster when following lines, most scrupulously respect the wires and poles.

Ledr 1869

A NEW MODE OF PLANTING TELEGRAPH POLES.—The following method has recently been tried in Tuscany, and is described in the *American Manufacturer*, has been tried with success in Titusville, Pa. The ground being sodded off at distances of about 300 ft. apart, a small charge is fired off with a percussion cap, which, by means of a connecting wire, explodes another charge placed in the bottom of a hole about 5 ft. deep. The explosion of the second charge forms a hole about 3 ft. in diameter at the bottom, and 2 ft. at the surface. The pole is then placed in the hole, and the earth and stones thrown in, when a hole about 2 ft. in diameter is formed above the charge. The pole is then rammed down, and the hole filled in with gravel and earth, and the job is complete. It takes about one minute, and three persons can put up from 100 to 150 poles a day, or ten poles per hour. The cost, therefore, of this new and improved process is about two thirds less than the ordinary method of planting telegraph poles, as now practised. *March 17.*

A TELEGRAPH TO THE CAPE.

Feb 17

The recent disaster to our arms inflicted by the Zulus renders it imperative that telegraphic communication should be speedily established with the Cape Colonies. The subject was brought to the notice of Sir Michael Hicks-Beach on February 12 by a deputation, headed by Sir J. Lubbock and Sir H. Barkly. These gentlemen advocated the construction of an overland line from Egypt to Pretoria via Zanzibar, the pet scheme of the colonists, and requested a Government subsidy to aid in the work, which they estimated to cost £180,000. The Colonial Secretary replied that the Government was prepared, with the Colonial Parliament, to subsidize any company undertaking the work; and that he believed at present a cable more feasible than a landline, though the latter might be more advantageous when once established. Before deciding in the matter he should, however, require a definite estimate of the time and money required for the land-line. It is to be hoped that this will speedily be furnished, and that, whether the line be overland or submarine, and the latter indeed seems to us the most feasible at this time, it will now be realised.

from the provinces as well as from London—the additional charges for provincial messages being abolished. In like manner messages from Germany and Holland addressed to provincial towns in the United Kingdom will be charged the same rates as messages addressed to London. For a prepaid reply to a message, the charge will not be less than for ten words, whether the number of words desired to prepay the charge for a reply of more than ten words, be more or less than the number of words, but no prepaid reply may consist of more than thirty words. For the acknowledgment of the receipt of a message the charge will be the same as for a message of ten words.

The Railway News, of London, in its financial summary for 1878, has the following in regard to telegraph companies: The shares of the Telegraph Construction and Maintenance Company, the Globe Telegraph and Trust Company, the Submarine Telegraph Company, the Anglo-American Telegraph Company, and the Eastern Extension, Australasia and China Telegraph Company, have all been active securities. The Eastern and Eastern Extension shares alone no important change. The latter system has been strengthened by arrangements for the duplication of the Australian section under a colonial subsidy. The Eastern Company has laid lines to Cyprus and Constantinople, and acquired the cable between Odessa and Constantinople. The question of establishing telegraphic communication with the South African Colonies is under the consideration of the Imperial Government, the Colonies being expected upon giving liberal subsidies. The receipts of the Atlantic lines continue satisfactory, and four cables are doing the work with remarkable regularity. Yet a fresh attempt seems on foot in France for raising capital for two new cables to New York. The highest price of Anglo-American was 65, the lowest was 54; similarly Direct Cable touched 141 and 112.

The Great Northern Telegraph Company has declared a dividend for the past half year at the rate of 5 per cent. per annum on its share capital of £1,500,000.

M. Linckens, of the Netherlands telegraph service, has been deputed to examine the results of the "urgent" message system which has been tried there since last October. He finds that while one-half of the Bourse messages are "urgent," hardly any come from private sources. M. Linckens is of opinion that the total number of "urgent" messages is not high enough to delay the ordinary traffic, and that these "urgent" messages render inconstatable secrecy to their senders.

According to the *Cologne Gazette* the Imperial German Government intend, during the present year, to push forward the works of the subterranean telegraph. It is proposed to lay the line between Cologne and Metz, which will cross the Moselle and the Sieg. The bridges of Coblentz and other places will be utilized for this purpose, but a river cable will be laid across the Sieg at Siegburg. The subterranean cable will be constructed to correspond with those already existing between Berlin and Halle, and Berlin and Frankfort-on-the-Main. The Reichstag will be asked to vote the necessary funds.

A telegraph line is being erected from Durban to Bungee, South Africa, a place about twenty miles from the Zulu border, and near the coast.

The *Journal Telegraphique* states that on taking possession of Dobrudscha the Roumanian Government established eleven telegraph offices, forming a permanent service open to international correspondence. The Russians, however, would not permit them to open an office at Sulina.

The *Japan Mail* is responsible for the statement that telegraphic insulators made at the village of Imaseki, in the province of Hizen, Japan, are so good that they find a large sale in Europe.

M. Blavier has been nominated director of the Paris Superior Telegraph School, during 1879. M. Mercadier is Professor of Physics, and M. Bontemps is Professor of Telegraphy.

The French Government recently presented to the *Corps Législatif* a project for laying a cable between Australia and New Caledonia.

M. de Lesseps is urging the French Government to extend the telegraph wires from Algeria across the desert of Sahara to the French colonial dependency of Senegal, in Western Africa.

The New Central Telegraph Station at Berlin, Prussia.

We learn from the *General Telegraphique*, of Berne, that the new central telegraph office at Berlin was formally opened for service on the 30th of November last. The inauguration took place under the presidency of the Postmaster-General in presence of the Director-General, the Councellors, a large number of officials of the Central Administration of Posts and Telegraphs, all of the employés of the central office, and including also a number of foreign savans and other persons of distinction. Doctor Stephan, in a happy and appropriate speech, welcomed the employés, and congratulated them upon the occupancy of the new building. He also referred in fitting terms to the many illustrious men whose names will ever be remembered in connection with the inception and growth of the telegraph. The following is a brief description of the operating department: The space forming the ground floor of the new building is about 110 feet long and 80 wide. It is composed of a central hall lighted by skylight, and forming the principal portion of the whole, and three latteral galleries running north, west and south. The central hall is nearly 23 feet high and the galleries over 12. Communication between the former and latter is established through double rows of richly decorated columns. The whole interior, besides, is fitted up with much taste and elegance, and forms a very pretty effect. The central room is principally reserved for the Hughes apparatus, of which it now contains 36, and 10 Morse sets, but the space is so large and the arrangement of the present apparatus has been such that the number of instruments can be doubled in case of need. The switch connecting with the Hughes apparatus is placed in the portion of the building, as are also the pneumatic tubes connecting with various outside points, and the slightly elevated desks for the use of the chiefs, from which they can command a complete view of the floor.

The galleries are principally devoted to the Morse apparatus, of which 169 sets are in actual service. They also contain two large groups of lightning arresters and the general switch, as well as a smaller one for the accommodation of the city lines. A number of electric clocks, ten in all, and controlled by a single regulator, are placed at various points about the rooms, so that the employés on any part of the floor are enabled to ascertain the hour without the slightest inconvenience.

The central station contains 250 lines, which are supplied by some 6,000 cells of battery placed in the basement, beneath the operating department, and all the wires leading from the instruments to the batteries and to earth are covered with gutta-percha protected by an outside covering of lead.

An Artist Telegraphist.

Mr. Geo. Cochrane of the Western Union main office in this city, has a picture in the Water Color Exhibition at the Academy of Design called "Color Glow," a continuous rectilinear spectrum. It possesses not only an artistic but a scientific interest.

THE PROPOSED TELEGRAPH THROUGH CENTRAL AFRICA.

It has been very difficult for any one to gather from the expressed opinions of the exponents of this scheme any clear idea as to the means they propose to adopt in order to carry it into effect. One estimate gives as the cost £500,000, but the principal speaker in the deputation to the Colonial Secretary on the 18th February gave as the cost £700,000. We can hardly suppose that any really scientific estimate has been made, but what has thus been stated is the outcome of a casual glance at the subject. The engineering difficulties in the way of such a work are enormous, and when these have been surmounted, as they can be, *at a cost*, electrical difficulties must be encountered, and how these are to be overcome has not yet been satisfactorily explained. According to Captain Mayes, for hundreds of miles over part of the proposed tract the tropical vegetation holds sway, and if a road of twenty feet in width be cut and the roots of the trees grubbed up, in a few months, unless there is a constant stream of traffic, the whole is again covered with an impenetrable jungle. Then all the materials, posts, wires, insulators, tools, and even the food, or merchandise wherewith to obtain food, must be carried in some parts by the aid of coolies. Electrically, the insulation of the line would be about as bad as one can suppose a line to be. Portions of its course being in two tropics, there would be a double rainy season to be guarded against; and be it remembered that rain in England is one thing and rain in the tropics another. It would be extremely difficult to send messages during a tropical downpour over long lengths of land line—and, if we consider the effect of the luxurious vegetation probably coming into contact with the wires, we should say almost impossible. We are glad to see that Mr. Donald Currie, the able advocate of the West Coast cable, has no word to say for the land scheme, but says if there is greater difficulty in laying a cable by the West Coast than by the East Coast, by all means let us have the latter. He believes, as must every one who has studied the subject, that telegraphic communication with the Cape by means of a cable is essential—essential commercially, essentially politically. Mr. Young, in a communication to *The Times*, says:—"I am interested in a scheme of laying a telegraph to the Cape through Central Africa. I consider such a project to be altogether impracticable for some years to come, for the following reasons:—A great portion of the country through which it is proposed to construct this line of telegraph is altogether unexplored, and only with the greatest difficulty have travellers penetrated to those parts which are better known. How, then, could the requisite material be transported thither? Supposing even this objection to be overcome, the elephants, which abound nearly everywhere and delight in uprooting even immense trees, would speedily lay every post level with the ground. The poles, which the climate would render dry, in six months would be totally destroyed by the fires which every year entirely consume the grass and bush. It would be impossible to keep the line in repair; most of the native tribes, instead of so doing, would soon be using the wire for ornaments."

We trust that after these statements have been considered we shall hear no more about a scheme which, upon the face of it, bears no stamp of practicability. According to a casual statement of Mr. Donald Currie, made on the occasion of the departure of the Dublin Castle with troops for Natal, the Government has practically decided to give the required support for the laying of the East Coast Cable, from Aden to Zanzibar.

USE OF "EARTH" FOR COMPLETING A TELEGRAPHIC CIRCUIT.—According to Mr. John Finlaison, Prof. Aldini, about the year 1802, sent the current from a battery of eighty cells across Dublin Harbour through a wire supported on the masts of boats, using the sea for the return circuit. It was not until 1837 that Steinheil perfected his telegraph, and showed that the return wire between two stations might be dispensed with; whilst the experiments of Mr. Alexander Bain, at the "Serpentine River," in Hyde Park, in which water and metal cards were made a portion of the circuit, did not take place until 1842.

SOUTH AUSTRALIA.—This colony has nearly 5,000 miles of telegraph line in actual operation. This includes the line, 2,000 miles in length, through the continent, in connection with the submarine cable system to India, England, and other parts of the world.

JAPAN TELEGRAPHY.—We learn from the *Journal Telegraphique* that Japan has joined the St. Petersburg Telegraph Convention, having adopted the extra-European rules and tax per word, without conditions as to minimum of words. The cost of a message in Japan is fixed at 40 Mexican cents, or about a shilling per word.

THE International Telegraph Conference will meet on June 10 in London, and not on June 2 as at first arranged.

FOR three years the German Telegraph Administration have published statistics of the faults on their air lines, a plan which is worthy of imitation by all other telegraph managements. In 1878 some 382 posts were broken on 17,700 kilometres of wire, 1,097 broken wires on 15,700 kilometres, 2,251 leakages on 24,000 kilometres, 1,342 damaged insulators on 25,000 kilometres, and 242 loose wires on 19,800 kilometres. These figures show a remarkable reduction of mishaps as compared with the previous two years.

TASMANIA has 850 miles of telegraph line connecting 46 stations, besides being connected by cable to Australia.

TELEGRAPH CONSTRUCTION AND MAINTENANCE COMPANY (LIMITED).—Subject to the audit of the accounts, the directors propose paying a dividend of 15 per cent. (£1 16s.) per share, in addition to the *ad interim* dividend of 5 per cent. already paid, making 20 per cent. for the year 1878.

Bamboo poles, for use as telegraph posts, are being sent to Natal from Madras.

The Telegraph.

ANNUAL MEETING OF THE DOMINION TELEGRAPH COMPANY.

THE report of the directors of the Dominion Telegraph Company for the year 1878, presented at the annual meeting of the company, held at their office in Toronto, February 12th, was as follows:

The directors beg to report that the gross revenue of the company for 1878 has amounted to $167,807.31, as compared with $177,086.88 for 1877, showing a decrease for the year of $7,244.55; while the working expenses for 1878 have been $122,215.23, against $121,297.58, or a reduction of $2,082.39 on the previous year's total.

The net revenue for the year has amounted to $47,592.08, leaving, after payment of interest on bonds, the sum of $35,257.97 available for dividend, from which the directors have declared an interim dividend of 3 per cent. for the half year ending the 30th June, and a further dividend of 2½ per cent. for the closing half year ending the 31st December, making for the year a total dividend of 5½ per cent., and leaving at the credit of profit and loss account a balance of $1,891.47.

The directors have to congratulate the shareholders on the completion of their connecting lines in the Maritime Provinces, and feel warranted in assuming that the extension now consummated will prove a valuable boon to the public and a profitable acquisition to the company. The Dominion is now the only telegraph company transmitting public business over its own wires between the Upper Provinces of Ontario and Quebec and the Lower Provinces of New Brunswick and Nova Scotia. Its lines, moreover, form the shortest as well as the only direct communication with the Atlantic cable, connecting Canada with Great Britain, thus affording to Canadians the independent national telegraphic communication with the mother country, so long desired. The directors confidently hope the public will not fail to appreciate the advantages and facilities thus possessed by the Dominion Company, especially when it is known that the transmission of the telegraphic business between the Maritime and Upper Provinces and between Canada and England, and the whole of Europe, by any other line than by the Dominion, necessitates a foreign and hostile operation. Such an objection does not exist against the Dominion Telegraph Company. Moreover, its cable traffic from Canada by any other route involves the transfer and repetition to an intermediate telegraph company in New Brunswick, over whose lines it has to be retransmitted to Cape Breton, where a further retransmission has to be made by cable to Newfoundland before it is finally despatched by the trans cable. In the case of the Dominion line no transfer to intermediate company is involved, as the trans Atlantic cable is reached directly by their own wires at Torbay.

Since the last report was submitted the pole multiage of the Company has been increased to 4,618 poles, and the wire mileage to 8,982 miles, and the number of offices now open is 402.

A conference having been proposed by the Montreal Telegraph Company to the Dominion Company, through Captain Mayne, R. N., C. B., to discuss the subject of a division of the gross earnings of the two companies, with a view to enable them to reduce their expenses and minimize the effects of the diminished traffic by the general and serious depression in commerce which unhappily continues to prevail, your directors appointed to enter into negotiations for the accomplishment of so desirable an object; it being first distinctly stipulated that both companies should maintain their independent legislation, and that the public should have continued to them the option of using whichever line they preferred. Under this arrangement it was proposed to establish joint offices at all those places where one telegraph office would amply suffice, but where duplicate offices were now maintained at heavy cost to both companies. The agents at these joint offices were to be equally the servants of both companies, acting under the instructions of a Joint Committee and not under separate authority, except in matters appertaining to the routine business of each company. While this arrangement would have continued to the public, a first-class and independent service by either company's line, as the use thereof might be chosen, it would have acted to both companies the expense of many superfluous offices which have been the natural offspring of keen rivalry. The business of both companies having fallen off, and there being little prospect of a speedy reaction, your directors deem it proper and wise to try the means which appeared to them to be most practicable and effective to conserve all interests. It seemed to them that, in the case of keenly competing companies, as in the case of railway companies, the means mainly existed in the ability possessed in the companies to bring about, by agreement with each other, the largest possible reduction of expenses, and so keep up the net earnings, while any attempt made to maintain an increase of earnings by raising rates, in the present depressed state of business, would be strongly opposed by popular feeling, and productive so little, if any, benefit to the companies themselves.

The directors, under the circumstances, felt it their bounden duty to take the whole matter into consideration, and decided to recommend their shareholders to accept of the division of gross earnings which both parties had agreed upon, with each an administration for the management of the joint offices, as they believed it would be greatly beneficial to the interests of both companies and through with the least possible inconvenience to the public. A difference having arisen between the parties, it was mutually arranged to refer the matter to the arbitration of Captain Mayne, whose decision it was agreed should be binding on both companies, subject to the approval of the shareholders. The directors, however, regret to have to announce that the negotiations were eventually terminated by the Montreal Company declining to carry out Captain Mayne's award.

During the past season the company's entire system of lines has been thoroughly overhauled by repairing and renewal gangs, and put in condition to make transmission of business reliable, and to afford every facility and promptness of despatch.

The directors trust that by these means, and by the addition of such important premises as New Brunswick and Nova Scotia to their system, whereby the resources of the company have been much augmented, they will be enabled to offer such commercial facilities as will enable them to retain their old business generally, as well as secure the shareholders permanently satisfactory results, more particularly when trade revives and public confidence is restored.

The directors find it desirable to obtain some amendments to their charter, and will submit, for the shareholders' approval, the bill they propose to introduce to Parliament.

The following is a general statement showing the liabilities and assets of the company on the 31st December last:—

LIABILITIES.	
Share capital authorized	$1,000,000 00
Share capital paid up	713,700 00
First Mortgage bonds issued	200,000 00
Balance on account, and bills payable	74,372 92
Due connecting lines, unpaid dividends, &c.	10,351 66
Dividend now payable on six months ending 31st December, 1878, at 2½ p. c.	17,760 17
Balance at credit of profit and loss account	1,891 47
	$1,018,076 22
ASSETS.	
Capital expenditure account	$1,009,324 53
Plant and stock on hand	63,186 48
Accounts due from railways, governments, connecting lines, agencies, &c.	58,264 86
Cash on hand and in Bank	10,272 61
	$1,141,048 31

Respectfully submitted,

THOS. N. GIBBS, *President*.
THOS. ROBINSON, *Managing Director*.
F. BOURN, *Secretary*.

Toronto, 12th Feb., 1879.

The report was adopted.

The managing director then read the draft of a bill proposed to be submitted to the Dominion Parliament, asking for an extension of powers of the company, which was approved, and the directors fully authorized to promote its passage; and empowered to deal with any alterations that may be found necessary.

A resolution was also adopted "that, with reference to the bill now proposed to be submitted to Parliament, the directors be requested to obtain the following amendments to those 10 of the company's Act, 34 Vic., cap. 32: The powers of the company shall be managed by a Board of Directors, to consist of nine members, and each such director shall be the proprietor of at least ten shares in the stock of the company, or such other increased number of shares as the shareholders shall by any resolution from time to time determine, and the said Board of Directors shall be elected and hold office as hereinafter provided."

The Executive of the company also sustained in the course pursued with the Montreal Company.

A vote of thanks to the President, Managing Director and the members of the Board for their course in the discussion of the scheme for pooling receipts of business rendered by them, and for the efficient manner in which they have conducted the affairs of the company during the past year, was also carried.

A ballot for the election of directors for the ensuing year was then proceeded with. At the conclusion of the ballot the scrutineers reported that the following gentlemen had been unanimously elected directors of the company for the ensuing year: Hon. Thos. N. Gibbs, Hon. Wm. Cayley, Hon. Frank Smith, Messrs. James Michie, Thomas Swinyard, John Smith, James Cooderham, Wm. Ramsay and H. S. Northrup.

At a subsequent meeting of the new Board, Hon. T. N. Gibbs was elected President; Mr. James Cooderham, Vice-President; Mr. James Michie, Treasurer, and Mr. Thomas Swinyard, Managing Director.

The following gentlemen were appointed honorary directors: Messrs. John J. Mackenzie and Anthony Cope, Hamilton; Sheriff Waddell, Colborne; M. H. Gault, Montreal; A. Joseph, Quebec; James Taylor, St. Catharines; J. S. Maclean, Halifax; and C. B. Fairweather, St. John, N. B.

Do the good you can in the world, and make as few enemies about it as possible.

TWENTY-FIVE years have passed since the first Danish electrical telegraph line was opened for public correspondence. It was on the 1st of February, 1854, that a line 180 miles long was opened between the two terminal points, Elsinore and Hamburg; but, besides these two terminal stations, there were intermediate stations at Copenhagen, Corsoer, Nyborg, Fredericia, Flensburg, Rendsburg, and Altona, besides three postal stations of a certain importance. On the 1st of January, 1855, a Danish controlling station was established at Helsingborg, in Sweden, to control the Swedish correspondence that passed through Denmark; a cable having in the meantime been laid out from Vedbek, near Elsinore, to Helsingborg. A wire was then put up from Helsingborg through Sealand, Fiona, and the two duchies to Hamburg, where the messages for Germany and England were exchanged. In the year 1858 a new line through the eastern part of Jutland was built between Fredericiahavn and Hamburg, and at the same time a short wire was put up from Copenhagen to Frederickberg. On the new line in Jutland, which was 270 miles long, stations were established in all the greater towns of the east of the Peninsula in the following year, and in Sealand and Fiona two new lines were erected, with a station at the town of Odense. In 1858 the controlling station at Helsingborg was removed to Copenhagen as a new line had been erected for the Swedish traffic. Private companies were very active in erecting telegraph communications, and Denmark is indebted to those companies for the many stations that were opened during a short period. These lines were from Nyborg to Svendborg, Ruddkjöbing, and Nastad—the two last towns, which are situated on the islands of Langeland and Aarce respectively, being connected by cables—from Hobro to Skive, Viborg, Nykjöbing on Mors, and Thisted, and the lines from Aarhus to Silkeborg, and from Fredericia to Middelfart and Assens. In 1859 Flensburg was put in direct connection with England via Tönning and Vesterveste. A line from Copenhagen to Helsingborg, with a branch to Landskrona, in Sweden, was opened in 1860, so as to have means for the increasing traffic with foreign countries. In 1861 a new line of a length of 138 miles was built, which connected all the towns of western Jutland from Flensburg to Lemvig; and many new private companies got a license to erect stations, of which the westerly towns of Sealand were the most important. All these private lines and stations were bought by the Government on the 1st of February, 1871.

The loss of the duchies of Schleswig and Holstein diminished the total length of the Danish telegraphs by about 400 miles, and the stations by 16, including the two great stations at Flensburg and Hamburg, which were in direct connection with Copenhagen as well as the most important Swedish towns, and forwarded all the traffic abroad from Denmark, Sweden, Norway, and in part also from Finland. Sweden had then no other connection with Germany. At present it has a line from Trelleborg to Saigen, one from Gothenburg over the northern extremity of Jutland (and wire) to Newcastle, and one from Landskrona (Stockholm) to Elsynd Fiuland—the two last belonging to the Great Northern Telegraph Company.

The war of 1864 with Germany for some time kept all development of the Danish telegraphs at a standstill; but a few years after, in 1869, they were commenced again by connecting Bornholm into the system. Meanwhile, cables were laid down to England (Newbiggin, near Newcastle) in 1868, and to Norway (Arendall) in 1869. In 1869 the Great Northern Telegraph Company connected Russia (Libau) with Prussia via Memel, and with Gothenburg and Fredericksham. New lines between small towns had also been built, and the three following semaphoric stations were installed: viz., Hirshalm (Skagerak), Hanstholm (North Sea), and Hornsrevhuus on Bornholm, as well as four stations, which are only open in severe winters for ice-boats—viz., Nienodd, Sprogö, Knudshoved, and Slipshavn.

Copenhagen has a great local traffic, but is of little importance as a transit office. It is Fredericia that must be regarded as the most important of all the telegraph stations in the Northern Europe, from an international point of view. Some towns it is as far as 3 hours, connected with all the railway foreign countries through cables as this very little Danish town. For this reason the employés must know and speak several languages to a certain degree of perfection, for they correspond with Paris, six Calais; with Nice, via Novaggio; with Russia, via Libau; with Stockholm, via Gothenburg; with Norway, via Arendal; and, finally, with Germany, via Hamburg, Flensburg, and several other towns. Most of the telegraphic traffic between Russia, Libau, Sweden, and Norway (the Danish route) passes on one side, and England, France, and a portion of the United States' traffic to China on the other side through this town, which is unknown to the world at large. At Fredericia there are about 20 clerks, and 30 to 40 messengers, of which the most part are boiveiture of Siemens-Halske's improved system.

The Danish telegraph lines occupies 1,870 English miles, including 4,990 miles of wire, of which 1,870 shall at the end of last year numbered 30, of which there are ten engineers; 17 managers or superintendents, who generally are large stations; 21 clerks-in-charge, of clerks, divided into 1st, 2nd, and 3rd beginners; and 20 postmasters or other persons who have a station to take care of, but have other business.

The Swedish telegraph, including land lines and cables, amounts in 1872 Swedish miles to 10,673 Swedish miles of wire. The total number of Government stations and railway stations is 301, of which 179 are Government, and the remainder are railway stations.

vaneur général de l'Inde, se trouve à Simla, dans l'Himalaya, en communication constante avec le cabinet de Saint-James.

Le réseau des États-Unis de Colombie

Le *Journal télégraphique de Berne* fait remarquer que, sans l'héliotrope des États-Unis de Colombie, l'extrémité du Sud serait reliée télégraphiquement à l'Amérique du Nord, d'une façon anormalement coûteuse.

Le *Journal télégraphique* ajoute, que le gouvernement attend la fin de la guerre civile pour relier les lignes qui existent dans ses États. Nous n'avons que ces bonnes intentions seront certainement suivies d'exécution.

Mais cet incident soulève une question théorique importante.

Jusqu'à quel point une nation a-t-elle le droit de faire obstacle par guerre ou autrement à l'extension du réseau universel?

Le bureau central de Berlin

L'inauguration de la grande salle d'en haut le nouveau par un discours dans lequel M. Stephan, directeur général, a célébré la gloire de l'empereur et de l'empire, après avoir dit quelques mots des grands inventeurs au nombre desquels nous devons reconnaître qu'il n'a point oublié Jacquard.

Le nombre des télégraphes Hughes réunis dans la partie centrale est de trente-six, auxquels on a associé dix-huit Morse.

Dans les *Annales* il y a trente-cinq Hughes et trente-neuf Morse. Le nombre des appareils Morse est donc supérieur à celui des deux autres réunis. Les batteries se composent de cinq mille éléments, où on voit bien longtemps on ne remplit d'un nouveau, analogue à celui du bureau de Genève. Martin-de-Fonvi (voir la description que nous en avons donnée). Mais nous ne craignons point de dire que si la télégraphie hélicoïdale brille par sa simplicité, elle n'est point encore qu'elle ne donnait point cet contact de tout progrès, qui se trouve le souvenir.

Les poteaux du télégraphe électrique placés le long du Southern-Pacific Railway étaient construits avec des morceaux de bois tordus qui ont pris racine, de sorte qu'une magnifique ligne d'arbres donne de l'ombre aux voyageurs se servant de cette nouvelle artère transaméricaine.

Le câble écossais qui traverse le golfe, au fond duquel se trouve la ville d'Edimbourg, a été victime d'un accident fort peu ordinaire. Il a été mis hors de service par un incendie.

Pour comprendre comment cette catastrophe a pu se produire, il faut savoir que le bout de terre traîne amarrés à alimenter en feu de jolie.

Le caoutchouc et la gutta-percha n'ayant pas tardé à fondre, les six fils de cuivre ont perdu leur isolement.

Les comptes du *Western-Union* prouvent que, depuis 1868, le prix moyen des messages a diminué de 0,09 par les lignes de la Compagnie, tandis que de 0,09 par les messages envoyés à quadruplé. Si le nombre des messages envoyés a diminué des prix de revient de chaque message a diminué de 0,09, un employé le salaire des employés ait été augmenté. Actuellement la longueur totale des lignes est de 120,000 kilomètres; celle des fils, de 320,000; le nombre des bureaux, de 8,000, et celui des messages, de 22 millions.

CHRONIQUE

Le "Western-Union" a donné ces très-curieux détails de l'apparition de flammes électriques au fils Salsi-Elmo, qui donnent une preuve de l'énergie de la tension positive possédée par la terre.

Le 17 décembre dernier, M. Mac Nab traversait le pont l'on de Stockton à Tolgomouth (Angleterre), lorsqu'il s'aperçut que les deux côtés du pont étaient illuminés régulièrement de distance en distance par des lueurs pâles ressemblant à celles que donnent les becs de gaz de temps de brouillard. La première impression fut naturellement de s'imaginer que la corporation avait fait allumer le gaz pour avertir les barques circulant sur le canal, mais en examinant de plus près ce qui se passait, il n'eut point de peine à se convaincre que cette illumination singulière était produite par des phénomènes naturels et qu'il voyait sous forme lumineuse l'électricité, du sol qui s'élançait dans l'atmosphère par les masses métalliques dont ce magnifique pont est formé. En effet, chaque pointe de fer portait sa flamme d'environ deux pouces de haut, composée d'une multitude d'étincelles accompagnées d'un sifflement aigu, signe incontestable de l'existence d'une décharge d'une *tension positive*.

Pendant qu'il admirait cette illumination étrange, un passant le héla et lui dit : Monsieur, prenez garde, vous portez une flamme au bout de votre parapluie. — « C'est précisément comme vous », répliqua M. Mac Nab à son interlocuteur qui, sans en deviner, servait également de pôle pour l'écoulement de l'excès d'électricité positive de la terre.

Une municipalité intelligente

Nous apprenons à l'instant que le maire de New-York vient de signer une ordonnance autorisant une compagnie télégraphique à établir un réseau souterrain à condition que deux fils servant exclusivement à la ville, et mis gratuitement à sa disposition pour le service municipal. Les fils devront être enfouis à 4 pieds au-dessous du sol à plus d'un mètre des trottoirs, et disposés de manière à ne pas gêner les conduites d'eau et les conduites de gaz.

Nous recevons d'Italie la circulaire par laquelle M. Capparoni nous apprend que l'*Electricista* cesse sa publication et qu'il le remplacera en prenant le nom du *Nature*. Tout en félicitant nos habiles directeur de l'extension prise par sa publication, nous ne pouvons échapper à un sentiment de tristesse lorsque nous voyons diminuer le nombre des organes spéciaux consacrés à l'électricité. Si nous regrettons ce mouvement instinctif, nous irions presque jusqu'à appliquer à M. Capparoni le mot de Cormier lorsqu'il apprit qu'après avoir remporté la victoire de Marengo le premier consul allait se faire proclamer empereur : « Je ne comprends pas

The Telegraph Construction and Maintenance Company.—Cables Manufactured in 1878.

The report of the directors of the Telegraph Construction and Maintenance Company, submitted to the meeting of shareholders, held in London, March 6th, states that the principal operations carried out by the company during the year 1878 were as follows: The laying of two sections of the Western and Brazilian Company's cables on the coasts of Para and Maranham in the Brazils, amounting to 553 nautical miles, in accordance with the terms of a contract entered into with that company; an endeavor to repair the Anglo-American Company's cable of 1869, which proved unsuccessful, the decayed condition of portions of the outer covering rendering it impossible to raise the cable, except in short lengths. Two of the company's ships were employed on this operation between the 25th of May and the 27th of June. The manufacture and laying of a cable for the Eastern Telegraph Company between the Island of Cyprus and Alexandria, and the manufacture of certain lengths of cable to enable that company to duplicate and connect up portions of their system with the islands of the Levant and Constantinople. The manufacture of 280 miles of cable for Her Majesty's Government. The total quantity of cable manufactured during the year was 2,651 miles. To replace the steamship *Hibernia* the steamship *Scotia* has been purchased, and she, together with the *Galatea*, is undergoing extensive alterations and improvements, which, when completed, will place the company in possession of four large and efficient vessels, equal to the performance of any cable-laying operations that may offer.

Nous avons déjà fait connaître à nos lecteurs que l'administration des télégraphes en Allemagne a fait des essais pour immerger en ligne souterraines la plupart de ces lignes télégraphiques aériennes.

Les essais ayant réussi, on a étudié un plan du futur réseau souterrain. Celui qui a été conçu par le directeur général des postes et qui a été approuvé par une commission, devra être terminé en dix-huit mois. Deux lignes diagonales, traversant l'Allemagne du nord-ouest au sud-ouest et du nord-est au sud-est, relieront alors Konigsberg et Strasbourg, Hambourg et Bâtiber. Ces deux lignes se croiseront à Berlin.

En outre, à l'ouest, un câble souterrain formant arc reliera Strasbourg et Hambourg par Cologne, et à l'est un autre câble formant également arc reliera de Bâtiber à Konigsberg.

Enfin, un câble traversera toute l'Allemagne du Sud, de sorte que toutes les villes de commerce importantes et toutes les forteresses seront reliées entre elles par sept fils souterrains à toute perturbation atmosphérique. La ligne la plus ancienne, celle de Berlin à Berlin, a été soumise à un examen des plus rigoureux, et n'a donné lieu à aucun signalement même au temps des violents orages.

Cette remarque s'applique aussi aux câbles. Les travaux du télégraphe souterrain à l'est n'offrent pas de grandes difficultés, car le sol n'est presque nulle part montagneux, et les anciennes chaussées de Berlin à Stettin et à Konigsberg forment pour de courtes. Le passage du câble sous les rivières se fait aujourd'hui facilement, grâce à l'expérience acquise, par des procédés analogues à ceux que l'on emploie pour la traversée des bras de mer.

General Science.

The Brooks Underground Telegraph system, the details of which, though familiar to telegraphic engineers, have received but little publicity, appears during the past two years to have been quietly establishing its claims as a simple and effective solution of the problem of underground telegraphy; and, from the developments of the last few days, it is very probable that it may soon come into general use, in this country at least, as the statement is made, apparently on good authority, that the exclusive right to the use of the system has been purchased in the interest of the Western Union Company.

The system of Mr. Brooks differs from all others in the fact that the material employed for maintaining the insulation of the line is a liquid—paraffine oil, which is known to possess, for this purpose, a higher specific inductive capacity than, in being in the wire—thirty, forty, or fifty, as may be required—covered with cotton binding, are placed in a lead pipe, continuously located, and the pipe line filled with oil, allowed to run in until full, the maintenance of the supply being assured by providing an elevated vessel of the material at intervals, so that a constant pressure will be kept within the pipe. This is practically all there is about it, and its extreme simplicity appears to be not the least of its merits, as one of the great objections advanced by the advocates of the past system has been the great expense of laying and maintaining underground lines.

Upon the question of its practical working we now have very good testimonials, which we are pleased to be able to state, is unqualifiedly favorable. The first line constructed upon this system, and which was actually put to work, was laid about two years ago. It was about a mile in length, and is reported to have been successful beyond all expectations of its inventor at the end of two years having imposed rather than delayed. H. Railroad, a submarine line being laid across the Schuylkill. It gave good results, and has ever since been in operation, its insulation, like that of its predecessor, having increased. Since first time, a number of lines the Pennsylvania Railroad west of the passenger depot in West Philadelphia; another across the Christina and Brandywine creeks at Wilmington; negotiations are pending, awaiting your authority, for connecting Camden with Philadelphia by a line across the Delaware, for the laying of a line across the Hudson at New York, and for a line between New York and Philadelphia. The advantages of a meritorious and reliable system of underground telegraph over the old aerial system have been so often pointed out in the JOURNAL that their repetition here would be useless. We have simply to record the progress of events from week to week, a task in the case of this item that we perform with peculiar gratification.

On a essayé, paraît-il, d'établir des lignes électriques à Sumatra, mais les singes, les tigres et les éléphants paraissent être des ennemis irréconciliables des câbles. Leur acharnement est aussi grand que celui de MM. Cézmencau, Blanqui et consorts contre notre jeune République.

Depuis que la ligne a été établie pour la première fois, les pachydermes insurgés l'ont renversée à plus de trente reprises différentes. Les ingénieurs espèrent parvenir à les empêcher de nuire en diminuant le nombre des poteaux et en les rendant plus solides; mais il sera plus difficile d'empêcher les singes de venir se balancer à des lianes d'un nouveau genre qu'ils trouvent bien préférables à celles que leur offre la nature. Peut-être pourra-t-on employer l'électricité d'induction qui a protégé les poteaux de la ligne de Kemberley et de Natal au Cap contre les Hottentots et les Cafres.

Subterranean and Aerial Telegraph Lines.

THE *Odeport* (Germany) *Gazette* says:—"The storms which have lately raged have demonstrated in an unmistakable manner the superiority of subterranean to overhead telegraphs. During the heavy storms in 1876, for instance, telegraphic communication in Germany was frequently interrupted, sometimes for long periods, and immense inconvenience was thereby occasioned. This winter, however, long reports of the debates in the Reichstag have been sent by the subterranean tele-graph from Berlin to Cologne, and, in spite of snow and storm, not the slightest interruption has ever taken place in the service. Throughout the winter the telegraphic communication between the two towns has been regular and unbroken. Nothing has had to be spent in repairs, while with the overland wires large sums have constantly to be expended in making good damages occasioned by inclement weather or other causes. Ultimately, therefore, the subterranean telegraphs will, there is every reason to believe, prove cheaper than the ordinary system, despite their greater original cost."

TELEGRAPHIC.—A Parliamentary paper has been printed giving the agreement, dated May 9th, 1879, entered into by the Government with the Telegraph Construction and Maintenance and Eastern Telegraph Companies for establishing telegraphic communication with the South African colonies. The route decided upon, as already announced, was the one submitted by Mr. Pender on behalf of the two companies—from Aden to Natal, touching at Zanzibar, Mozambique, and Delagoa Bay. The Government subsidy was fixed at £5,000 per annum. The tariff was fixed at 9s. a word between Aden and Zanzibar, and 5s. a word between Aden and Mozambique, Delagoa Bay, or Natal; and neither these charges nor the present charge of 3s. 9d. a word between Aden and London are to be altered without the concurrence of the official director. The cables are to be capable of transmitting fourteen words a minute. The Governments of Victoria and New South Wales concur in the postponement for a short period of the duplication of the Australian line, in order that the cable already manufactured for that purpose might be used in laying the Cape line.

Aluminium for Aluminum.

The value of aluminium in telegraphy has for some time been well known, and has lately attracted special attention. This metal possesses double the conducting power of iron, and can be made into extremely thin wires for various purposes.

The high price of aluminium, however, and the difficulty of large production, have proved very considerable obstacles in the way. But the statement is now made in the *Alls. Tel. Zeitung*, that it can easily be produced in quantities sufficient to give an alloy with iron suitable for use as telegraph wire, and thinner and better conducting than the ordinary iron. Owing to its light weight, such wire must be well specially adapted for military telegraphy, since great lengths can be carried on one bobbin. With regard to the production of aluminium, it is thought that the tolerably abundant cryolite found in Greenland might furnish the raw material, and that the reduction of it in smelting works, by means of silicious iron or zinc-ore, might be practicable.

TELEGRAPHIC INVENTIONS ADOPTED AND APPRECIATED.

The Americans are an eminently practical people. This is forcibly shown in the readiness with which electrical and telegraphic inventions and improvements are brought into general use. The activity of inventive genius is stimulated by the free competition which exists and the prompt utilization of any invention which will increase the facilities for business and social purposes.

The duplex and quadruplex telegraph improvements were perfected and first brought into general use in this country, as is well known, and after their practicability had been fully demonstrated here, are being adopted in Europe. The quadruplex is as yet used elsewhere to but a very limited extent, but is gradually overcoming the obstacles and prejudices which it has had to encounter. In this country it was promptly welcomed and adopted as a most valuable addition to telegraphic facilities.

The telephone, although of very recent date in a practicable form, has already entered into general use, and the demand for it bases severely the ability for their manufacture. The Telephone Exchange system has already attained a deserved prominence among the telegraphic facilities offered to the public use. It supplies at a moderate cost to individual subscribers the means of general telegraphic communication, and although of so recent origin, they have become indispensable to the communities where they have been established. Even comparatively small places afford an adequate support for these institutions, and it is scarcely possible to meet the large and growing demand for their introduction.

The enormous development of the telegraphic interest in this country, and the load which it has taken in practical telegraphic inventions, is undoubtedly due in no small degree to the fact that it has not been hampered and restricted by government control and management, as it is almost everywhere else throughout the world, but has been left to private enterprise and competition. Under such circumstances it is essential to the success of any such enterprise that all real improvements shall be promptly adopted, and for this reason inventions, instead of being repressed and discountenanced, have been encouraged and stimulated. The result of this policy is seen in the universal application of electricity to the service of the public. The adaptation of electrical apparatus to special service, as in the fire alarm, the distribution of commercial reports, and private telegraph lines by the Gold and Stock Telegraph Company, the American District Telegraph Company, and other minor arrangements, and lastly in the telephone, are so well known that they now attract but little attention, and are regarded as matters of course. Yet each has in turn been hailed by the press and people as wonderful developments of inventive genius and scientific study. In fact, so much has been accomplished in this direction that people are ready to give credence to claims of invention for new discoveries, however improbable they may seem, until they are shown to be unfounded and impracticable. Another element which has contributed to the development of inventive genius in this country is our liberal patent system, which is intended to throw no unnecessary impediment in the way of securing to the inventor the fruits of his labor. Although of the multiplicity of patents granted, but a small per centage prove of value, yet to restrict the right to obtain patents would probably prove more injurious in the end than the granting of applications for those which are not shown to be of value or importance.

It is now generally conceded that in telegraphy the United States are in advance of the rest of the world, and this lead will undoubtedly be maintained, so long as the conditions of private ownership and management of telegraph interests, and a liberal patent system are maintained.

Natural Enemies of the Electric Telegraph.

There is, apparently, no apparatus so liable to be interfered with by what we may call natural causes as the electric telegraph. Last week we saw what perils from vermin and fungus environ the subterranean wires. Fish gnaw and mollusks overweight and break the submarine conductors; while there is at least one instance of a frolicsome whale entangling himself in a deep sea cable, to its utter disorganization. It is stated that within the three years ending 1878, there have been sixty serious interruptions to telegraphic communication, in Sumatra, by elephants. In one instance, these sagacious animals, most likely fearing snares, destroyed a considerable portion of the line, biting away the wires and insulators in a cane brake. Monkeys of all tribes and sizes, too, in that favored island, use the poles and wires as gymnasia, occasionally breaking them and carrying off the insulators; while the numerous tigers, bears, and buffaloes on the track render the watching and repair of the line a duty of great danger. In Australia, where there are no wild animals to injure the wires, which are carried great distances overland, they are said to be frequently cut down by the scarcely less wild aborigines, who manufacture from them rings, armlets, and other varieties of barbaric ornament. It has been suggested as a means of protection in this case, that the posts should be constructed of iron, which the battery could be used to astonish any native climbing them with felonious intent.

Congrès universel de Télégraphie

Paris 1879

Il est intéressant de faire connaître à nos lecteurs quelles sont les compagnies sous-marines qui ont l'honneur de faire partie du Congrès international de Télégraphie tenu à Londres le 15 de ce mois, et le nom des délégués à qui a été confiée l'importante mission de les représenter.

D'après les renseignements que nous avons fait prendre, nous sommes en mesure de donner la liste de toutes les compagnies électriques qui seront représentées et des personnages qui auront l'honneur de faire entendre la voix de l'industrie libre, indépendante, au milieu des délégués des états civilisés.

Anglo-American Telegraph Co. — H. Weaver Brazilian Submarine. — T. Fuller Cuba Submarine. — T. Buchen D.C. — Direct Spanish. — C. Gerhardi. — Direct United States. — Captain R. Mayne, R. N.; and J. W. Fuller. Eastern, Eastern Extension, Australasian, and China. — John Pender, M. P.; *sir James Anderson*, Col Colaver, Lewis Wells, and Jules Despeches, Blue Sea. — Jules Bert, German Union. — H. Louard, Great Northern. — H. A. Prideaux, Captain E. Swanson, and Captain W. von Hedemann, Indo-European. — Mediterranean Extension. — E. A. Tombs, Submarine. — Sir Gilway, M. P.; and S. M. Clare. West Coast of America. — R. S. Gray Western and Brazilian. — Major Wood.

C'est avec plaisir que nous avons appris que la France devait être représentée dans cette haute assemblée par le ministre des postes et télégraphes; mais nous fesons avec peine dans les journaux anglais que l'honorable M. Cochery n'a pu se rendre de l'autre côté du détroit.

L'administration française est représentée par M. Richard, directeur-ingénieur des télégraphes, et par M. Ferdinchet, chef de section au ministère des postes et télégraphes.

Parmi les notabilités présentes, nous devons citer M. Nielsen, directeur-général des télégraphes de Norwège; M. Frey, directeur-général des télégraphes suisses; le directeur du bureau international, M. Gardesci; son secrétaire et le député-gérant-comptable du bureau.

C'est le premier congrès dans lequel la Roumanie, puissance si nouvellement constituée, a l'honneur d'être représentée.

On a admis également des délégués de la colonie de Victoria, de l'Australie du Sud, de la Nouvelle-Galles du sud et de l'Inde anglaise.

Parmi les délégués des compagnies sous-marines, nous voyons des Danois, des Anglais, des Allemands et des Américains. Il n'y a pas un seul nom français. N'est-ce pas facheux à plus d'une sorte de la décadence dans laquelle notre industrie électrique est incontestablement tombée?

C'est une puissante considération pour savoir gré à la Compagnie transatlantique, dont la création vient faire cesser pour les sociétés de l'avenir l'exclusion dont la France se trouve frappée.

La première séance s'est ouverte, sous la présidence de lord John Manners, directeur-général des postes à Grosvenor Place, le 18 juin. Lord Manners a prononcé quelques mots de bienvenue auxquels il a été répondu par le général Lefebvre, directeur-général des télégraphes russes.

Lord Manners s'étant retiré, la session s'est ouverte sous la présidence de M. Patey, délégué anglais.

Le soir, les délégués se sont réunis dans les salons de Willis Rooms où lord John Manners les a invités à un grand banquet.

CHARTER TELEGRAPHY.

[*Washington Correspondence of the Hartford Times.*]

One very important piece of legislation, connected with the Army bill as an amendment—that which gives the railroad companies the right to use their wires for general telegraph business—has escaped public attention. It is also true that was blocked up about the There must be a reason for this neglect, for the Western Union Telegraph Company has been exerting its efforts of influence to get the provision in conference report. It is a matter of great moment to the business interests of the country that the question in connection with the Western Union Telegraph Company be fully investigated before it is finally settled. The Baltimore and Ohio, the Pacific, and other companies, and have no bill to offer to-day to do a telegraph business of their own. It will be worth while to have a month or no will be settled in the interests of the people.

SPEECH OF HON. RAY AND OTHERS

Machine for Testing Telegraphic Poles.—The French Commission appointed in 1879 to study the question of employing iron poles on telegraph lines, have designed a new machine for measuring the bending stress on these poles when in an erect condition; It has been constructed by M. Thomasset, Paris, and consists of an erect iron frame for stressing the upright pole by means of a horizontal rope, and a mercury manometer for measuring the stress.

A "South Jersey Telegraph Company" is also being organised at Camden, N. J. United States.

The Telegraph in Arizona.—The railroad wire (leased by the Western Union) has been extended eastward through Arizona. It is now reached beyond the Gila river, 80 miles east of Fort Yuma, which latter is said to be the best point on earth, to the place known as Mericopa Wells in the centre of Arizona, and communication has been suspended during the last season, until cooler weather in the fall. Within a fortnight or so, it is anticipated that the overland and all-rail trip can be made by this southern route.

Telegraph Posts in Cochin-China.—For temporary lines bamboo is sometimes employed, but they cannot withstand the long-continued action of the dry and wet alternations of climate in these regions. The best posts are made of "tien" (white and red), a wood which is remarkably durable in water and moist earth. It is a kind of eucalyptus, but instead of being a febrifuge it is said to cause fever when growing in masses, and is known as fever-wood. The "chay" is excellent for poles set in damp places; the "son," the "ten ten," which endures for over fifty years in dry soil, and the "thee." These last three furnish posts from thirty to sixty feet long.

Cape Telegraphy.—The *Kangaroo* had not begun to lay the first section of the Cape cable, from Durban to Zoutfiver, up to June 17. The *Standard* correspondent, writing from Landsman's Drift, June 15, states that the land wire, as laid by Major Hamilton and Lieutenant M'Gregor, and the C. Troop Royal Engineers, will be completed very shortly to Dundee. The work has been carried out with great zeal and activity; but the company must now, so far as regards the further laying of the telegraphs, remain idle, the War Office, having, with its usual precidence, sent out a well-organised body of officers and men, with plenty of working material, but omitted to send sufficient wire. He also reports that the demand was made by the corps for 100 miles of semi-permanent wire, which, if laid, would have stood the whole campaign. The field wire has now joined the colonial wire at Osgorp's Kraal, through Dundee and Landsman's Drift to Dsoenberg. These places will be in telegraphic communication by signals, with a party of Royal Engineers, Lt. M'Gregor, R.E. Engineer, and Chelmsford's headquarters. Had the home authorities sent sufficient wire from Europe we should have been direct communication to Chelmsford with all stations throughout the country. The men of the Royal Engineers, working the telegraphs, have had very heavy work, owing to the quantity of Government and Press work telegraphed.

SOUTH AFRICAN TELEGRAPHY.

Telegraphy is making great strides in South Africa. Early in January last the line from Durban to Port Pearson was opened. In February the grand trunk line from Maritzburg, inland to Pretoria was commenced, and it was completed and opened as far as Utrecht in the Transvaal in the middle of May. The telegraphic communication is now complete from the Zulu border at its two extreme points, the south-east and the north-west to Cape Town. The advantages accruing in a military sense from such a fact are self-evident; they cannot be over estimated. The credit of this most useful work is due to the untiring energy and able organising power of Mr. Siversright, in whose hands is now vested the general management of South African telegraphs in both the Cape Colony and Natal.

The *Natal Mercury* on this subject says:—Mr. Siversright may be regarded as the practical harbinger of Confederation, as he has done more to unite the erstwhile separated communities of South Africa, and to identify their interests and concerns, than any living man. Most effectively aided by his indefatigable constructor, Captain Fraser, he has brought the Cape and Natal, the Diamond Fields and the Cape, Natal and the Transvaal, Zululand and Natal, within speaking range of each other. He has done this in spite of apathy, sloth, and division amongst ourselves, and he deserves all the credit and thanks that we can accord him for valuable services zealously and successfully rendered.

South African Telegraphy.

Telegraphic Journal and Electrical Review, June 15, 1879

The latest specimen of telegraphic enterprise, styled the American Union, appears to be having a lively time in the construction of its lines through the State of New Jersey. The laws of that State have some stringent requirements upon the construction of lines, especially through the cities, to which proper attention seems not to have been paid by the managers of the Asiatic Union. In consequence they find themselves in trouble when they attempt to build their lines through the cities and villages, in Newark, Bordentown, Rahway and other places their poles have been cut down, and the company prohibited from putting up its lines, until all the legal conditions are complied with. The officers of the Continental Telegraph Company, a company having lines between New York and Philadelphia, are zealous in insisting upon the enforcement of the legal conditions upon the new company. The result has been that the construction of the new line has been temporarily, entirely or partially suspended.

In Jersey City orders have been issued to the police force, by the Chief of Police, to prevent the setting of poles by the company anywhere within the corporate limits, until proper authorization is obtained, and to arrest summarily any persons who may attempt it.

The new Imperial Telegraph Office of Berlin is a very fine structure, admirably appointed. The underground telegraphic system, now nearly completed, has been attended with great cost and difficulty. The cable laid, in places, to be embedded in rock or mortar, depended in rapid flows, and carried beneath the walls of fortresses. Germany has now 1,118 telegraph offices.

South African Telegraphy.

Telegraphic Journal and Electrical Review, June 15, 1879

Telegraphic communication between Durban and Fort Pearson was opened. In February the grand trunk line from Maritzburg inland to Pretoria was commenced, and it was completed and opened so far as Utrecht in the Transvaal in the middle of May. The telegraphic communication is now complete from the Zulu border at its two extreme points, the south-east and the north-west to Cape Town. The credit of this most useful work is due to the untiring energy and able organizing powers of Mr. Sivewright, in whose hands is now vested the general management of South African telegraphs in both the Cape Colony and Natal.

The *Natal Mercury* on this subject says: "Mr. Sivewright has done more to unite the one-while separated communities of South Africa, and to identify their interests with one another, than any other living man. * * * He has done this in spite of apathy, sloth, and dire ill-concealed enmity ourselves, and he deserves all the credit and thanks that we can unfeignedly tender." — *The Telegraphic Journal.*

Telegraphic Excitement in New Jersey. — A Row.

Journal of Telegraphy, June 1, 1879

The latest specimen of telegraphic enterprise, styled the American Union, appears to be having a lively time in the construction of its lines through the State of New Jersey. The laws of that State have some stringent requirements upon the construction of lines, especially through the cities, to which proper attention seems not to have been paid by the managers of the Asiatic Union. In consequence they find themselves in trouble when they attempt to build their lines through the cities and villages. In Newark, Bordentown, Rahway and other places their poles have been cut down, and the company prohibited from putting up its lines, until all the legal conditions are complied with. The officers of the Continental Telegraph Company, a company having lines between New York and Philadelphia, are zealous in insisting upon the enforcement of the legal conditions upon the new company. The result has been that the construction of the new line has been temporarily, entirely or partially suspended.

In Jersey City orders have been issued to the police force, by the Chief of Police, to prevent the setting of poles by the company anywhere within the corporate limits, until proper authorization is obtained, and to arrest summarily any persons who may attempt it.

The Work of the Telegraph Construction and Maintenance Company.

At the half yearly meeting of the Telegraph Construction and Maintenance Company, held in London, July 22d, the chairman made the following statement in regard to the work the company now have in hand: "There being no accounts to present, the proceedings resolved themselves very much into telling the shareholders shortly what the company was doing with regard to cables. At the last meeting some questions were asked about the cable to the Cape, and he then stated that they were negotiating at that time, and were unable to give any information further than that negotiations were going on; since that the negotiations had been completed, and they were now laying that cable. One of their ships had been on the ground for some time, and he had no doubt had laid the cable, and the *Seine* was also on the ground now, and he hoped by this time had also laid her portion of the cable, or was just about laying it. The remainder of the cable had been constructed and would be sent off, and, he hoped, laid before the end of the year. They had also made a contract with the Eastern Extension Company for duplicating the cable from Penang to Australia. That cable was partly laid, and, as the *Seotia* also had left with the second portion of the cable, 600 miles, on board of her, that cable, he hoped, would be finished before the end of the year, or very early next year. Then they had also made a contract with the Spanish Government for a short cable of 650 miles, and also for a short cable from Norway to Germany."

No Authority to Allow Telegraph Lines on the Canals.

Journal of Telegraphy, July 1, 1879

The Superintendent of Public Works of this State having referred to the Attorney-General the question of his authority to authorize the occupation of the berme bank of the canals under his charge by a telegraph company for its poles, he replied as follows:

In answer to your communication of July 1st, inst., requesting the opinion of the Attorney-General "as to your power to grant a permit to a telegraph company to construct a telegraph line on land owned by the State on the berme bank of the canals," I have the honor to say that in my opinion the Superintendent of Public Works has no power to grant a permit of that character. The Superintendent of Public Works like other public officers, has only the powers conferred by law, with such as are incidental to the due execution of his duties. Conceding the advantages which may arise from the use of a telegraph line upon the property of the State along the canal, with stations at convenient points, and free use of the line for the business of the State, it does not follow that the Superintendent may authorize its construction. The Legislature alone has authority to authorize the use of the property of the State by private corporations or by individuals, except in cases where that authority has been delegated for specific purposes to some public board or public officer.

Telegraphs in China.

Journal of Telegraphy, July 15, 1879

Mr. J. Hannaman, Superintendent of the Great Northern Telegraph Company, in a communication to *The Electrician*, corrects the erroneous statement which has been copied in the *Journal* and the Telegraphic Journal as well as in the press generally, "that the first telegraph line in China to be opened for public correspondence in China is now in construction between Tientsin and Taku, a distance of about thirty miles," etc. This line which he says has been "in construction" a little over three years, according to the newspapers—is not the *first*, but the fourth telegraph line in China opened for public correspondence. The three older lines were built and opened as follows:

1. Between Shanghai and Woosung, a distance of about ten miles, built by the Great Northern Telegraph Company, and opened for public correspondence in September, 1873. This line is still working, and carries three wires, two for the Company's cables and one local wire.

2. Between Foochow and Pagoda Anchorage, a distance of a little over eight miles, built by the same Company, and opened for public correspondence in July, 1877. This line was sold to the Chinese Government a year later, and has since been worked by native operators united by the Company. It is in operation still, and has been open to the public all through its existence.

3. Between Tamsuifoo and Takoe au Formosa, a distance of nearly thirty miles, built in the summer of 1877 by native engineers, and worked by native operators trained by the Company. This line was opened for public correspondence somewhere in September, 1877, and has been so ever since.

I am, he says, of course, only taking into account *overland lines*, to which I suppose your contemporary refers, as it is well known that the Great Northern Company has connected the ports of Shanghai, Amoy, and Hong Kong with cables since 1871.

Ocean Telegraphy.

Journal of Telegraphy, July 15, 1879

The Canadian Government has let the contract for the construction of the new shore line for the maritime provinces to connect lighthouses on promontories with the telegraph system of Canada, in aid of which the Canadian Parliament last session voted a bonus of 20,000 dols., has been awarded to the Dominion Telegraph Company. The construction of this line is the first step toward the completion of the scheme for connecting the island of Anticosti and Magdalen Islands with the shores of the St. Lawrence by telegraphic communications, and for which purpose Parliament has voted a subsidy of 15,000 dols., to be continued annually. This system has been inaugurated by the government with a view to rendering timely assistance to vessels in distress, thereby lessening loss of life and destruction of property.

The Russian Special Telegraphic Commission has recommended a large extension of lines throughout the Empire in three classes. The first class, 21,340 versts and 400 stations, to be finished in five years, at an outlay of 840,000 roubles yearly; the second class, 16,485 versts and 139 stations, costing 2,565,620 roubles; and the third class, 12,822 versts and 99 stations, at an outlay of 4,845,959 roubles, for completion as found practicable. These lines are very distant, little used, but important for the Government.

American United States Cable Company.

Journal of Telegraphy, July 15, 1879

The directors report that the revenue for the half year ended the 30th of June last, was £37,706, as against £39,849 in the corresponding half of 1878. Working expenses, interest, &c., took £30,573, leaving £67,183 as net profit, to which falls to be added £3,323 brought forward, making £71,416 in all. The cost of repairs for the half year came to £8,952, and has been charged against the reserve fund. Two quarterly dividends, the second of which is now due, absorb £30,355, and £31,705 is carried to reserve, increasing it to £100,000, after writing off a further £1,000 from preliminary and arbitration expenses, £2,243 is left to be carried to the new half year.

The agreement with the Dominion Telegraph Company, of Canada, referred to in the last report, has been completed, and came into operation as from the 1st of January, 1879.

The break in the company's main cable, which occurred on the 4th of January last, was repaired on 20th of March, and the interruption on the 22th of February last, of the short section, was repaired on the 22d of April. Both sections of the cable are in good working order.

The New French Atlantic Cable.

A DESPATCH to the Liverpool *Post* from London, says, that up to the 11th inst., the steamer *Faraday* had laid successfully *upwards* of a thousand miles of the new French cable.

The French Atlantic Cable Repaired.

The Atlantic cable—St. Pierre to Brest—which was broken February 22, 1879, has been repaired. This restores direct communication between the United States and France, and through France with the rest of Europe.

The Caspian Cable.

The correspondent of the London *Times* at St. Petersburg gives the following information relating to the cable intended to be laid across the Caspian, recently manufactured for the Russian Government at the Silvertown Works: Six large mooted barges, towed by three steamers, lately arrived in St. Petersburg from Cronstadt heavily laden with the cable destined to be laid between Baku and Krasnovodsk, and orders have been given to hurry it to its destination. The wire, which measures about 147 nautical miles, including the expenses of insurance and sinking, will altogether cost about £62,000 sterling, and has been specially manufactured for the Russian Government by the Messrs. Siemens and Gatts Persha Telegraph Works Company in London, and has been conveyed to Cronstadt in the Great Northern, a vessel specially constructed for laying cables. The little fleet of barges and steamers will proceed by the Empress Maria Canal from the Neva to the Volga, whence it will descend as far as Astrakhan, where the cable will be transshipped into a large steamer and sunk in the Caspian at its narrowest parts between Baku and Krasnovodsk.

Engineer Aug 1 1879

Aug 16 1879

Extension of Telegraphs in Uruguay.

The following short description of telegraph lines in this country will given an idea of the persistency of the Anglo-Saxon to have some connection with progress wherever and whenever it is to be found. Uruguay boasts of two principal telegraph companies—(1), the *Platino-Brasilera*, the greater portion of which line is owned in England, and quite recently the direction has been transferred to London under the presidency of Mr. J. Fowler, M. P., who has shown so much energy and ability in all that concerns telegraphy. The line is about 200 miles long, following a westerly direction from Montevideo to Santa Rosa, the latter place being close to the Brazilian frontier. The company also possesses a submarine cable line from Montevideo to the river Chui, half way between Montevideo and the river Grande. (2). The *Oriental Telegraph*, extending from Montevideo in an easterly direction to the river Yaguaron on the Brazilian frontier. This line has little or no English capital involved in it. (3). The *River Plate Telegraph*—This valuable property is entirely in English hands. The land line extends a distance of 150 miles from the city of Montevideo to Colonia, their submarine cable to Punta Lara (twenty-seven miles) on the opposite Argentine coast. There is, moreover, a direct submarine cable line from Montevideo to Lara (120 miles), and from thence to Buenos Ayres per land line. The total length of the River Plate Telegraph Company's land lines is about 177 miles, submarine cable line about 120 miles.—*The Electrician.*

At the recent meeting of the Direct United States Cable Company, Mr. John Pender, M.P., the chairman, said they had purchased from the dissentients in the reconstruction of the company, shares and debentures of the nominal value of £90,550 for £73,055. Alluding to the new French cable, he said he believed it would meet the fate of the old Direct United States Cable Company, and that it would ultimately be purchased by one of the existing Atlantic Telegraph Companies for half its price.

It is reported that the French and Belgian Governments have requested that a complete set of the American quadruplex apparatus be placed at their disposal for quadruplexing the line between Paris and Brussels.

1873. Electric Telegraphs, *Sir C. T. Bright*—Dated 25th November, 1878. 6d.

In type printing telegraphs between the stations for which is to be employed a single line wire, the transmitting instrument is placed in the sending station. At the receiving station one of the elements of a differential relay is placed in circuit with the line and with one pole of a battery (called the line battery), the other pole of which is connected to the ground, and a second coil of the relay is connected at one end to one pole of the line battery, the other end being connected to the ground. The relay actuates two magnets, and the coils are so connected to the line battery that when the current through one coil is stronger than the current through the other coil the armature of the relay is attracted, and, whereby a circuit is brought into connection with a local battery, causes the movement of a shaft on which the type wheel is fixed. The paper is impressed against the type by an electro-magnet in the local circuit, which is actuated by a suitable contact in automatically transmitting commutator. In a modification the type wheel is replaced by a perforated paper. The type wheel is caused to move in either direction, instead of in one direction only as hitherto.

Specification No. 1,873, A.D. 1878.

IS A TELEGRAPH DIRECT, or is it known chiefly as secondary battery, composed of chloride of lead and sulphuric acid, allows weak currents to pass, while stopping those of high tension. Prof. MacLeod therefore inserted a secondary battery of platinum plates between the line and the telephone, but this stopped both the induction and the vocal currents. When platinum wires were substituted for the plates, however, the induction currents were stopped, while the vocal currents could be feebly heard.

THE TELEGRAPH IN NORWAY.

The Journal Aug 11 1879

By Th. Bowtz.

Among the nations of the earth Norway occupies but a subordinate position. Even with the modern facilities for rapid travel, measured in time, its distance from New York is about fourteen days.

Since regaining its independence in 1814, Norway has been exclusively engaged in the development of its home interests. Although its resources are limited as compared with most European countries, the advantages of modern improvements and inventions are appreciated and their benefits are earnestly sought to be secured for her. Among these the telegraph is recognized as one of the most important. The first telegraph line constructed in Norway was between the capital, Christiania, and Drammen. This was built in 1854, and was only four Norwegian (about 28 English) miles long. Now the net-work of lines extends all over the country. At the present time the Norwegian telegraph system includes 124 Government or public, and 105 railroad telegraph offices. The latter are employed mainly in railway service, and are not connected with the Government telegraph system.

The electric telegraph is in operation in most generally used lines from railroad trains, although no extensions the Morse register is employed. The operators in these railroad offices are boys and young girls. Their telegraphic knowledge and experience is small, and their salaries are in proportion thereto.

Of the 124 offices controlled by the Government telegraph system, 16 are open only during the winter to accommodate the sporting and social interests, and one (Oscar, near Christiania), if merely a semaphore office. Christiania, the capital, is the only city in Norway that has more than one office, and in her case, for only a portion of the year. There, in addition to the central office, during the sessions of the Storthings, or Norwegian Parliament, which, commencing February first, continues four or five months, a branch (Storthing) office is maintained.

Only in Christiania is there continuous day and night service, where it is necessary on account of the connection with the International telegraphic system. Of the other offices 7 are kept open from 7 or 8 o'clock, a.m. (according to the season), until midnight; 41 until 9 o'clock, p.m.; 53 to 8 o'clock, p.m., and from 5 to 9 o'clock, p.m.; and 5 offices have full day service during the fisheries season, about three months.

Norway is telegraphically connected with other countries by lines from Christiania and Trondhjem to Sweden, by submarine cables from Arendal to Denmark (Jutland), and from Egersund to Scotland.

The Morse register is principally used, although at a few of the offices, and upon the cable to Scotland, the Wheatstone apparatus is employed. At Christiania and Bergen duplex working has been established.

A new apparatus invented by the Norwegian electrician, Mr. Obere, of a system somewhat similar to the Hughes, is being tried at Christiania. The use of the register is reliable and expeditious, as the paper-tape is preserved for the rules of inspection. In case errors that may occur. The majority of the operators, however, are able to receive by sound. Every office of course has its signature, as "C" for Christiania, "D" for Drammen, "Td" for Trondhjem, etc. The International alphabet is used, as on most European lines. After sending a message the sender gives his signature, and the number of the message, and a collation of the cipher and the signature of the receiver are exchanged.

All the offices are well furnished, that of Christiania splendidly, as it was formerly the mansion of one of the richest merchants of Norway.

The Astronomical Observatory at Christiania has a line connecting it with the telegraph office, and twice a week, Tuesday and Wednesday, it is for a short time put in circuit with all the offices of the country, and the standard time is transmitted. The time at all offices is thus regulated to correspond with Christiania time.

Four hundred and fifty persons are employed in the telegraph service. Of these one is the director, one intendent, 11 are inspectors, with 284 male and 88 female operators. The salaries of the employés is fixed by the Storthing and is paid at the end of every month. The director submits to the Ministry of Postal and Naval affairs, in which department the telegraphs belong, a budget for the year, which includes everything connected with that branch of the service; and on this basis the estimates are submitted to the Storthing for its action thereon.

As the early years of the telegraph the pay of the employés was small, and those who competed for telegraphic employment were, some of them, possessed of but little learning. At present the salaries are better, and the requirements in reference to the knowledge and ability of candidates more strict.

It might interest the reader to know some of the salaries paid.

The Director receives about	.....	1,030 dols
" Intendants	.....	1,080 "
" Inspectors	.....	870 "
" Managers	.....	650 "
" Male Operators (second class)	.....	520 "
" Female "	.....	250 to 350 "
" Pupils (ladies)	.....	190 "

For managers, and for male and female operators who are not managers, there are some intermediate grades of payment. The salaries paid are not high, it is true, but, on the other hand, the country is not wealthy, and the cost of living is moderate.

Promotion of employés from a lower to a higher grade is based exclusively upon seniority in the service.

In the organization of the service, the director is the chief executive authority, subordinate only to the Postal and Naval Department. This position has been held from the first establishment of the system by the present director, Mr. Carsten F. Gulleen. This gentleman, who is much esteemed and loved by his subordinates, and who is a knight of several orders, was originally a lieutenant in the Royal Navy. Indeed, in 1854, the establishment of the telegraph in this country was discussed, he furnished to the Storthing the plans and estimates therefor, and was appointed to superintend its construction and management, which duty was performed so efficiently and satisfactorily as to insure his retention in the position.

The intendant, Mr. Jonas Collett, has co-operated with the director, Mr. Gulleen, from the first, and is a most efficient official. The inspectors are superintendents of a certain number of offices. The managers of the offices in the towns to which they belong.

Once or twice a year a school for pupils is opened at an office in a town where an inspector resides. The director advertises in the newspapers when and where the school will be held, how many pupils will be admitted, and the qualifications required of the applicants. The number of pupils admitted is usually 12 to 15. The qualifications requisite are that, if a male, the candidate must be from 17 to 25 years of age; if a female, from 20 to 25 years; must be in good health, which fact is certified to by a physician's certificate; must have passed at least an examination in a lower school (in such schools arithmetic is taught, also German, French or Latin, mathematics, history, geography, physics, etc., etc.). It is expected that applicants for admission into the telegraphic service as operators shall understand the English, German, and French languages, and they must be of good character and reputation, which latter must be certified to by responsible parties. The successful applicants for admission into the school receive three months' instruction in a theoretical and practical course, under the direction of the inspector. The latter delivers a lecture of an hour's length daily to the pupils, who are also required to practice six hours daily. At the end of the course the inspector gives each pupil a certificate which specifies their order, exactness, diligence, and progress, and they are then appointed to fill vacancies as they occur.

A pension fund has been established to which all engaged in the telegraphic service are required to contribute, and to the benefits of which all are entitled. To this fund the men are required to contribute one and two dollars and the women about one dollar per month. On the record from the service on account of disability or old age, each employé is entitled to a pension from this fund.

The male operators have, besides, a voluntary pension fund, through which the widows of deceased members are provided for. To this fund they contribute 1½ per cent. of their monthly salary. Hitherto the widows entitled to the benefit of this fund have received *yearly* an amount equal to the entire amount contributed thereto by their deceased husbands. It has been possible to pay this high pension, as the operators enter the service at an early age, and generally remain unmarried for several years.

JOURNAL OF THE TELEGRAPH.

VOL. XII. NEW YORK, SEPTEMBER, 1879. WHOLE NO. 281.

The male and female operators work in the same office, and as they are gentlemen and ladies the effect of their association has proved beneficial and elevating to the tone of the profession. Occasionally such business association results in a more intimate relation being established for life. In one case only are both of a married couple in telegraphic service. The lady operators are all highly educated, and belong to families of distinction. The men employed as operators are most of them graduates from the Royal University, and some of them have other subordinate employment, such as assistants in offices of advocates, banks, or as teachers, editors, &c. In a few instances the telegraph and post offices are combined. Two of the operators are Stortlingsmand (Members of the Parliament, which consists of 111 members.

A telegraphic situation was for some years not particularly coveted by, but since the salaries have been raised, the posts have grown to men, the intellectual standard has been elevated and made more uniform, and the service has become an object of public consideration and aspiration.

The telegraph service has been of great importance to the industrial emancipation of females. The first employment of ladies in the service was in 1859. Two women, the Misses Bech, paved the way. Previously women were not employed in any public position, now they are found as clerks in the offices of the Ministry, executive house offices, teachers in public schools, &c. Their admittance in the telegraphic service gave the first shock to the prejudice against their employment with their brethren in public positions; and women are not yet admitted to the privileges of the university.

Operators employed in the day service are on duty from 2 to 9 o'clock a.m., and from 2 or 8 o'clock a.m. to 2 o'clock p.m., the next day. They are then free from duty until 2 o'clock p.m. the following day. In some cases, however, when the operator engaged in the day service has other employment, a special arrangement is made so that their service is only required in the forenoon or afternoon.

This is, in brief, the situation of the telegraphs and telegraphers in this little country. We do not flatter ourselves that we can teach much in the telegraphers of a country where the electro-magnetic telegraph was invented, and has been so highly developed. It would, however, give us pleasure to know that a little interest is felt, by our telegraphic brothers and sisters in America, in such distant members of the fraternity.—*Journal of the Telegraph.*

EXPERIMENTAL RESEARCHES INTO MEANS OF PREVENTING INDUCTION UPON LATERAL WIRES.

BY PROF. D. E. HUGHES.,

(Concluded from page 249.)

"We have seen by the preceding experiments that should have perfect freedom from induction if employed a return wire at equal distance from inductive wire, and instead of a metallic circuit we have seen might serve, it would be best to employ two separate gutta-percha covered wires, and in order that each wire should have absolute equal effect, a slight twist of these two wires should be given, this twist would then successively bring each portion under equal influences.

Since making these experiments we have learnt that Mr. David Brooks, of Philadelphia, suggested a closed double wire as above described as a preventative against induction, and that it has also been patented by Professor Bell.*

A more perfect solution of this question than that of using a double wire with one as a return, giving double resistance to that of an ordinary wire, would be to use a double wire having a slight twist, each wire acting as an independent line with its own earth at each station, and its own separate battery at the transmitting station. The transmitting instrument should be so arranged as to send simultaneously positive to one line and negative in the other—these, if of equal force, would exactly balance each other as regards induction on other lines. The receiving electro-magnet should be wound differentially, or what would be still better, should have two separate wires wound together. The external end of one of these wires should be to one line, and the internal end to earth; the other wire should, on the contrary, have its internal extremity to the other line and its external extremity to earth.

The effect of this would be, that if any current of same polarity passed both wires at the same instant, no effect whatever would be felt on the balanced electro-magnet, but if two currents, each of opposite polarity, passed through the coils or electro-magnet, then it would work at its maximum effect; we should then have a double line wire with less resistance than the single wire, with complete freedom from earth currents, dynamo-induction, and from all extraneous disturbing causes.

If two ordinary metal lines are thus used, they should have the twist given to them wires by crossing their position relatively to other wires from vertical to horizontal, and *vice versâ*, at each pole or station, thus if we had two lines A and B they should make—thus if we had two lines A and B they should have these four relative positions repeated as often as possible, viz.:—A B, then $\frac{A}{B}$, then B A, and $\frac{B}{A}$.

We have tried to find a theoretical remedy by means of which a single wire would be free from the disturbing influence, and we have found that there is no possibility of a perfect solution of this question, provided that we send and receive on alternate wire at the same end, but if all the wires send in one direction during a stated period only, or work constantly in one direction only with one set of poles, receiving by another series of set of poles, then the resolution of this question becomes positively theoretically possible, but, I believe, practically impossible, for the lines are, as in France, all arranged in one plane, or nearly so—but only diagonal wires for vertical ones are available in the wires being alternately strung on each side of the poles—and this is perfectly followed by the commencing statement I have the honor to present this evening for the first time to general notice.†

Suppose three or more parallel lines A, B, and C, now, A indicates a current, an N and C proportional to its force of battery power and the several distances of these wires from the inducing wire. If we can send into the wires B and C an opposing current of very little more strength and duration to that of the indicated current, we evidently reduce the induced current to zero, and have consequently no disturbing effects on those wires.

After numerous experiments, I have found that if coils of wire be so placed in relation to each other, that their relative distances represents the relative distances of the wires from each other, and if each line at its transmitting station be joined to earth through these coils, then in passing the battery current through one of these coils to its line, it would exert through one of these coils to its line, it would induce a current whose direction would be contrary in itself; and as this would be exactly what takes place on the line itself, we should (supposing the coils to have equal inductive force to the lines) simply double the inductive force to the lines) and thereby double the inductive effects that they were before the use of the coils; but if at the same instant that we put battery to line we reverse the terminals of the coil in relation with it, then the induced current sent by the coil will be in the same direction as battery current on the primary, and this would neutralize every current on the primary, and this would neutralize the contrary direction of the induced current, reducing it to an absolute zero.

I have embodied this idea in the instrument which we present this evening, consisting of a series of coils of insulated iron wire. There are two of such coils, 10 centimetres diameter, 190 metres long, connected together so as to form a single line; these are placed at a distance of 10 centimetres from two similar coils, and between them, at the distance of 5 centimetres, is a single coil. We have thus two long lines, and one intermediate short one. The induction of these coils on each other represents the

* Professor Bell has lately written to me, stating that the date of this patent is Nov., 1877.

† Mr. Chas. H. Wilson, of Chicago, devised a plan for a series of induction coils permanently received in relation to each other. The induction coils thus be neutralized between two wires.—"Speaking Telephone," by O. D. Tuscott, 1878, page 203.

same distance as the aerial wires; the effects, however, are much greater with coils than on straight wires, and the last allows us to reproduce, with a hundred metres of wire only, the full amount of induction on a line of a hundred miles or more. The reason why having a shorter intermediary coil is, as I represented at a we have found, the most difficult problem of the problem.

The mathematics for the induction on three lines, as above there small No. 22 copper (covered) coils; these are so arranged on a graduating scale that they can be gradually approached until the exact balance for each line is found; and this is found very rapidly, for we have only to strike it until complete balance is obtained. Since the induced currents passing through each wire, these coils have no necessary relation, as to length or power to that of the battery, but simply the force by approaching them, as we said before, to the wires, and consequently to the force of intermediary wires, and also current wires of many or unequal length, the coils should have a definite ratio to the length of line, viz: the number of copper coil to 100 miles of line; but, from the powerful effect I obtain with the short lines, I have not yet, with 1 believe that 100 metres per 100 miles of line would be amply sufficient.

Each coil should be reversed by the key of the instrument at the instant of putting on the battery, and with this the disturbance the commutation is now perfect, and lines that were full of powerful induced currents all become perfectly free from them, whilst by the methods as we say utilizes the induction of the battery current on its own line. But as our object this evening is not to bring forward as our object this evening is not to bring forward new instruments, but to discuss the question generally, I will at once sum up my conclusions.

There are three points on ordinary telegraph line or lines where we may attempt a solution of the difficulty by experiment or other nominating effects, namely—the receiving, intermediate, and transmitting stations.

At the *receiving station*, ordinary induction coils, or the compensating coils I have described, would be injurious, as they could not be reversed in relation to each other, and would thus increase the induction.

Voltaic currents, direct or by derivations from the primary line, would answer only where the battery consisted of a dot or a short signal exactly equal in duration and force to that of the induced current.

Polarization batteries, direct on the line, or where the induced current to pass, and if used as a derivation, would require a very great resistance, and would allow the entire current from the working electro-magnet to affect all the rest.

Condensers would be similar to the polarization or secondary batteries. Resistance coils would reduce the induction, but also in equal proportion reduce the voltaic current needed. Magnetic condensers would absorb the induction, but also absorb that first part or the part most needed of the voltaic current.

At the *intermediate station* all these would give con-

Brooks' Underground Telegraph Wires.

The Silvertown Works Company have been carrying out some experimental trials of the system for insulating underground telegraph wires, devised by Mr. Brooks, and already described in these pages. It is found that all qualities of paraffine oil do not answer for this purpose, and there was great difficulty in finding the right kind of oil. When, however, this was secured, the specific inductive capacity was found to be very low; but it is also stated that electrification is greater than with any known insulator. Several lengths of wire insulated on this system are being worked in America.—*The Electrician.*

Telegraphing Without Wires.

Prof. Loomis continues his experiments in the mountains of West Virginia, to demonstrate the theory that at certain elevations there is a natural electric current, by taking advantage of which telegraphic signals may be sent without the use of wires. It is said that he has telegraphed a distance of eleven miles by means of kites flown with copper wires. When the kites reached the same altitude, or got into the same current, communication by means of an instrument similar to that of Morse was easy, but ceased as soon as one of the kites was lowered. He has built towers on two hills about twenty miles apart, and runs the tops of them has run up steel rods into the region of the electric current.

Anglo-American Telegraph Company (Limited).

At a meeting of the Directors of the Anglo-American Telegraph Company, held Sept. 25th, it was resolved, (after placing 47,500 to the credit of the renewal fund) to declare the following dividends, all free of income tax and payable on Nov. 1, 1879, leaving about 27,000 to be carried forward to next quarter's account:—1. An interim dividend of 1½ per cent. upon the ordinary consolidated stock for the quarter ending Sept. 30, 1879; 2. An interim dividend of 1½ per cent. upon the deferred stock for the same quarter; and 3. A balance dividend for the year 1879 of 1½ per cent. upon the six per cent. preferred stock. No further dividend will be payable upon this stock for the year 1879.

Brief Mention.

The Cleveland Electrical Society will resume its monthly meetings, Tuesday evening, October 21st, at the usual time and place.

The Sydney International Exhibition was opened on Wednesday, September 17th, by Lord Augustus Loftus, the Governor. The Governors of the Colonies of Victoria, South Australia and Tasmania were present, together with the Foreign Commissioners. There are 800 British industrial exhibitors and 151 fine art entries, including photographs. Germany has 635 entries, including 168 fine arts; Austria, 170; France, 350 industrial and 168 fine art; Belgium, 236 industrial and 50 paintings; America has 150 industrial collections.

At ten o'clock Saturday night, the 11th inst., the Cincinnati Industrial Exhibition closed. A chime was rung, all the bells were sounded, while the steam whistles joined in a deafening scream. The total attendance was 122,622. The cash receipts will meet all expenses and leave a surplus of about $10,000.

BEAUX-ARTS — INDUSTRIE — MARINE — ART MILITAIRE — MÉDECINE

2e SÉRIE — N° 16

20 AOUT 1879

Dans son prochain numéro, l'Electricité *rendra un compte-rendu de la partie électrique des séances de l'Association britannique à Sheffield, où, seule des puissances européennes françaises, elle sera officiellement représentée par un de ses rédacteurs.*

Le lecteur verra plus loin qu'un intérêt spécial s'attachera cette année à ces grandes assises de la Science britannique, dont malheureusement les travaux de l'Association Française pour le progrès des sciences ne sont qu'une pâle copie.

ACTUALITÉS ÉLECTRIQUES

Notions générales sur le service télégraphique

Nous voyons avec plaisir que l'Administration supérieure s'est rendue au désir que nous avons exprimé, et a publié des notions générales sur le service télégraphique, qui confirment en substance les indications que nous avons déjà données. Nous ne reviendrons point sur les renseignements que nous avons déjà donnés, mais nous trouvons dans ce travail quelques détails sur lesquels nous devons appeler d'une façon spéciale l'attention de nos lecteurs. Ce petit volume, orné d'une couverture jaune, se vend dans tous les bureaux télégraphiques de Paris pour la somme de 50 centimes.

Nous apprenons que l'article 1er de la loi du 29 novembre 1850 donne à chaque employé du télégraphe la faculté d'exiger du tout expéditeur de justifier de son identité.

Heureusement, les employés ne paraissent user que d'une façon tout à fait exceptionnelle d'une faculté qui doit paraître d'autant plus exorbitante que cette loi, si prématurément conservée à travers tant de révolutions, a omis d'indiquer les modes légaux de faire ses preuves.

Nous sommes donc les interprètes du public en soumettant respectueusement M. Cochery d'indiquer quelle doit être la manière légale de satisfaire à une pareille exigence, si elle se produit inopinément.

Nous prendrons même la liberté de suggérer la photographie légalisée, ce passeport si facile à se communiquer et dont l'usage général répondrait à un besoin si universel.

Il n'est pas inopportun d'ajouter qu'une disposition très-vague de la loi accorde à chaque expéditeur la faculté de faire constater son identité. La taxe exigée dans ce cas est très-peu élevée. En effet, on n'exige que le paiement du numéro de mots nécessaires pour indiquer l'accomplissement de cette formalité souvent nécessaire.

Ce libéralisme est assez rare pour que nous devions lui accorder notre approbation sans limite.

Nous voyons avec regret qu'il n'est pas fait mention dans la circulaire des articles de loi punissant d'une peine soit afflictive, soit infamante, les personnes faisant usage d'un faux nom dans l'expédition d'un télégramme. Il y a dans cette omission une lacune des plus graves, montrant combien les rédacteurs du *Guide sommaire* sont encore peu au courant de la nature de leurs devoirs.

Une des absurdités fiscales que le *Guide sommaire* met involontairement en lumière est la suivante :

Le service international admet le *collationnement* ou *répétition*, moyennant le paiement d'une taxe égale à la moitié de celle du télégramme.

Mais le service intérieur n'admet que la *reconnaissance* qui donne lieu au paiement d'une taxe égale à celle du télégramme, c'est-à-dire double de la première, toute proportion gardée.

S'ils soient collationnés ou recommandés, les télégrammes donnent lieu au remboursement quand le texte a été altéré dans la transmission.

Nous engageons les chambres de commerce à ne point s'en rapporter au zèle souvent bien tiède de l'administration, et à adresser au Gouvernement les représentations les plus vives, les plus pressantes en

AYRTON'S METHOD OF COVERING WIRE FOR ELECTRICAL PURPOSES.

A improved method of covering wire used for electrical purposes, has been patented by Prof. W. E. Ayrton, of Cowper-street, E.C., which is of especial value when several wires are arranged alongside one another. In certain special applications of electricity it is desirable to have a large number of wires, either convolute or uncoiled, on a narrow space alongside of each other, and where the temperature is experienced by reason of the difficulty in maintaining the different wires, and of the metal of the conductor used by the current electric currents. In other cases, as in resistance coils, it is desirable to lay several wires side by side in the same wire side by side in such a way that the whole has no external magnetic action and no self-induction. Professor Ayrton's invention insures the complete insulation of any individual wire at any point by the use of a special insulation in the web or ribbon, prevents an easy and certain means of destroying mutual insulation when the wires are arranged parallel as well as a simple method of constructing a coil of a single continuous conductor which has no external magnetic action nor self-induction. He finds it, when the relative insulation of the several wires from each other, or of the different layers of the same wire from one another, as well as of the whole from any metallic frame that is sheathed on the web, to be as good as when the ordinary method of covering with silk, cotton, gutta-percha, or other insulating material is employed. Further, the best arrangement of the conducting wires obviously is that in which they touch one another in the narrowest conceivable manner, and therefore available. This fixed arrangement also affords exceptional facilities for destroying external induction by surrounding a coiling wire with the current in the opposite direction, the simplest form being that in which the coiling wire has one return wire on each side of it, either a ribbon or web. The web, which is composed of a warp of wire and a weft of insulating material, or of a warp of silk made of insulating material and a weft of wire, may be twisted, be stamped in or passed through a bath of insulating melted paraffin-wax or of other kinds of insulator, and has the necessary of insulation and solidity is thus obtained. It may be rolled or twisted up whenever to be placed in the coil. The web or ribbon, in the flat state as woven, is then to be neatly painted with any fatty compound if desirable to ordinary paint being used, and the wires of the warp of the web or ribbon may be covered with gutta-percha, or with some similar substance, by being passed through a die where the compound is under pressure.

The practical application of the invention are numerous and advantageous for simplicity and economy, as for instance—In the preparation of cables for communication by telegraph or telephone, for use of the ribbon, will be extremely advantageous, as a coiling each wire to be easily obtained at any point of the circuit, and for improving the working of the instrument by the substitution of wire on wire to be badly distorted. Again, it is extremely important at the present time, in the manufacture of cheap and accurate resistance coils for schools and general laboratory purposes, that the resistance should be constant. This may be thrown wire, platinum, silver, &c., or strictly in course, is wound backwards on the shuttle and used as the weft, being woven with the warp or other suitable insulating material. Another suitable material employed as the warp. In order to give the resistance required, it is first bracketed over with a flat brush with a mastic paste, and then a single continuous conductor is wound on in the form of a ribbon, which is then placed flat between two sheets of paper, and the whole pressed flat after having been folded doubled along its length. It is a little wider than the width of the web, and the length of this copper, iron, or other metal, a little longer than the parallel. The web, or cloth, and wire ribbon, a width that after having been folded doubled along its length it

FIELD TELEGRAPHY.

A German paper gives a detailed description of the apparatus designed by Captain Buchholtz, of the Prussian railway regiment, and recently adopted in the German army, for providing telegraphic communication between the different fractions of an outpost line, or between the outposts and the main body of an army in the field. The whole apparatus consists of two small Morse's receiving instruments, a Siemens' and Halske battery, and a cable about three millimeters in diameter. It being impossible with a movable apparatus to use the earth to complete the electric circuit, a return wire is provided in the cable. An ingenious but extremely simple arrangement has also been devised for joining lengths of the cable together, the operation being rendered so simple that it can be performed by any one without any previous instruction or practice. The cable itself is manufactured in lengths of 500 metres, each being provided with a loop for attaching a harness, in such a way that as the men carrying it walks forward, the wire unrolls itself behind him. The cable can therefore be laid as quickly as a man can walk. The receiving instrument is fitted in a small box, on the outside of which is the sending key and a bell. The weight of the box, which also contains a small galvanometer, is about 8 lbs., and it can be carried in front of a man by means of a strap across the shoulder. The battery is carried in another box, and consists of ten elements, the whole weighing about 22 lbs. It will act for months without the materials being renewed, all that is necessary to keep it in order being to add to it occasionally a few crystals of sulphate of copper and a little water. The whole apparatus is to be carried in time of war on one of the wagons accompanying the battalions of infantry, and, when required for use, will be given to the men who are to employ it in exchange for their packs.

Sc. Amer.

Aluminum Telegraph Wires.

German telegraphic engineers have lately been experimenting with aluminum as a material for telegraph wires. This metal can easily be drawn out to a very much finer gauge than is possible with iron, and its conductibility is twice as great as that of iron wire. Its excessive cost has hitherto prevented its use for the purpose indicated, but it is found that an alloy of aluminum and iron can easily be made, which will produce a wire both finer and stronger, and less susceptible to atmospheric changes than iron wire, while it is much superior as a conducting medium.

COURANTS ACCIDENTELS

SUR LES CIRCUITS AÉRIENS

Lorsque, en 1841, on installa en France les premières lignes télégraphiques, on voulut reconnaître sur les fils métalliques qui les constituaient des traces de passage des dépêches, et je me rappelle encore certaines personnes douées cependant de quelque intelligence, qui s'étonnaient de ne pas voir courir les dépêches sur les fils; d'un autre côté, on trouvait extraordinaire que les oiseaux perchés sur les fils ne fussent pas foudroyés par les charges électriques transmises; enfin, quand on entendit ces bruits souvent si intenses produits par les fils télégraphiques dans certaines conditions d'installation des lignes, on crut y voir la manifestation de la transmission du fluide électrique. Bien que toutes ces idées soient évidemment absurdes, il est cependant un fait certain, c'est qu'une ligne télégraphique, par suite de sa disposition elle-même, et, en dehors de tout effet électrique qui lui est communiqué par une pile, subit une foule d'influences perturbatrices qui entravent considérablement le service des transmissions, et qui proviennent de beaucoup de causes différentes. Ce sont ces effets dont nous allons nous occuper aujourd'hui.

Une ligne télégraphique étant un conducteur d'une grande longueur exposé aux différentes actions atmosphériques, à des effets calorifiques très-variés et aux effets magnétiques du globe terrestre, doit nécessairement être impressionné dans divers sens par toutes ces actions, et, de plus, comme ce conducteur est en rapport à ses deux extrémités avec la terre que l'on peut regarder comme une sorte d'électrolyte, il doit se trouver impressionné par tous les effets dont il a été question dans un de mes précédents articles, et qui sont la conséquence d'un circuit complété par un conducteur humide. Si l'on joint à ces causes perturbatrices celles qui résultent de l'influence des charges électriques sur les objets extérieurs, celles qui sont la conséquence des effets d'induction des fils les uns sur les autres, des courants de retour et des courants induits provenant des appareils télégraphiques eux-mêmes, on pourra voir qu'une ligne télégraphique est toujours sillonnée par des courants étrangers à ceux que l'on envoie, et dans l'étude est importante pour le régularisation du service télégraphique.

D'après ce simple aperçu, on voit déjà que les courants perturbateurs dont nous venons de parler peuvent être classés en plusieurs catégories : 1° les courants atmosphériques; 2° les courants dus au magnétisme terrestre; 3° les courants thermo-électriques; 4° les courants permanents dus à une action voltaïque et généralement désignés sous le nom de courants telluriques; 5° les courants induits. De ces différents courants, nous n'indiquerons aujourd'hui que ceux qui sont dus à l'action tellurique et thermo-électrique.

Courants telluriques. — Si on plonge dans un milieu humide quelconque deux plaques métalliques d'un métal différent réunie l'une à l'autre par un fil conducteur, un semblable par le fait un couple voltaïque dans lequel le métal le plus attaquable par l'humidité représente le pole négatif. Or, la terre étant un conducteur relativement humide et d'une résistance très-minime, comme on l'a vu dans un précédent article, doit fournir à travers un fil télégraphique mis en communication avec elle par deux plaques de métal différent, un courant qui sera dirigé de la plaque la moins attaquable à la plaque la plus attaquable; et ce courant sera naturellement d'autant plus énergique que l'une des plaques sera plus

86

AN IMPORTANT INVENTION.

A Progressive Development in the Method of Constructing Telegraph Lines.

Mr. A. B. Turner, a prominent citizen of Saugerty County (Md.), rustling at Mount Savage, has just taken out letters patent on a very important invention, and one that, in all probability, destined to work a speedy, remarkable in the method of constructing telegraph lines. Mr. Turner has long been connected with railroads, and the nature of his occupation has given him the fullest opportunity for observation. His invention is an arrangement for an underground telegraph line, and consists of a system of apertured insulators, with the apertures extending longitudinally through them. The insulators may be made of glass, furnace-slag, or any other non-conductor of electricity having the requisite strength and capable of resisting the effects of air and moisture. They may be made of any desired length, and range in diameter according to the number of wires to be accommodated. These sections are provided at one end with a projection and a pin or tenon, and at the other end with a socket or recess, which receives the correspondingly shaped projection and end or tenon, so that any number of the sections may be united and formed into a continuous tube, water-tight at the joints and side. The pin or tenon regulates the position of the longitudinal apertures in the different sections, so that a wire may be pushed through a long distance or withdrawn at pleasure without meeting with any obstruction or coming in contact with the other wires.

The tube is laid in a prepared ditch in the ground, and rests upon a bed of concaved blocks of any suitable material.

At certain intervals risers are provided between the insulator-sections. These consist of ordinary insulators secured upon a crosspiece upon an upright post planted in the ground, and carry the wires from one insulator section to another. They serve to detect a breakage or any defect that may arise in any of the wires, and provide facilities for testing the wires and for turning corners or forking angles.

By this method each wire is separate from the others and thoroughly insulated, without the additional heavy cost of inclosing or covering the tube that has heretofore been found necessary. It can, and we believe all, instances, and which is objectionable because of the difficulty experienced in withdrawing or removing the wires from insulator-sections underground. In this case the wires can be inserted or removed with facility. On the whole the invention is perfect, and just what is wanted.

The advantages of this invention are numerous. One of these is the comparatively small cost of construction, which will be much less than that incurred in erecting the pole lines or putting down underground lines by the methods heretofore employed. Another is that it does entirely away with the unsightly poles, which are often a serious nuisance in the cities, and links in opposite sections by fire and storm. Another is in safety. The disconnect of the lines by wind and rain, as often occurring in the pole lines, is avoided, and numerous drawbacks are overcome.

It must be a matter of pride to all the people of this county that one of our own citizens has worked out the important invention, and we sincerely hope he may reap the reward his genius and enterprise so richly deserve.

Already he has received from prominent telegraph officials in several cities letters of congratulation and expressive of the highest praise of his invention, which, we have no doubt, will ere long begin to take up place of the unsightly cisplosions [illegible]

EDISON'S TELEGRAPH SUIT.

WASHINGTON, Feb. 16, 1875.

The suit of Thomas A. Edison and George Harrington against the Western Union Telegraph Company for an injunction against the use of the duplex and quadruplex telegraph transmitters, which Edison invented in 1874, was argued in the Supreme Supreme Court, before Judge James, to-day on the bill, answer, replication, and proofs. Ed. Ord, Esq., and Messrs. Dickerson and Dyer, of the firm of Dickerson, Brown & Dyer, of Philadelphia, appeared for the complainants, and Messrs. C. C. Lemoyne and W. D. Mooney for the defendants. The former argued that the patent granted to Edison entitled him to have and exercise every right which the law gives to inventors, and cannot be followed that two suits were necessary, being for infringements of his patents in different years. The latter argued that the patent was conditional to sell the patent for Edison and Harrington on such circuit to the company, on which no royalty was to be paid, and that the Western Union having used in a particular way which he had consulted with Herrington in 1870, he had agreed not to sell his invention without the latter's consent. The company had also transferred the transmitters from one circuit to another, which was a violation of the agreement to purchase the contract. The Court took the papers and reserved its decision, after giving the defendants leave to file the record of the New York suit in this case.

THE TELEGRAPH SET SCREW.

The decision of Judge Blatchford sustaining the Page Electrical Patent was noted in our issue of March 6.

April 4 Judge Blatchford heard motions by the American Union Telegraph Company, the Wabash, St. Louis and Pacific Railway Company, and the Union Pacific Railway Company, praying to have the decision referred to so modified as to exempt them from the payment of royalty to the Western Union Telegraph Company, on the grounds that they have always used the machine and device invented and patented by Prof. Morse, and that it could be proved that the original Morse instrument on exhibition in the office of the Western Union Telegraph Company was made by Prof. Morse as early as 1835, and contained all the essential parts of the apparatus and devices set forth in the eleventh, twelfth, and thirteenth claims of the Page patent.

The petitioners allege further that the defense in the previous suit could have proved (though they did not) that the testimony of Page in the suit of French against Rogers related to these essential parts of the Morse apparatus and devices; they could have proved by Thomas Hall of Boston that in 1847 he manufactured a machine under the Morse patent, which contained a device and combination for setting or regulating the length of the vibration at the armature of an electro-magnet by means of a set screw as described in the fifth claim of the Page patent; they could have produced an affidavit of Mr. Page himself, taken in 1866, in the suit of Morse against O'Reilly; also, the defendants could have proved by the Rev. S. Irenæus Prime that Mr. Page wrote to the Hon. Amos Kendall in 1848 that he had never claimed the invention of the receiving magnet used in the Morse telegraph; and the defendants could have made use of the depositions of Professor Morse, taken in 1850, in the suit of French against Rogers, and of Leonard D. Gale in the suit of Morse against O'Reilly.

The petitioners further asserted that they were ready to produce before the court one of the machines now and for many years past used by them in telegraphing, and the machines used by Mr. Hall, and if aided by the process of the court they will cause to be produced by the Western Union Company the machine used by Prof. Morse and presented to the company after his death; upon a comparison of which it would be seen that the machines now used by the petitioners and that made by Mr. Hall and that used by Prof. Morse are alike in their essential parts, and that all of them have the designs and appliances mentioned in the eleventh, twelfth, and thirteenth claims of the Page reissued patent.

Two weeks were allowed by Judge Blatchford for the plaintiffs to make answer. When the case was called the counsel for the Western Union Telegraph Company stated that due diligence had not been used in obtaining evidence in the previous trial, and produced the original model of the Morse telegraph instrument, to show that the disputed set screw governing the play of the armature was not there and never had been. It was held by the opposite side that the original screw had been removed and another substituted, whereat an excited colloquy ensued between the opposing counsel; but no evidence could appear to have been brought to show the real function of the screw which the model now carries.

The arguments of the counsel being undinished for lack of time, the case was carried over to Monday April 26, and again to April 30.

TESTING THE POSTAL PNEUMATIC LINES.

WHEN Mr. W. H. Preece, the chief electrician of the Government postal telegraphs of this country, paid an official visit to the United States a few years ago in order to report upon the working of the telegraph apparatus there, and note any improvement that might be introduced with advantage into the British system, one of the novelties which he inspected from America was the method of testing the wires by "received currents" or currents received at the end of the line.

He has adopted this plan to the telegraph system under his superintendence with very great success, thanks mainly to the professional ability of his assistant, Mr. H. R. Kempe, who at a recent meeting of the Society of Telegraph Engineers, gave an interesting account of the method now followed in testing the inland lines throughout the country in this way.

Mr. Kempe began his remarks by disputing the observations of Mr. Latimer Clark, published in the Indian Telegraph Service, in his recent book of instructions to Indian electricians, to the effect that a system similar to that in use in India would be suitable to England. The speaker pointed out that a system admirably adapted to the long Indian lines through a barbaric country, would be unnecessary in a populous country like the United Kingdom, where the lines are divided into testing sections of twenty miles. The system followed in each of the two counties was, he contended, best adapted to that country.

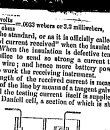
The old method of testing the lines consisted, as is well known, in measuring as stated above the resistance of the line in ohms; the new method consists in measuring the strength of current in webers, or rather in millionthers, or thousandths of a weber, as proposed by Mr. W. H. Preece. A standard received current is fixed upon for the particular line to be tested, and if the line is in good order the received current actually measured should be equal or nearly so to the standard current. The percentage of deviation from the standard value shows the faultiness of the line. The falling-off from the normal condition is thus observed, and obviously this is all that is practically necessary.

The standard received current for a particular line is chosen as the current which flowing through the proper resistance of that line will work a Morse instrument. For example, the current from a two-cell Daniell battery, giving an electromotive force of about 10 volts, and flowing through a line of wire resistance of 3000 ohms, will work a Morse instrument when the insulation of the line is perfect. Now the current in this case is

10 volts
3000 ohms = .0033 webers or 3.3 millwebers,

or 3.3 millwebers is the standard, or as it is officially called, the "undisturbed current received" when the insulation is perfect. When the insulation is defective ten coils will not suffice, and it would be strong a current to the end of the wire; and hence more battery power is required to work the receiving instrument.

The strength of the received current is measured at the end of the line by means of a tangent galvanometer; and the testing current itself is supplied by a standard Daniell cell, a section of which is shown



in the figure. The vessel is a square box of ebonite divided into two equal compartments by an ebonite partition. The right-hand compartment contains water, and is merely a receptacle for the porous pot containing the copper plate C and the sulphate of copper solution and crystals when the cell is not in use. The water keeps the pores of the pot from choking up with crystals, while the advantage of placing the sulphate of copper classifier there when the cell is out of use is that the exposure solution will not go on diffusing itself in the sulphate of zinc liquor or left-hand compartment. The latter compartment contains a zinc plate Z, which is the negative element of the cell, and a piece of zinc rod Z' which lies on the bottom. The solution of sulphate of zinc is half saturated, and when the cell is out of use only reaches to the bottom of the zinc plate. The function of the separate piece of zinc Z' is to decompose any sulphate of copper solution that may diffuse into the sulphate of zinc solution from the porous pot when it is immersed for working amidst the sulphate of zinc. Metallic copper deposits on the zinc rod, and the cell is then purified when not in action. The above set may be arranged from time to time and thus rendered efficacious again. To put the cell in use the porous chamber is removed from the right-hand compartment and immersed in the sulphate of zinc solution in the left-hand one. The latter solution then rises till the zinc plate is covered and the cell is ready for use. When done with, the porous chamber is withdrawn from the left-hand compartment, and replaced amongst the water in the right compartment. As the standard battery is only required for a few minutes at a time it keeps constant for a long time. The electromotive force is 1.079 volt.

The tangent galvanometer devised by Mr. Kempe for these tests deserves a passing notice. It is designed to give a current of a millionthers when one standard cell is passed through it. The electromotive force of such a cell being 1.07 volts, the resistance of the galvanometer is 1070 ohms, made up of 320 in the instrument itself, and 750 added to it for the purpose of practically lengthening the line being tested, in case a fault should exist very near the end of the line next the instrument. This galvanometer has four grades of sensibility.

Elaborate tables have been calculated by Mr. Kempe to facilitate the working out of these reciprocal current tests, so that as little time as possible is consumed in the process. Official returns have also been drawn up for registering lines from day to day and month to month, the form being tested twice a day and once a month. The monthly tests are for insulation resistance and continuity of the wire. The insulation tests are taken with the zinc current on the line. The conductivity tests are taken as usual with the Wheatstone balance, both zinc and copper currents being applied to the line. A novel arrangement of the switch for changing the currents permits that the deflections of the galvanometer in the "bridge" wire shall always indicate plus or minus resistance in the same direction, whether the current be positive or negative.

The British climate is very unfavorable to telegraph lines, but notwithstanding this fact, such is the excellent efficiency of their management, that out of the whole 1200 circuits in constant work, consisting of 120,000 miles of wire, there are rarely ever more faulty circuits at a time; often there is only one, and some time none at all. This remarkable success is largely due to the new system of testing by received currents, which proved of special service during the recent general election.

NEW BATTERIES.

THE ELECTRICIAN, AUGUST 21, 1880

The action of batteries and the conditions governing it are so little studied that the following results of M. D'Arsonval are very welcome. According to that savant, the chemical action in batteries with two liquids when the circuit is opened is never entirely stopped. This effect pertains to cells in which the liquids diffuse into each other across the walls of a porous chamber, or by actual contact without porous separators, as in the Callaud cell.

To remove this defect M. D'Arsonval has devised the two following plans, which, he says, succeed very well :—

The first means is founded on the absorbant properties of animal charcoal, and is applied to all batteries wherein the liquid diffusion cannot diffuse itself over the zinc. For this purpose he deposits a layer of pulverised sulphate of copper, covered with clean animal charcoal in powder. The zinc is placed at the upper part of the vessel, and is, consequently, separated from the sulphate of copper by a layer of animal charcoal. The voltaic element thus constituted resembles a Minotto cell, in which the sand has been replaced by animal charcoal.

In these circumstances the zinc remains completely unaltered. For over three years already M. Gaiffe has employed this cell of M. D'Arsonval's without experiencing the least change in its power.

The only inconvenience of this form is the increase of internal resistance which arises from the presence of the animal charcoal, an inconvenience that soon also brings with it, without the corresponding advantages. M. d'Arsonval has, it is said, M. Gaiffe, to manufacture porous vessels of agglomerated animal charcoal, but hitherto he has not succeeded. M. Carré, who at M. d'Arsonval's request undertook to try, was not more successful. But, even as it is, the form of cell is very serviceable for producing constant currents.

The second method followed by M. d'Arsonval for getting rid of waste action in batteries is of much more general application than the first, and consists in taking as a depolarising body a liquid which gives a precipitate by its mixture with the liquid attacking the zinc. The diaphragm separating the two liquids is in this way rendered impermeable. The precipitate formed in the pores of the vessel ought to satisfy two conditions; 1st, it ought to be a conductor of electricity, and 2nd, it ought to be electrolysable.

The combinations satisfying these conditions are exceedingly numerous. M. d'Arsonval recognises at least twenty, the chief of which are—

I. *Precipitate formed by the mixture of two salts. Nitrate of silver battery.*

This battery is constituted in the following manner. In the exterior vessel there is a zinc plate and chloride of zinc solution; in the porous vessel there is a platinum plate, a mixture of nitrate and a silver plate. These two liquids can mix, and thereby give rise to a precipitate of chloride of silver, which fills up the pores of the porous vessel and renders it impermeable. This precipitate conducts electricity very well, and is moreover electrolysable. Such a battery has very little resistance; its electromotive force is equal to 1·1 volts, whilst the same pair with chloride of silver only gives 0·9 volts. The high price of silver salts renders the method only applicable under particular circumstances, as in medical electricity or the charging of electroscopes, and, M. D'Arsonval might have added, in cable testing.

A more practical combination is the following. Zinc sulphate solution surrounding a zinc plate, and nitrate of lead surrounding a lead plate. The electromotive force is, however, very feeble, being 0·6 volts to 0·75 volts.

II. *Precipitate formed by the mixture of a base and a metallic salt.*

In this case the zinc is attacked by a base, potash, soda, or ammonia. M. d'Arsonval has tried the following combinations :—

First—Soda and sulphate of copper, which gives an electromotive force of about 1·2 volts.

Second—Soda and perchloride of iron, which gives about 2·5 volts.

Complex with potash have an enormous resistance, probably because the carbonate of potash, formed by the air, disengages its carbonic acid in contact with sulphate of copper, and the gas bubbles collect in the pores of the diaphragm, and destroy its conductivity. The solution of potash can, however, be made more conductive by the addition of sea salt or of sulphate of soda.

Scientific Notes.

Among the exhibits at the recent Daveldorf Exhibition, the wire manufactured Messrs. Felten and Guilleaume were conspicuous. Specimens of telegraph wire were shown to suit five specifications, amongst which was that of the English Government, the conductivity required being unusually high. There might be observed also a huge reel dressed in the colours of the Imperial German post office, and wound on this reel a length of underground telegraph cable from the Imperial German underground lines. The conducting wire is a strand of 7 iron copper wires, covered with a thick covering of gutta-percha. Seven of these conductors are twisted into a strand and then covered with tarred jute yarn. To shield the conductors against being mechanically disadvantageously affected, three of the galvanised wires is put on and then a waterproof coating of hemp and asphalte. All the telegraphic main lines of the German Empire are provided with cables M 7 conductors, and only the branch lines have cables M 4 conductors. The telegraphic underground lines of the German Empire are to have a total length of more than 5,000 miles with altogether 19,000 miles of conductors, as they are intended to be completed before the end of this year. By their means nearly all the principal towns of Germany are put into telegraphic communication with one another and with Berlin. The last larger underground telegraphic line was built by Siemens, Felten and Guilleaume, 4 years ago, from Berlin to Halle.

ENGINEERING NEWS.

The Chicago exchanges has 844 miles of trunk wires, 1,000 miles of branch wires, 250 miles of wires on the roofs of buildings. There are 1,033 telephone stations actually connected. The exchanges are seven offices in different parts of the city, having a capacity of 2,381 wires. The exchanges make an average of 7,691 connections or conversations per day, which requires including trunk line connections, an average of 1,000 employés. During the first 24 months of 1880 1,420,600 of these connections were made by the Chicago exchange. The cost of making a long distance at Chicago for the 40 minutes was 4·16·3 cents a piece. This result was not satisfactory to the telephone men, who considered such connections not likely to be profitable.

Early on a recent morning, "on the storm of a fire in the Whitehall-road, Leeds, being alarmed, the foreman of the *Leeds Mercury*, [illegible] engines, and in its passage along Whitehall-road the escape caught the wires stretched across the road in connexion with the telephone recently [illegible] by the Leeds District Telegraph Company with as much force as to [illegible] the wires were stretched [illegible] the roof of the building [illegible] and the appliances rapidly extending, it would be well if [illegible] were [illegible] to place the wires in the safest possible positions." Some time since the Post-office authorities in London put the telegraph wires under ground, but telephone wires are now getting so thick in the air that fires [illegible] would be facilitated to examine as to see if we had wings in order to learn whether the overhead wire nuisance was to keep on at home.

It is reported that the Chinese are about to construct a land line of telegraphs from Tatcnsin to Pekin with a cable across the Tongtsee. The Great Northern Telegraph Company have offered to supply the material at cost price, and to work the line. One of their staff has already surveyed the line down the Yellow River.

Marshall, Sands & Co., of Hongkew, have lately made a contract to supply the necessary machinery for the local [illegible] near Tatcnsin, and to work them. The machinery consists of a portable engine, which can be worked at high pressure a pitband chain, shafting, connecting gears, drums and baskets. Packing gear will not be used.

A new survey is to be made by the Siamese government for a telegraph line. The line will be put into service.

Railways are being rapidly built in Japan. Col. Crawford is building on the line which is to connect Yokohama with Suppore at the rate of a mile a day, and as the distance is only seventy-five miles, it will soon be ready for traffic. Such rapidity of construction is now practically unheard of in Japan.

It would seem that the telephone has been a real boon to the merchants of Gensan (Japan), who, we are told, were overworked by the process of communicating orally, which necessitated many a weary tramp. They now feel relieved.

The survey o the rail from Tokio to Jakaseki is completed, but it is yet uncertain whether the 10th National Bank (Japan) undertakes its construction.

***

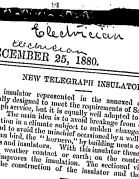
Important Telegraphic Discovery.—We learn from the *Journal de Genève*, 25th August, that the Swiss Federal Council has just received a communication from Messrs. Hipp, Bürkli & Co., of Cortaillod, in Neuchatel, Switzerland, which announces that they have made a highly important discovery in practical telegraphy. After a long and expensive series of experiments they have succeeded in discovering a method of laying cables whereby the Indiarubber insulation of the electric current from one wire to another, although *the wires are in juxtaposition*, is prevented. This discovery, it is asserted, entirely removes the last obstacle in the way of the widest possible extension of facilities for telephonic communication.

Electricity at the Brussels Congress.—At the recent Congress of Commerce and Industry held at the Brussels Bourse in connection with the International Exhibition, the first discussion of electricity, namely, telephony, electric lighting, and the transmission of motive power, were the subjects of three [illegible] delivered by Professor of the Liege University, in treating of telephone exchanges, strongly recommended the use of phosphor-bronze for wire instead of [illegible] for the electric [illegible] as it has a greater than that of [illegible] while [illegible] four times greater than that of steel. Aërial wires are more easy of execution than underground ones, but they are dangerous to life and property, and M. Hulz very justly remarked that the inventor who would devise a cheap mode of constructing underground lines, permitting of rendy of receipt, would render a great service to telephonic progress

DECEMBER 25, 1880. 69

NEW TELEGRAPH INSULATOR.

The insulator represented in the annexed engraving was originally designed to meet the requirements of South American places. The main idea is to avoid breakage from expansion and contraction in a climate subject to sudden changes of temperature, and to avoid the mischief occasioned by a well-known South American bird, the "bottero," by building nests of mud on the brackets and insulators. With this insulator these nests cannot be made, as a weather crotch, or curb, on the contrary, the nest rather improves the insulation. The accompanying figure shows the construction of the insulator and the manner of

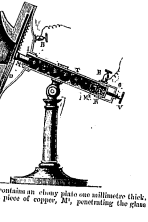


fastening it to the cross iron or bracket. A rubber ring is placed between the upper end of the porcelain insulator and the cross arm, and another similar ring is placed between the head of the suspending screw and the bottom of the insulator. It will be noticed that with the construction the insulator cannot be broken by the construction of the screw or by the swelling of the cross-piece. The insulator can be used on an iron bracket and in connection with either iron or wooden posts, and is in every way more secure than the insulators in common use. The first cost of these insulators compares favourably with the cheapest in the market, while it is less liable to breakage, lasts longer, and gives better results.—*Scientific American.*

NEW MICROPHONE.

BY M. BOURBOUZE, OF PARIS.

This microphone, with multiple contacts, as shown in the accompanying figure, is composed of a mouthpiece, B, affixed to the end of a glass tube, T, one centimetre in diameter, itself fixed on a pointed stand, thus enabling the whole apparatus to be moved at any inclination.



The mouthpiece contains an ebony plate one millimetre thick, on which is fixed a piece of copper, M, penetrating the glass

Phosphor Bronze Telegraph Wire.

M. E. Bene, formerly Professor at the Liège University, has recommended the use of phosphor bronze for wires instead of iron, phosphor bronze having four times the conductibility of iron, and being from three to four times as strong as steel. Aerial lines had the advantage of being easily inspected, but the disadvantage of being liable to accident, while underground lines are almost free from accident, but difficult of inspection. That inventor would render great service to telephonic communication who should devise a cheap method of constructing underground lines that should at the same time permit of easy and complete inspection.

PHILADELPHIA newspapers report that the American Union Telegraph Company are about to try in that city the experiment of putting their wires underground. The plan works well enough in European cities, and there would seem to be no reason why it should not succeed here, save the indisposition of the companies to bear the first cost of working the change. For some months the Western Union Telegraph Company has had the matter under consideration, and probably will await only the result of a rival company before it undertakes the work. Almost all the wires in the forest of Fontainebleau, the shortest line to Paris, are buried to such a depth that the ploughs of cultivators cannot reach them. Sooner or later the poles and wires must come down, and it is altogether probable that a change will be beneficial to the companies in the long run, owing to the immense cost of maintaining a pole-and-wire system. It will certainly be an advantage to the community.—*Scientific American.*

A Telegraph War in New Jersey.

The officers of the State of New Jersey are beginning to realize the importance of keeping their records in safe quarters. Many valuable documents are destroyed each year by fire, and the State House is not a fireproof building, yet as all the documents of importance are kept there it is considered best to keep them in safe quarters, and accordingly the Secretary of State, Gen. Stryker, has given notice to the Legislature that he will not provide for the rent of any more rooms in the State House, and that after the present year all documents and records will be removed to some other building. The Legislature will probably provide a fireproof building for the purpose.

POLES CHOPPED DOWN.

A War in Montclair for the Defence of a Historical Grove.

The Postal Telegraph Company, consolidated with the Baltimore and Ohio, is now in operation near Montclair. The right of way has been secured between Montclair and Jersey City. In Montclair, however, the company's poles encountered opposition when they were put up. In the centre of the town is Church Grove, about half a mile long, shaded in places by old and beautiful trees, while young trees have been set out in the vacant spaces and these are already becoming shade trees. The residents of Montclair are very proud of this grove of trees, and have always objected to the cutting of their trees limb of their house, although it was necessary to trim the trees in order to keep the wires clear. Among the property owners were Samuel Dyer, J. Van Cott, Dr. Bogert, Jacob Crane, Jr., F. H. Van Blarcom, John J. Merritt, E. Brady, F. Sutton, A. J. Crane, and Mrs. Cornelius Crane.

These gentlemen held a love on the evening the telegraph line appeared on the avenue and decided to take immediate steps to protect the shade trees. A committee was formed consisting of the first three named gentlemen and Mr. Dyer was appointed chairman. Mr. Bogert then drew up a formal remonstrance against the cutting up of the poles in front of their homes, and the document was signed by every property owner with only two exceptions. Mr. Bogert, who was president of the Montclair Railroad Company, and who was formerly in business with Jay Gould, had left town on the morning before the poles were put up, and Mr. Merritt, who was also interested with Gould in the Manhattan Beach Company, was out of town at the time.

The remonstrance was presented to the Common Council on the evening of the 15th inst., and the Council at once passed a resolution directing the Street Committee to notify the Postal Telegraph Company to remove the poles from the avenue. The Street Committee, consisting of Messrs. Bogert, Merritt, and Crane, met on the following morning and served the notice on the company. The company refused to remove the poles, and the Street Committee then directed the Chief of Police to have the poles removed. Chief of Police Hall detailed Officer Hoffman to the duty, and he, with a force of men, proceeded to the avenue and began to remove the poles. The men had not proceeded far when they were arrested on a warrant issued by Justice Bedle, charging them with malicious trespass. They were taken before the Justice, and were released on bail to appear for trial on Monday next. At the request of Mr. Bogert, Officer Hoffman left a police guard during the morning to watch the poles before they arrive. A lawyer was employed by the company to defend the suits brought against the officers. In the meantime the poles are up to stay, to the regret of the property owners who had hoped to be successful in preserving the shade trees.

MONTCLAIR'S TELEGRAPH WAR.

The Question of Setting Up Poles in Claremont Avenue Taken into Court.

The armistice in the telegraph pole war in Montclair continues in force. This is an extension of the temporary injunction obtained by Street Commissioner Stephen Merritt, Chairman, and by certain the Bloomfield Turnpike Company from planting poles in front of their residences. Many other residents in Claremont avenue, most of whom are New York business men, are also about to join the alliance of the shade trees in front of their beautiful shade trees and their New York gentlemen. When Overseer Decalmes and his workmen set some poles along the avenue about three weeks ago the poles were mysteriously cut down. The residents in the avenue in the east day handed themselves into an organization to protect the property of the citizens. The officers of the Postal Union Telegraph Company, who have the contract for putting up the line they had not intended to run the proposed line through the avenue, or any other shade trees in Montclair, but to keep on the property owner. The action of their agents had, they said, been hasty and ill-advised. However, as the question of the right of way had been raised the latter he applied for an injunction to take the matter to court.

Mr. Thomas S. Purdy of the Postal Union Telegraph Company said yesterday that the injunction papers had been served on the Chief of Police, and that the case in question will probably be considered at the same time. The telegraph company has a contract with the Bloomfield Turnpike, of which is through Claremont avenue. This is the most direct line to Newark, whereas the telegraph line is longer and on the company preferred the way through Claremont avenue. The line will be run through the upper route will be accepted. This telegraph line is a branch of the main line, and runs only to Newark.

The Sanitary Engineer, Aug. 25. 1881.

The Philadelphia *Times* states that the National Underground Electric Co. are arranging to lay telegraph wires from the public buildings to the Delaware, a distance of about one mile. The wires are to be insulated, and placed in terra-cotta pipes, "pierced longitudinally with nine holes."

Inland from the promenade *Bizarre*, at the law offices for the erection of the poles. The property owners said last evening that written permission had been given to the company from only one man on the avenue.

The law of New Jersey concerning the putting up of telegraph lines declares that after the line is located the company may proceed to construct it so long as the legality under the charter, despite all opposition, except such as is based on their offices in New York on Monday last. At the request of Mr. Bogert, Officer Hoffman left a police guard during the morning, three hours before they arrive. A lawyer was employed by the company to defend the suits brought against the officers. In the meantime the poles are up to stay, to the regret of the property owners who had hoped to be successful in preserving the shade trees.

MONTCLAIR'S TELEGRAPH WAR.

The Question of Setting Up Poles in Claremont Avenue Taken into Court.

The armistice in the telegraph pole war in Montclair continues in force. This is an extension of the temporary injunction obtained by Street Commissioner Stephen Merritt, Chairman, of the Montclair Turnpike Company, from planting poles in front of their residences. Many other residents in Claremont avenue, most of whom are New York business men, are also about to join the alliance of the shade trees in front of their beautiful shade trees and their New York gentlemen. When Overseer Decalmes and his workmen set some poles along the avenue about three weeks ago the poles were mysteriously cut down. The residents in the avenue in the east day handed themselves into an organization to protect the property of the citizens. The officers of the Postal Union Telegraph Company, who have the contract for putting up the line they had not intended to run the proposed line through the avenue, or any other shade trees in Montclair, but to keep on the property owner. The action of their agents had, they said, been hasty and ill-advised. However, as the question of the right of way had been raised the latter he applied for an injunction to take the matter to court.

Mr. Thomas S. Purdy of the Postal Union Telegraph Company said yesterday that the injunction papers had been served on the Chief of Police, and that the case in question will probably be considered at the same time. The telegraph company has a contract with the Bloomfield Turnpike, of which is through Claremont avenue. This is the most direct line to Newark, whereas the telegraph line is longer and on the company preferred the way through Claremont avenue. The line will be run through the upper route will be accepted. This telegraph line is a branch of the main line, and runs only to Newark.

Telegraph, Telephone, and Cable Wire, &c.—For the marvellous success which has attended the adaptation of the discoveries of electricians to practical uses the world is indebted in no small degree to such firms as that of Messrs. William Cooke & Co., of the Tinsley Steel, Iron, and Wire Works, near this town. The requirements of the age in this matter have been with them a close and practical study, and as a gratifying result they have distinguished themselves in the manufacture of wire for telegraph, telephone, cable, and kindred purposes. Mr. William Cooke, the founder of the firm, has been for the last forty years intimately associated with our heavy industries, and has taken an active and important part in their development to their present great proportions. He had for many years the management of the Swinton Works, which now belong to Messrs. John Brown & Co.; and in 1859, while still in that position, he discovered and brought into successful issue the manufacture of steel-iron. Under the old process of "piling" there were blisters and stratification in the iron, but by the new process those defects were entirely obviated, and steel-iron came rapidly into use. In 1866 Mr. Cooke entered into partnership with Mr. John Cooke and Mr. T. A. Mann, and they were the first to break ground in the hitherto purely agricultural district of Tinsley. On the six acres of land they had purchased they erected puddling-furnaces, steam-hammers, rolling-mills, and other machinery specially adapted to the production of steel-iron, which was then largely used in the sheffield trades—especially in the manufacture of heavy railway springs and similar goods. In 1873 the concern was converted into a limited company, and the business assumed a position in the world of trade. The area was extended to 16 acres, and the company put down new puddling-furnaces, steam-hammers, forge trains, a 10-inch and 16-inch merchant-mill, a mill for rolling steel and iron hoops, three charcoal fires for the purpose of making charcoal iron for wire, mills for rolling Bessemer into wire rods, drawing-blocks, and so forth. There were also erected two blast-furnaces, which are capable of turning out 250,000 tons of pig iron per year, the use for the smelting of which is drawn chiefly from the mines belonging to the company in Lincolnshire. When the company had been established about two years an outlay was thrown upon them, and a change of front had to be made, such as had not been anticipated. Then came the extraordinary expansion of the Bessemer steel trade, and the result of the experiments of the inventor and the improvements introduced in the manufacture of that material. In the course of a short time Messrs. Cooke used very largely supersoded steel-iron, for it was cheaper and of a considerably higher degree answered the same purpose. To meet these altered circumstances the company's plant had to be altered to an appreciable extent, especially as a new one. Since that time the company have given their attention more particularly to the manufacture of wire for telegraph, telephone, and similar uses, and they have brought to such a degree of perfection as to more than meet the severest tests demanded of it. By way of illustrating the capabilities of their Bessemer rod-mill, it may be stated that they recently rolled one rod which weighed 2½ cwt. The average weight of the rods rolled under ordinary circumstances is 120 lbs., and they measure 300 yards in length. As the result of prolonged experiments, and after an expenditure of much time and trouble, they have succeeded in producing steel for telegraph wire with remarkably high resisting-power per statute mile—a prominent advantage, arising from the use of which is that in great distances less battery-power is required to send the current of electricity along it. In the tensile strength of the wire is seen in the fact that 0·075 will bear with ease the required strain of 22 tons to the square inch. At the same time, this wire has also to stand a very severe torsion test. It must twist round its own diameter four times, and return to the straight without breaking. It is comparatively easy to make wire that will stand either the strain or the torsion test; the difficulty is to combine the two without either breaking. The wire that is intended for telegraph purposes is tested in another way. A length of it inches has to stand the strain of being rolled not less than 18 times round its own axis without breaking, and a defective wire will not do that. Messrs. Cooke & Co. have exceptional facilities for subjecting the wire they produce to these and all other tests required, as well as for ascertaining the resisting-power of the wire to the utmost extremities. Another rod-mill belonging to the firm is occupied almost entirely in the making of best charcoal, best puddled, and bending rods, for which there is a large demand for the colonial and South American markets. In the iron-wire mill they have recently introduced improvements by which they are able to roll considerably longer lengths, and finish the wire at a higher temperature than was possible under the old process. The mill is now capable of turning out on an average 150 tons of wire per week. All the subsequent processes necessary to the making of wire—such as annealing, galvanising, and so forth—are also conducted on the premises. During the past year they were favoured with some exceedingly good orders both from home and foreign markets. They have also just received an order for upwards of 1,000 tons of Bessemer wire for the American market. Iron and steel rods they produced nearly 11,000 tons, and finished wire for telegraph, telephone, cable, and fencing purposes, several thousand tons. This is a branch of their business they intend steadily and persistently to cultivate, as, for the making of wire for all the purposes indicated, they believe they have special facilities. Since the reconstruction of their mills Messrs. Cooke have been very successful in producing a brand of iron specially adapted for the use of agricultural engineers, and by them it has been received with much favour. Their output of merchant iron last year amounted to many thousands of tons. The firm have established a laboratory on their premises, under the care of an experienced chemist, and specimens of the raw material as it goes into the works, and of the finished goods before they go out, are carefully analysed and tested, that their precise temper and quality may be ascertained. At the present time Messrs. Cooke have good orders on their books, and their works are in full operation. It might be added that the firm have been very successful when placing their productions in competition with those of other firms. They received a first award for their goods at the Sydney Exhibition, and a similar honour has been conferred upon their exhibits at Melbourne.

Hoddinott's Record
Remembered!!!

THE telegraph system in Japan, which dates from 1871, comprised at the beginning of last year 3923 miles of line, with 8245 miles of wire. The number of despatches during the year was 1,227,236, of which about 25 per cent were in Japanese, while international messages numbered 21,693. The Japanese have now a system of telegraphy of their own invented by the telegraph superintendent from a combination of Morse characters to represent the sound of the syllabary known as the Kiritsu. This is now affected by using the letters of the international code, supplemented by others formed of dots and dashes (figures excepted), to produce a total of forty-seven signs, and the alphabet thus established is stated by Mr. Morley of the Japanese Department, to have given tolerable satisfaction during the nine years that have passed since its introduction. A telegraph school has been started for training Japanese youths as operators, and during the last year two hundred and twenty-seven were appointed to the offices—of course not to the exclusion of foreigners, forty-seven under million. They are taught to write and speak English and French, and receive the rudiments of an English education. The average rate for twenty thousand words of the Japanese language for a distance of sixty miles is about three sen, or rather less than a penny, taking the native Hiragana Takio to be worth a penny. The average for shorter distances is higher, but messages between Takio and Yokohama are transmitted for seven sen, or 7d. for twenty miles. In 1878 there were one hundred and twelve offices open for general traffic, local and international, and seventy others connected with government departments. Of these offices thirty-four were kept open day and night. Despatches between London and forty-eight Morse in-circuits in use, twenty-six single needle, three double needle, and nineteen Hughes and Bell pattern. Seventy-one instruments of various patterns are used in the school for the students to practise upon. Including the five submarine cables across the Straits of Shimonoseki, the total receipts for the year were £168,325, and the total expenditure £160,674, leaving the first year in which the revenue exceeded the working expenses. It may be mentioned that when the Satsuma rebellion in 1877 the telegraph was largely used in the field, and greatly contributed to bringing the war to a close. The Satsuma men were particularly skilful in the forest ambushes, but in almost every case they found that the wires were before them, and gave information of their whereabouts in sufficient time to defeat their object. For this purpose five hundred and eleven miles of line were constructed, and fifty-three office opened in the various villages at the rear of the victorious army. The materials employed in construction were light portable poles, rudimentic insulators, and No. 11 wire, every one being made of natural supports in the way of trees, and it was surprising how very few interruptions occurred under the circumstances.—*London Times.*

OUR FIRE ALARM SYSTEM.

IMPROVEMENTS IN SUMMONING THE FIRE COMPANIES.

Alarm Boxes and the Telegraph in Place of the Old Fire Towers—Steamers Stopped by Sawing Timber Instead of Burning Wood—Its Use—Importance of the Repairs shown.

The bells that rang out from the lofty wooden towers known as the fire towers twenty years ago drew out the firemen with less haste, hurry, and alert vehemence firemen, a modern fireman that received the slow compulsively unintelligible pulles and embarrassed the over-numerous alarm-bells. Steamers, the ground alarm from the towers also silenced thirteen, who convinced in steal whatever was easily portable from the property exposed from the flames. The alarm of the fire bells is a thing of the past. The towers have, with few exceptions, fallen at the command of the Commissioners of the said and electrified Fire Department. Force of them still stand in the old parts of the city as a precaution against the failure of the system of telegraphic that moves the present department with the exactness of a machine. This precautionary measure was proved to be a wise one last winter, when for several days the great network of telegraph wires of the city was rendered useless by a storm of sleet that covered each wire into a sutural of crystal beautiful to every one but the anxious officials of the Fire and Police Departments and the exasperated operators of the commercial lines. In the years before the introduction of the existing system, the firemen often drew out the bells, heard by the chemistry of the apparatus, and the quickness of the firemen to answer the call.

Before then when were detailed to house duty, in the engine-houses, and added to the difficulties of the work of collectively mustered to the fires. Sometimes the delay in The city is reckoned with 215 miles of wire divided nearly to the Fire and Police Department, and to-day a system of electric signals is by fire stations in the work. Thirty-two are engaged by hundreds of small telegraphic known as "fire boxes," attached to the walls that support the wires, and distributed through out the length and breadth of the city, that summonins a fire station at a moment's notice. By a novel appliance of telegraphy, the alarm from the box, at any hour of the day or night, sounds on the gong of every fire company, and instantly summons every fireman and horse in the department to duty—calls from all the companies, ready to dash away to the scene of the fire. The same alarm rings in every police station, and sends the Sergeant at the desk to shutmen. So, without a fire-engine, a crowd, or a single movement of firemen, their horses on the pulling, and of policemen, of their most expeditious post, are on the way to a fire. Within an average of between two and three minutes after the sending from the hall a dozen steam engines upon the Bunker and a police line keeps out thieves and prevents a pressure of spectators on the flames. But in this phase of the firemen's duty are attended to the horse hills, crowded and jostled at fires, there are hundreds not, except in the instances of great fires that startle by their lurid light the whole entire community, the work of the police is easy. All of the great changes from the old volunteer system in the service may be summed up in the result, of which New Yorkers are vain to be boastful, that New York probably possesses the most efficient fire department in the world.

"The favorite objection of the veterans of the old Volunteer Fire Department to our system," said a fireman who worked his way up from the ranks to the Chief Engineership of the department, "is that we are cold for our services, and, therefore, cannot feel the interest that once made the fire-laddies of Gotham fight for love in competition. Any one who has stood in his wing Jem's and Jimmy, served in a fire, THE "E. Whitehouse" when he is said to go to the fire as soon as possible, and he knows the course of his assistant officers in the fight. There is nothing that can make an alert fireman more interested in the movement is knowing as he does, that his own life and the lives of his men depend upon it. Well, remembered our two main night, and I'll give you one of the most glorious experiences that any fireman ever had—a night when the thrilling on the pulses of an engine. I was on duty at the Chief's office in Jersey City, and the bells, heavy horses stood, pounding their at a three-minute pace, and making the streets re-echo with the thunder of their hoofs. Now, I don't have an opportunity to do something that will merit your confidence and approbation, and, consequently, my heart was beating against my breast-bone. I felt, in short, as I suppose a Field Marshal feels when ordered to lead a charge. Well, remembered our two main night, and I'll give you one of the most glorious experiences that any fireman ever had—a night when the thrilling on the pulses of an engine. A Note on the Sources

The pages which were microfilmed for this collection are in generally good condition in the original. There are some pages, however, which due to age are lighter than normal. Additionally, because some volumes are very large and have been bound tightly and cannot be unbound, there are intermittent occurrences of slight distortion of the edges of a small percentage of the pages. We have made every technical effort to ensure complete legibility of each and every page.
